ENGINEERING EDITION.

Index to Vol. IX.

New Series, Vol. I.

September, 1902, to August, 1903.

1903.

THE INDUSTRIAL PRESS,
66 WEST BROADWAY,
NEW YORK.

Index to Volume IX.

- Adjusting Motor, An (Lang) 87
- Air, Hydraulic Compression of 51
- Air Resistance Encountered by Moving Trains 20
- Alcohol for Industrial Purposes 466
- Allis-Chalmers Co., the Great West-Allis Plant of the 285
- American Methods, Westinghouse on 346
- American Turret Lathe Mfg. Co., New Shops of the 510
- Among the Shops; Notes from Shops of the Mergenthaler Co. 615
- Angular Milling and Planing Jobs 178
- Apprentice System of the Brown & Sharpe Mfg. Co. 327
- Armature Disks and Segments, Manufacturing, Jos. V. Woodworth 455
- A. S. M. E., Annual Meeting of the 254
- A. S. M. E. Meeting, The New York, 1902 211
- A. S. M. E. Papers, Saratoga Convention, June 23 to 26 585
- Automobile Show of 1903, The New York 307

- Barnay, John M., A Forty-four Foot Pit Lathe 279
- Batteries for Automobiles, Lead vs. Nickel 230
- Bearings for Lighthouse Lenses 390
- Bearings, Standard Roller Co.'s 396
- Benjamin, C. H.:
  - Effect of Vibration on Steel Tubing 307
- Blake, C. F.:
  - Worm Gearing 189
  - Efficiency of Mechanism, 365-410
  - Proportions of Gears 467
- Blanking Dies, Joseph V. Woodworth 13
- Blowing Engine for the Sharon Steel Co. 526
- Boiler Horse Power for Heating and Power, Chas. L. Hubbard 305
- Boiler Joints, Efficiency of 108
- Boiler Construction, Rapid Steam 464
- Boilers, Internally and Externally fired 240
- Bolts, Nuts for Clamping 54
- Booth, Wm. H.:
  - Superheating 84
  - Engine and Boiler Testing 570
- Boring Machine, A Spindle 278
- Boring Machine at the N. Y. Navy Yard, Large Vertical 337
- Boring Mill, Sixty-foot 578
- Brazing Cast Iron by the Pich Process 461
- Burlingham, William:
  - Electricity as a Motive Power for Machine Shops 1
  - Flywheels 520

- Camming Automatic Screw Machines 293
- Castings, Steel 524
- Chucking Carwheels for Turning the Tires, System of 437
- Concrete Foundations, R. P. King 613
- Cooley Epicycloidal Steam Engine, The 470
- Cooling Railway Motors by Compressed Air 255
- Correspondence Instruction, Notes on 239
- Cost, The Influence of, on Machine Design 404
- Countershafts, Strength of, Frank B. Kleinhaus 402
- Cramp & Sons Co., Philadelphia, Work in the New Machine Shop of Wm. 127
- Crane, "Hercules" Floating, at the New York Navy Yard 195
- Crankpin Turning Machine, A (H. B. Underwood & Co.) 427
- Cutting Tool Action, The Elements of 199
- Cutting Tools for Planer and Lathe, W. J. Kaup 644
- Cylinder Head Covers, Making, on a Steam Hammer 658

- Davis Armor Plate, The 17
- Death of I. McKim Chase 629
- Dies, Blanking, Joseph V. Woodworth 13
- Differential Indexing 275
- Drawing Room, The Lodge & Shipley, C. F. P. 68
- Drilling Jig Plates. J. R. Gordon 97
- Drum, A Large Hoisting 241
- Dunbar, J. H.:
  - Pistons and Packing Rings, 180-401-457-529-582-633

- Early Machine Shop and Mechanics 74
- Efficiency of Mechanism, The,
  - (1) C. F. Blake 365
  - (2) With Special Reference to Hoisting Machinery 410
- Electric Motors, Specifications for, for Operating Navy Yard Machinery 200
- Electric Railroading, The History of 351
- Electric Railway, Another Interurban 135
- Electricity as a Motive Power for Machine Shops. William Burlingham 1
- Emery Wheels, The Bursting of 568
- Engine, A New Internal Combustion 302
- Engine and Boiler Testing. W. H. Booth 570
- Engine, Blowing, for the Sharon Steel Co. 526
- Engine, Results of Tests on High-speed 481
- Engine, The Cooley Epicycloidal Steam Engine 470
- Equipments for Motor-Driven Planers, Standard 298
- European Engineering Wks. 513
- Evolution of the Change Gear, The, (1). Oscar E. Perrigo 501
  - (2) 572
  - (3) 621
- Editorial:
  - A Word of Discouragement 408
  - Apt Phrase for the Mechanic, An 300
  - Black Diamonds for Use in the Arts 80
  - Cannot be Prevented 576
  - Change Gear Devices and Geared Feeds 516
  - Combining Practice with Education 628
  - Danger from Gas Explosions 81
  - Davis Armor Plate, The 17
  - Effect of Gas on Coal Transportation 300
  - Eight Years 16
  - Electric Railroading 301
  - Engineering Edition of MACHINERY 16
  - Engineering and Shop Editions, The 132
  - Environment is Responsible 300
  - Graphite vs. Friction 184
  - Important Steam Turbine Development 17
  - Insurance Engineering 409
  - Inventor under Modern Conditions, The 464
  - Is it a Fad? 516
  - Light under the Bushel, The 132
  - Liquid Fuel, for the U.S. Navy 185
  - New Variable Speed Motor for Railways 81
  - Possibilities of Liquid Fuel, The 133
  - Rapid Steam Boiler Building 464
  - Rotary Pumps, The 185
  - Safe Cracking as a Fine Art 628
  - Shop Accidents 408
  - Status of Alcohol Motors, The 465
  - Steel as an Abrasive 464
  - Thermit and its Possibilities 352
  - Transportation in New York 352
  - What of the Large Gas Engine? 248

- Floors, Steel vs. Concrete for 412
- Flywheel Revolutions, Rule for Computing Safe 363
- Flywheels. William Burlingham 520
- Forced Blast Heating Systems, Notes on 509
- Forgings, Hollow 78
- Foundry of the Brown & Sharpe Mfg. Co., The new
  - (1) 561
  - (2) 623
- Foundry of the Vilter Mfg. Co., New 339
- Friction Test of Oils. Arthur W. Cole 631
- Fritz Medal, The John 188

- Garvin Machine Co., Notes from the 395
- Gas Engine Installation, The First Important (De La Vergne Co.) 233
- Gas Engines, Large Horizontal, Designed by the Westinghouse Machine Co. 302
- Gear Cutter Attachment for Cutting Internal Gears. (Arthur) 130
- Gear-cutting Extraordinary; A Huge Drill Press Job 508
- Gears, High-speed Helical. (Boston Gear Works) 54
- Gears, Proportions of. C. F. Blake 467
- German Milling Machine, Heavy 515
- Gold Dredging in New Zealand 240
- Gold, Reclaiming, from the Beds of Rivers; Novel Gold Dredging Machine 131
- Gordon, J. R.:
  - Drilling Jig Plates 97
- Governor, A Friction Waterwheel 389
- Grimshaw, Robert:
  - Internal Combustion Alcohol Motors 466

- Hammer Lifter, Semi-rotary Steam and Compressed Air. (Merrill) 256
- Heat Resistance the Reciprocal of Heat Conductivity 523
- Heating and Power, Boiler Horse Power for. Chas. L. Hubbard 305
- Heating Systems, Notes on Forced Blast 509

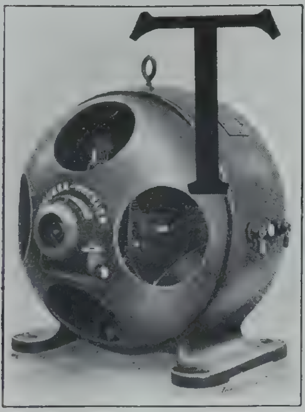
MACHINERY.

September, 1902.

ELECTRICITY AS A MOTIVE POWER FOR MACHINE SHOPS.

WITH SPECIAL REFERENCE TO THE ELECTRICAL EQUIPMENT OF THE WILLIAM R. TRIGG CO., RICHMOND, VA.

WILLIAM BURLINGHAM.



THE arguments against the installation of electric motors for machine shops are constantly decreasing with the increase of the motor systems. For new shops the argument against the use of electricity is nil. For rehabilitating old shops, there are naturally many points to be considered, the principal of which are: Dismantling the driving mechanism of old machines and installing new motors; loss of shafting and appurtenances, boilers, engines, etc. The boiler power necessary would then be, only that used for heating the plant. To reimburse a firm for so doing, necessitates that the economy and improved feed adjustment due to the electric motor driven machines must earn a good interest on money lost on old installation plus that invested in the new driving machinery. The convenience of being able to work one tool only, on a hurry job, without being compelled to run the entire line of shafting, is one factor of economy. The mobility of the tools is another especially on light machinery.

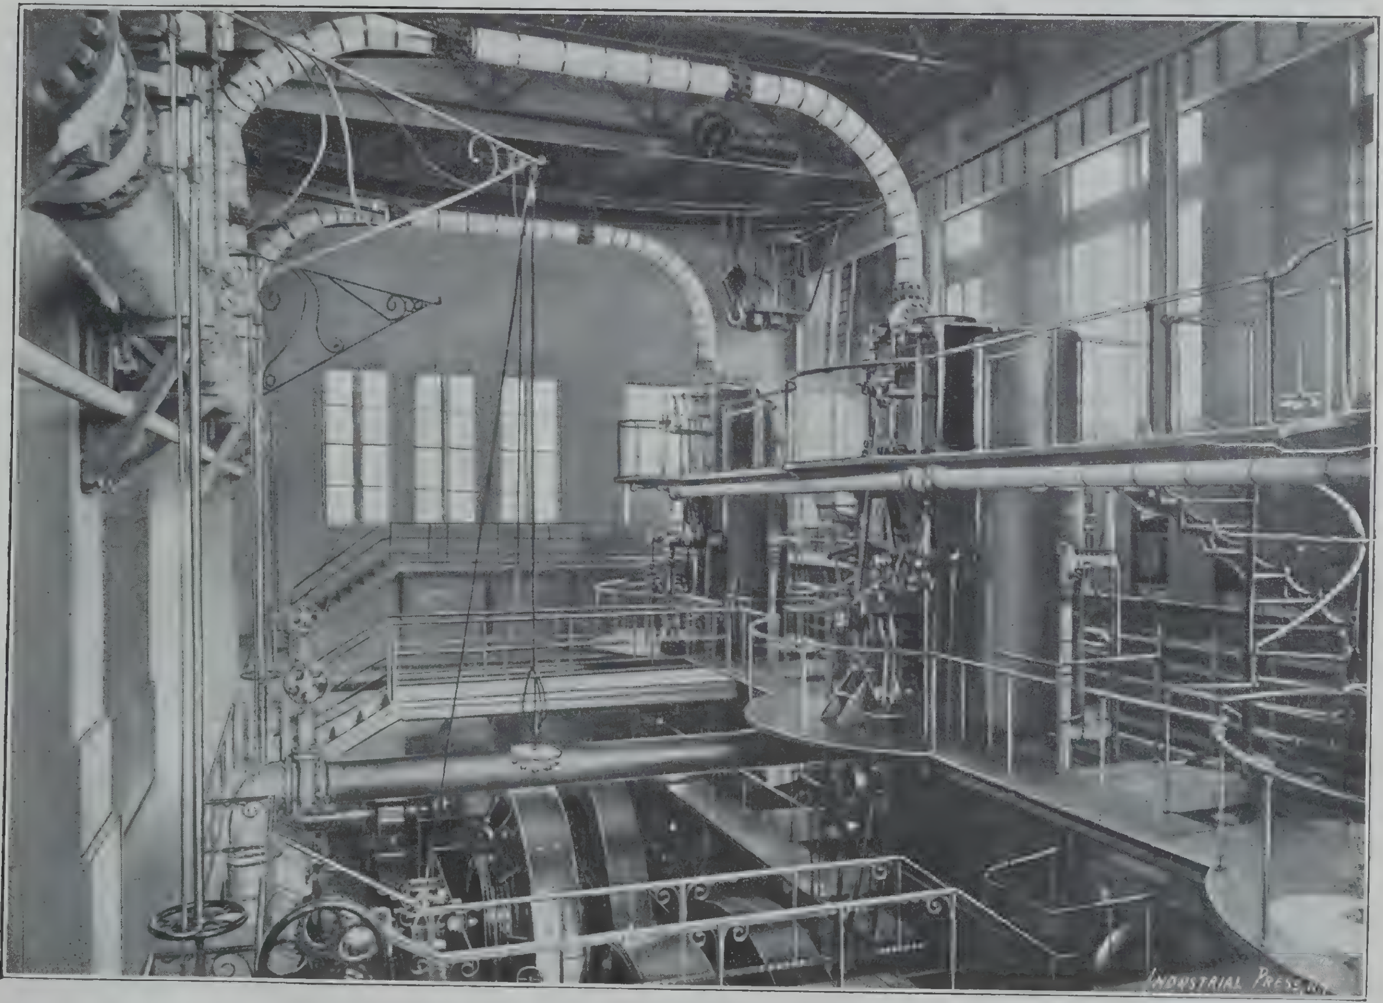


Fig. 1. Interior of Engine Room of the Virginia Electrical Railway & Development Co., which supplies the Current for the Shops of the Wm. R. Trigg Co.

The general impression is that in an electrical installation, the only saving factor is that due to the economy caused by lack of countershaft and main line shaft friction; by the smaller number of men necessary to manage the power plant; by getting rid of the condensation of steam in the pipes of a large plant supplied from a central boiler installation, and by the smaller amount of money invested in power conductors. The fact is that *the greatest* economy is often lost sight of, and that is the power of an electrically-driven machine of the modern type, if really driven, to save time and therefore money by its power of varying the cut to suit the work. The latest installations have twelve speeds under control of the operator and so it is comparatively easy for him to run his cut to the full capacity of the cutting tool. With the ordinary cone pulley and countershaft drive the best cutting speed is as liable to come between the cone speeds as it is to come exactly on the cone speed. This is the item in which experience in the use of motor-driven tools, has shown in a high degree the economical range of the electric motor. Another great advantage of the system is its adaptability to overtime work.

How many of us have seen an entire plant of 200 horse power in operation, merely to face off a flange or to turn a pulley. It can be easily seen that a few such jobs would pay for placing motors on all the shop machinery that is liable to be used for such purposes.

The improvement in the daylight illumination of such shops must be seen to be appreciated to its full value, and the extra space secured for the use of the cranes in the rapid handling of material is another argument in favor of its adoption.

This is also one of the factors by which the output is increased unconsciously.

For the old shops with low ceilings, of which there are many in this country, the low countershaft and short belts do not allow the machines to be used to their full capacity, because of the belt slipping. This may be a small item, it is true, but at the present time when competition is so keen, all these items count in the cost of the product. It has been found from experience that the personnel of the men is improved and that they are more apt to drive the machines to their full capacity.

The shop is neater and cleaner, there are fewer corners for the reception of dirty waste, and tools are not so easily mislaid. Another point seldom brought up is the increased floor capacity of a shop, due to the use of these tools. No room need be allowed for belt drives, and tools as a result can be brought closer together; and because there is no line shafting running in a fixed direction, the tools need not be located for favoring belt drives, but can be placed fore and aft the shops, or crossways, in fact in the direction best suited for their intended work, or in the space most convenient.

In a machine shop or manufacturing establishment of ordinary size the power is usually transmitted from one or more engines by means of belting, long lengths of line shafting and countershafts. The amount of power necessary to keep this mass of shafting and belting in motion is a very large percentage of the maximum output of the engine, as high as 70 per cent at times and an average of 40 per cent at least of this total power developed. It is evident that this same loss will take place whether the shop is running at its maximum or at one-quarter of its rated capacity.

The electric drive has, of necessity, a loss between the engine and the point of application of the power; but as electric systems are designed to-day this loss is comparatively small with everything under way—much less than with the belt system. It has the added advantage of being lessened proportionally as the various machines are cut off, and they do not remain a drag upon the generating plant. Such a system, therefore, permits of the use of one or more machines independently of the others, with a percentage loss referred to the machine in use, and not to the maximum output of the plant. It is also evident that with this great frictional loss in the belt drive, the power plant must be, on an average, twice as large as its more economical competitor, the motor drive. Now considering the comparative cost of all the elements of each system, we find that the first cost of the electric system is not at all expensive compared with its opponent, for the following reasons: First, the size of the power plant is cut down; secondly, the belts, line and countershafts are taken out, and thirdly, the steam pipe system is greatly decreased. Against this we have the addition of the generators, motors and wiring. It has been demonstrated in several factories that this favorable cost of installation of electricity as compared with steam is a fact. When we consider this cost, the economy of operation and increase in efficiency of cutting tools, the advantages of this system become self-evident.

It is not necessary that there be a large central station in the neighborhood as a source for the power, because one can generate one's own electricity cheaper than one can buy it in the majority of cases. We are not all located near Niagara Falls or the James River. I give a few figures from the plant of the Curtis Publishing Company, Philadelphia, Pa., from the "Electrical Review."

"This plant consists of three Babcock & Wilcox, 250 horse power, boilers at 160 pounds steam pressure, with a Green economizer of 600 horse power and induced draft. For regular work there are three large units of 200 kilowatts, 250 volts continuous current Westinghouse generators, each driven by engines 14½ and 28 inches by 18 inches stroke, tandem compound, at a speed of 200 revolutions equal 325 indicated horse power.

"For night and Sunday work, watchman's lights, etc., there is one small unit 50 kilowatts 250 volts driven by an engine 11 by 12 inches, 275 revolutions per minute, developing 80 horse power. The exhaust steam is used for heating purposes, and to keep the back pressure down in the low-pressure cylinder, the Webster system is used. The exhaust steam passes through a Cropson heater 600 horse power, returning to the feed water heater at a temperature of about 170 degrees F. The cost of running this plant for a month was $1,455.53, 41.3 per cent of this being for fixed charges (taxes, insurance, interest, depreciation, repairs, etc.). The heating cost averaged throughout the year, per month $211.83, leaving net cost of $1,244.50. During the month there was delivered to the switchboard 83,400 kilowatt hours or 111,510 horse power hours. The net cost therefore per kilowatt hour was 1.49 cent and per horse power hour 1.11 cent.

"The average price from a central station would be from 2 to 3 cents per horse power hour. The comparative economy of the isolated and central station plant can be easily seen."

The Power Plant of the Virginia Electrical Railway and Development Co.

The reasons for the higher prices of the central station are due to the fact that it costs them nearly as much to deliver the goods as it does to generate it, while the isolated plant has the added advantage of using the exhaust steam for heating the buildings. It must be understood that these figures refer to complete, up-to-date plants, and not to a motor stuck up in solitary grandeur in one corner of a machine shop. The machine, boiler, ship fitting shop, in fact the entire plant of the shipbuilding firm of the William R. Trigg Company, Richmond, Va., is fitted with the latest modern types of electric motors. This company do not generate their own electricity as they are exceptionally fortunate in their situation, their current being supplied to them by the Virginia Electrical Railway & Development Company. The power house of the Virginia Development Company is 250 feet long by 112 feet wide. The total available fall of water at the power house is 25 feet. The turbines are situated in submerged chambers beneath the boiler rooms.

There is also a complete steam auxiliary for use during one month in the year when the river is in flood from the spring freshets. The plans provide for 11,000 horse power in 11 units. The turbines were made by the Stillwell-Bierce & Smith-Vaile Co. They are the regular type of submerged horizontal turbines 2-51-inch working together making one unit. A Lombard water wheel governor is used for controlling them. The generators are from the General Electric Co., of the heavy railway type, rated at 750 kilowatts each; direct current 500 volts multipolars at 110 revolutions per minute. The armature shaft carries an 87,000-pound flywheel, which runs with the turbine as well as with the engine. When the engines are used, the coupling bolts are withdrawn between the turbines and generator and the engine coupled, the operation requiring about fifteen minutes. The engines are vertical steeple compound, made by Allis-Chalmers, and are 20 and 40 inches by 42 inches stroke, fitted with Reynolds-Corliss valve gear, operated by two eccentrics, the steam and exhaust valve being operated by different eccentrics. Their best economy is obtained when working at 800 horse power, with a maximum capacity of 1,500.

The main steam line is 14 inches diameter and the exhaust line or header is 36 inches, exhausting into a Worthington siphon condenser. There are six batteries of Babcock & Wilcox boilers of two boilers each, a total of 12 boilers; steam pressure 150 pounds, 500 horse power each, with a guarantee for 50 per cent. overloading. The Holly system of draining is used for the steam pipes, the water being returned to the boilers. The switchboard is built on a gallery about 26 feet above the engine room floor. An underground conduit system of Edison tubes is used. Those at present laid down in the city have a length of about 70,000 feet.

The capacity of the plant has been extended by the addition of a storage battery for use in the lighting system. During the morning hours when the demand for current is comparatively light, these batteries are charged and drawn on later for the evening supply. It was furnished by the

Electric Storage Battery Company of Philadelphia. There are 280 elements of their latest improved type, installed with 140 cells in series on each side of the three-wire system. The capacity of the battery at about 70 degrees F., is 180 amperes for 8 hours, on each side of the system, with a maximum pressure at end of discharge of 238 volts. This company are also part owners in the Richmond Industrial & Development Company, who have constructed a modern factory building of brick, in which tenants may rent any space they desire, with any amount of power, very suitable for small industries or experimental work. This venture is succeeding and is very well worth the consideration of other cities that are similarly situated.

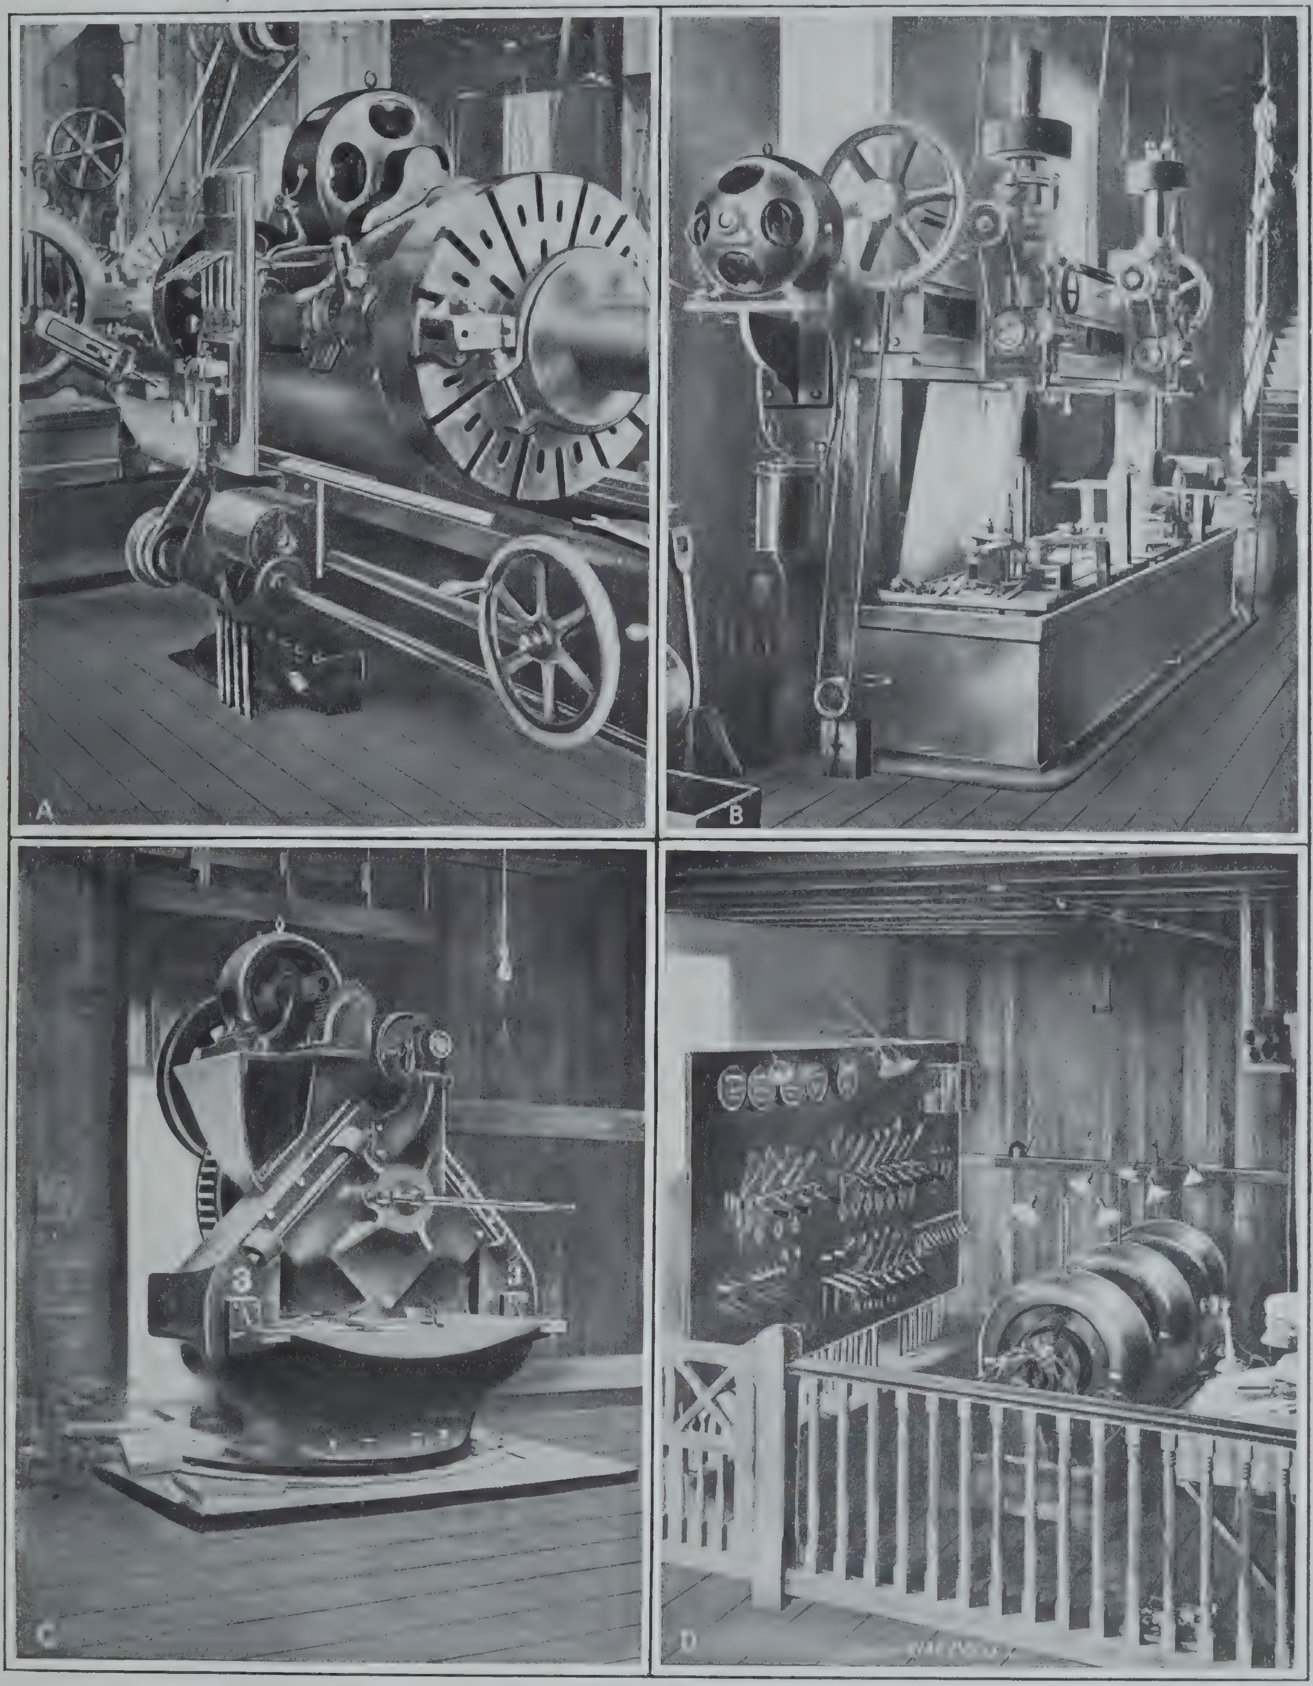

Fig. 2. A.—36 inch x 25 foot Putnam Lathe, 7.5 H.P. Motor. B.—Newton Duplex Rod Boring Mill, 7.5 H. P. motor. C.—Double Angle Shear, 10 H. P. motor. D.—Rotary Transformers and Switchboard.

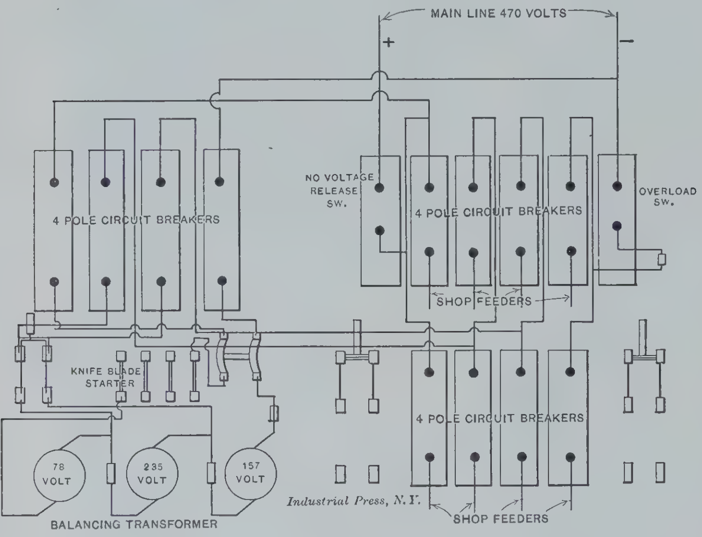
The Equipment at the William R. Trigg Co.'s Works.

The plant installed in the machine shop at the works of the William R. Trigg Company is the "four-wire multiple voltage system," as developed by the Crocker-Wheeler Company, Ampere, N. J. The ship fitters' tools, etc., are run by constant speed motors, all, with one or two exceptions, of the Crocker-Wheeler manufacture. The multiple voltage system works excellently in practice. One man looks after 96 motors in addition to his other work. The men easily become accustomed to the methods of operating the machines and express themselves as well pleased with the system, claiming that they would never go back to the old belt system if they could help it. Their work is under perfect control, as they are able to instantly stop the tool at any part of the work. The work is turned out quicker, it may be unconsciously, but the fact remains that less time is taken to do a certain job than with the old methods, even with the few months' practice they have had. The method of the electrical operation is shown in Fig. 3.



Industrial Press, N.Y.

Fig. 3. Plan of Wiring of Four-wire System used at the Wm. R. Trigg Works.

In one corner of the machine shop is the electrical department, which contains the balancing transformer, with polished slate switchboards, shown in Fig. 2, D. To this switchboard the current is delivered at a difference of potential of 470 volts. The positive wire leads to an I. T. E. 500 ampere, no voltage release breaker, or in other words, a breaker that automatically cuts or breaks the circuit whenever the voltage of the main supply ceases. There is also an ordinary breaker of the same capacity for the negative wire. The current is then conducted to 200-ampere breakers and from them to a Crocker-Wheeler cut-off blade starter, the latest type of which is shown in Fig. 4. A closing cut-off switch of iron and mica sections completes the circuit through the motor and starting resistance. The resistance is then cut out step by step by closing the knife blade resistance switches. An interlocking device prevents the switches from being closed in any but the proper order. If the line voltage fails, the cut-off switch opens, thus disconnecting the motor from the line, which cannot be replaced without opening all the resistance switches. From this the current is conducted to each end of the set of balancing transformers, one to the 78-volt and the other to the 157-volt machine. There are three rotary transformers on a common shaft, and they transform to a voltage of 78, 235 and 157 respectively. They run at a common speed of 1,100 revolutions per minute.

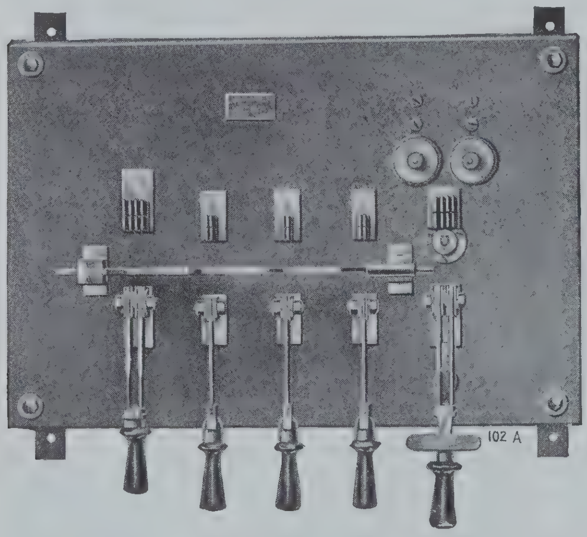


Fig. 4. Crocker-Wheeler Cut-off Blade Starter.

From a conductor connecting the 157 and 235-volt and the 78 and 235-volt transformers, wires are led to a double-pole switch. From this switch they are connected to two 150-ampere I. T. E. breakers; and from thence each line leads to a pair of 150-ampere breakers. It will be seen from the accompanying plan of wiring, Fig. 3, that there are two sets of four breakers on the panel board, one above the other, one for each side of the machine shop. The combination of voltage possible is as follows:

$$78 = 78$$
$$157 = 157$$
$$235 = 235$$
$$78 + 235 = 313$$
$$157 + 235 = 392$$
$$78 + 157 + 235 = 470$$

This four-wire system extends to each motor in the shop through a switch and circuit breaker, the object of the breaker being that if the tool should bite or gouge into the work and throw a heavy load on the motor, it will immediately break connections, saving burning out the armature, etc. From this controller, of which Fig. 5 shows a method of connections, the current enters the motor on the machine. The principle of operation is as follows: On the first notch of the controller the motor is thrown into circuit with the 78-volt current, and certain constant resistance in the armature circuit. The second notch throws out this extra armature resistance; the third notch, the 157-volt current with the same resistance as at first; at the fourth notch this resistance is thrown out and so on for twelve notches, giving the machinist twelve motor speeds, and on a lathe that is back-geared, this may give him forty or fifty speeds to work with, enabling him to find that requisite for any class of work. It is not until one has had this variation of speed at his command that the economy of it can be appreciated. Suitable fuses are, of course, distributed throughout the line, but the location of these is more for the electrical than for the mechanical end, as our province is to understand the general working of the system only.

Fig. 5. Connection Diagram of Controller for Reversing Compound Motor.

The circuit breakers used, I T E, have an adjustment from 25 per cent. below to 50 per cent above the actual rating, and at this actual rating they do not exceed 20 degrees above the temperature of the surrounding atmosphere.

The type of motor used by the William R. Trigg Company is that manufactured by the Crocker-Wheeler Co. With these machines the full load may be thrown on or off instantly without causing any sparking or necessitating any readjustment of the brushes. They behave similarly when the load is raised from one-fourth normal load to 25 per cent overload and they withstand loads 50 per cent greater than rated capacity without appreciable sparking. The rise in temperature is not greater than 40 degrees above surrounding air after a five-hour full load run. An overload of 25 per cent can be carried for an hour without increasing this rise over 5 degrees and a 50 per cent. overload can be carried momentarily. The armature is well ventilated, the commutator surface large, the field coils well protected and mechanical parts are amply strong. The field coils are wound upon cylindrical heavy insulated bobbins, which are removable from the poles by taking off the pole shoes. The armatures are wound with round wire triple cotton covered and the coils are continuous from commutation bar to commutation bar. Provision is made for circulation of air in the interior of the armature and out through the commutation connections. The current density of the brushes range from 20 to 40 amperes per square inch for ordinary carbon and for carbon interleaved with gauze as high as 70 or 80 amperes per inch.

The standard belt speed ranges from 2,000 to 4,500 feet per minute, depending upon the size of the machine. The number of square feet of belt surface per horse power averages from 70 to 90 per minute for single belts and 45 to 55 per minute for double belts.

The speeds of the standard load do not vary more than 5 per cent. when the load raises from 0 to full load. The moderate speed machines give increased output over the same size low speed and run nearer the sparking and heating limits, but are claimed to run in every way satisfactorily.

10	880	965		

Weight does not include pulley, base, frame or rails, or blade starter.

The present installation of motors at the Trigg Company's works is equivalent to 1,152.75 horse power and the present mean load with all air compressors running is 331 horse power, or 28.8 per cent of the sum total of motor horse power.

It is proposed to install a new air compressor, 200 horse power; 3 Gantry cranes, 75 horse power; a shaving exhaust system, 32 horse power, and 2 caisson pumps (25 horse power each), 50 horse power.

From the present figures we can see that only about 30 per cent. of the available horse power is in average use. With the engine and belt system we could easily use up this amount in friction on a 1,500 horse power plant and we would have this same amount of friction if we were running a 5 horse power machine or the entire system, whereas with the motor system the friction is practically proportional to the power used. With an isolated plant under ordinary conditions, we can probably figure about 1½ cent per kilowatt hour, or 1.11 cent per horse power hour.

The efficiencies of these motors are as follows:

H. P.	Full Load.	¾ Load.	½ Load.	¼ Load
225	93.5	92.5	80.4	84.7
150	92.1	89.8	86.3	76.5
100	93.0	92.0	89.6	83.1
75	90.7	89.5	86.5	77.2
50	90.1	88.5	84.8	74.4
35	89.5	87.5	83.5	73.3
25	89.4	87.0	82.5	70.5
20	88.5	86.7	82.7	71.5
15	86.5	85.3	80.3	68.3
10	85.5	85.4	83.0	74.5

This shows the high efficiency of these machines and the small loss due to their employment as an intermediary, compared with the usual belt pulley and shafting.

The motors in this shop are either compound series or shunt-wound. The diagrams of the windings are given in Fig. 8.

Chart I. shows the determination of the gearing ratios of a 100-inch wheel lathe operated by an electric motor on a multiple voltage system; also the spindle speed of the lathe for each gearing ratio and voltage.

Chart II. shows the proper gearing ratio and voltage to obtain a given cutting speed with work of a given diameter. Plotted for a range of diameters of from 10 inches to 100 inches on diameters over 30 inches, maximum depth of cut and feed. On diameters under 30 inches, two-thirds maximum depth of cut or feed.

Cutting speeds from 15 to 60 feet per minute.

A system of six voltages of relative values, 2, 4, 6, 8, 10, 12.

Controller positions 2, 4, 6, 8, 10, 12, corresponding to these voltages and controller positions 1, 3, 5, 7, 9, 11, intermediate between them.

A motor, of which the normal speed is 1,000 R. P. M., capable of supplying at half this normal speed the maximum horse power demanded, which is 20 horse power; and capable of supplying at one-third this normal speed the lesser horse power demanded by lighter cuts on diameters under 30 inches, which is 13.3 horse power.

Three combinations of gearing.

Fig. 6. Gearing Ratios and Speeds, 100-inch Wheel Lathe.

The charts, Fig. 6, page 5, of the gearing ratios and cutting speeds of a 100-inch wheel lathe show the method that is used for determining the correct speed ratios and the combinations of gears necessary for a certain cutting speed. This principle is applicable to all classes of machine tools and explains itself.

Electrical Equipment in Ship Fitters' Shed.

The ship fitters' shed of the Trigg Company is fitted up entirely with constant speed motors, equipped with double pole switch and Cutler-Hammer starters. The operation of the tools is very satisfactory. There is a line of shafting at each side of the shed; the west side driven by a Crocker-Wheeler, type D, 15 horse power motor, shunt-wound, 800 revolutions per minute, 470 volts and 27.5 amperes. This motor, as well as that in the east side, is attached to the lower chords of the roof trusses, which also hold the hangers.

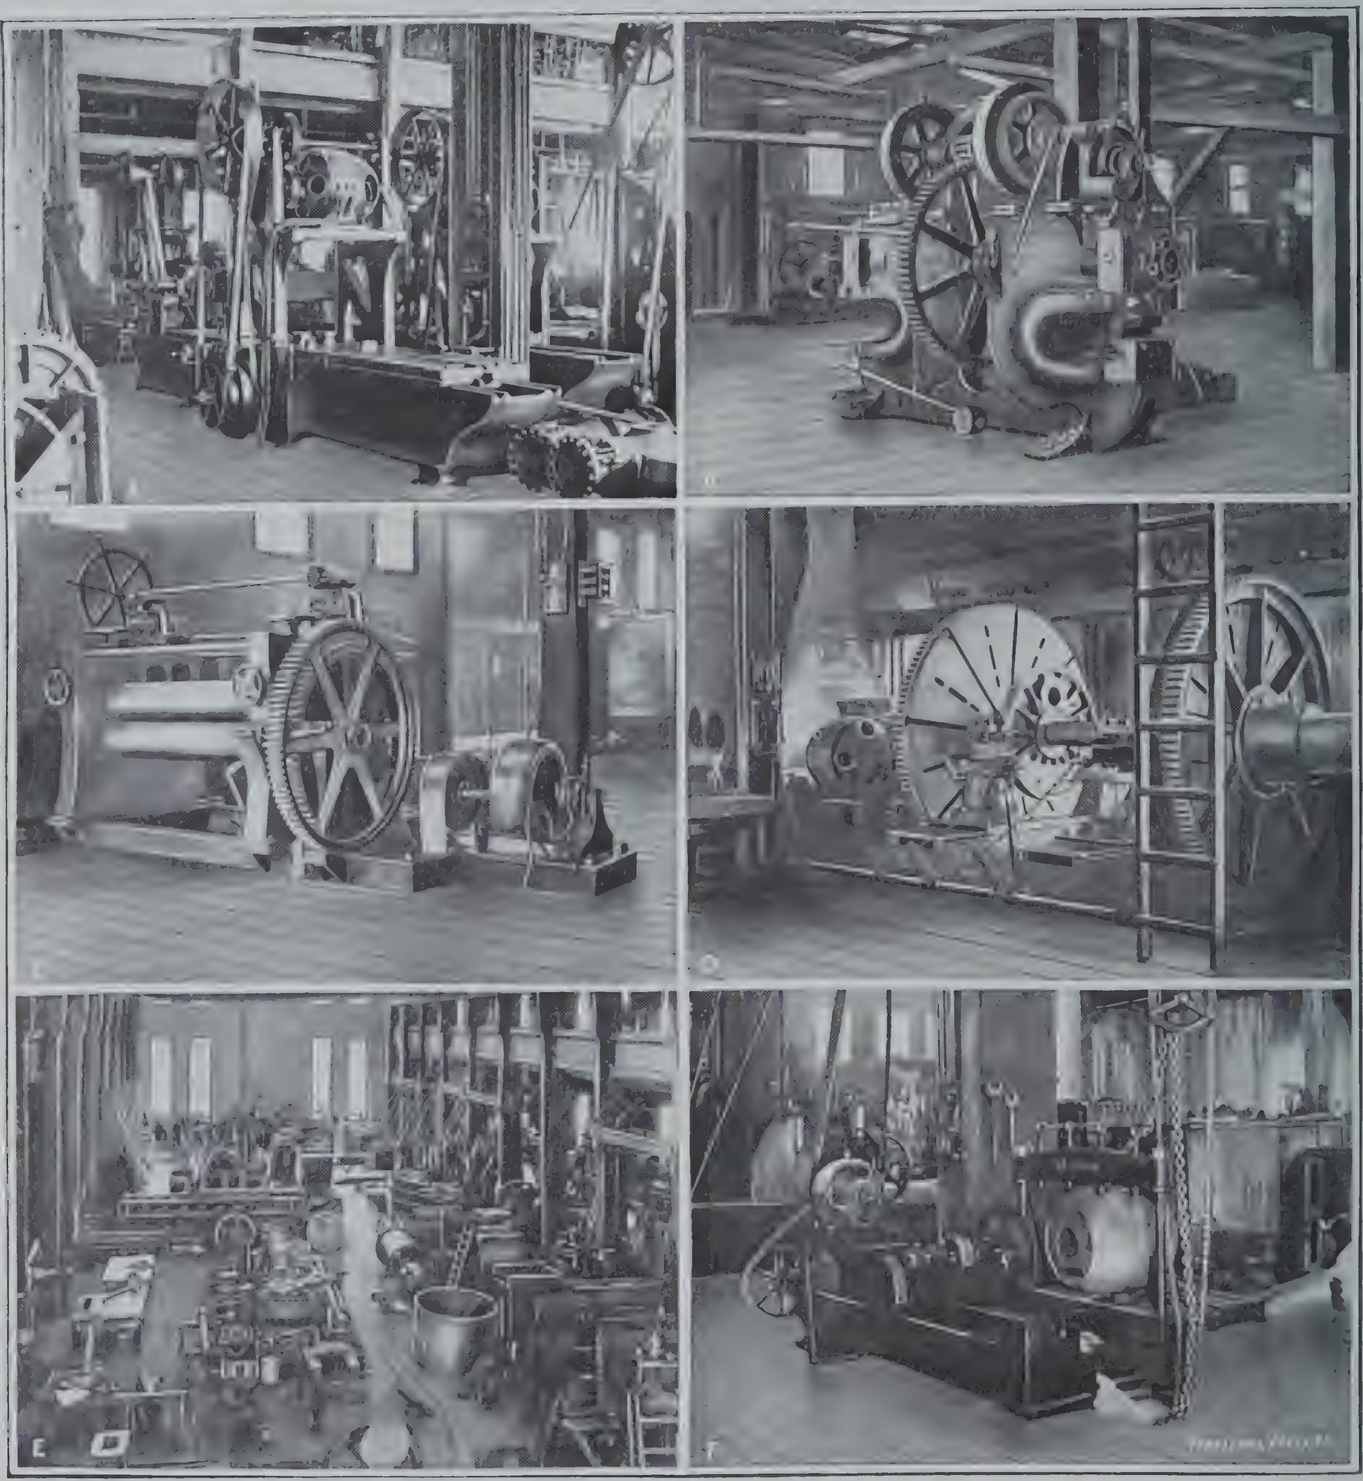

Fig. 7.

A.—36-inch Planer, 15 H. P. Motor.
B.—No. 3 Double Punch, 10 H. P. Motor.
C.—12-foot Straightening Rolls, 15 H. P. Motor.
D.—100-inch Wheel Lathe.
E.—View of the Machine Shop.
F.—Newton Cold Saw, 5 H. P. Motor.

This 15 horse power motor drives a grindstone and seven tools, viz.: One Bethlehem rotary shear, No. 4; two Hilles & Jones punches, No. 1; one Hilles & Jones punch, No. 0; one Hilles & Jones shear, No. 1; one set of straightening rolls, 8 rolls 6½ inches diameter 4 feet long, and one Hilles & Jones angle shear, No. 3.

On the east side there is a Milwaukee motor, shunt-wound, type 30 B, 30 horse power, 625 revolutions per minute, 500 volts (run at 470), 50 amperes. This motor drives a grindstone and six tools, as follows: One 5-foot radial drill; one small vertical drill; one rivet making machine, Acme; one counterboring machine, Fitchburg Machine Works; one plate planer, side, Hilles & Jones, No. 0, and one set of light bending rolls, 18 feet long, Hilles & Jones.

The other tools are separately driven, each by its own motor, viz.: Large bending rolls, Hilles & Jones, 22 feet 2 inches between heads, diameter of top roll 27 inches and diameter of bottom rolls 23 inches; three-roll machine. The roll-driving motor is of the C. & W. type, 35 D, compound-wound, 35 horse power at 470 volts, 58.5 amperes and 700 revolutions. The top roll is lifted by a C. & W. 10 D compound-wound motor, 10 horse power, 470 volts, 17 amperes and 800 revolutions. These motors start very gradually, as the resistance of the controller is thrown out and are fully up to their work. It would be preferable, however, to have the lifting motor series wound.

The straightening rolls, Hilles & Jones, are 12 inches diameter, 6 rolls each, 6 feet long, with a C. & W. compound-wound motor, 15 D, and 15 horse power at 470 volts, 27 amperes, 825 revolutions. The Hilles & Jones double punch, No. 3, has a capacity of punching 1¼ holes or using 14-inch shears, C. & W. motor, compound-wound, 10 D, 10 horse power, 470 volts, 17 amperes and 875 revolutions. The Hilles & Jones duplex, or side and butt planer, is 25 feet side and 8 feet butt, 2-inch plate, two 15 horse power, C. & W. type, 15 D, compound-wound motors, one for side and one for butt planing, each 470 volts, 17 amperes and 875 revolutions. The Hilles & Jones double angle shear is 8 x 8 inches, 1 inch angle thickness, 10 D, motor 470 volts, 17 amperes, 875 revolutions. The two Hilles & Jones punches, No. 4, have a 1½-inch punch or 16-inch shears, each of the C. & W. motor type, 10-I, compound-wound, 470 volts, 18.3 amperes, 850 revolutions, 10 horse power.

A total horse power, exclusive of the Sturtevant Blowers, which are in the Smith Shop, of 416½. With the compressors omitted, there is 196½ for the ship shed tools alone.

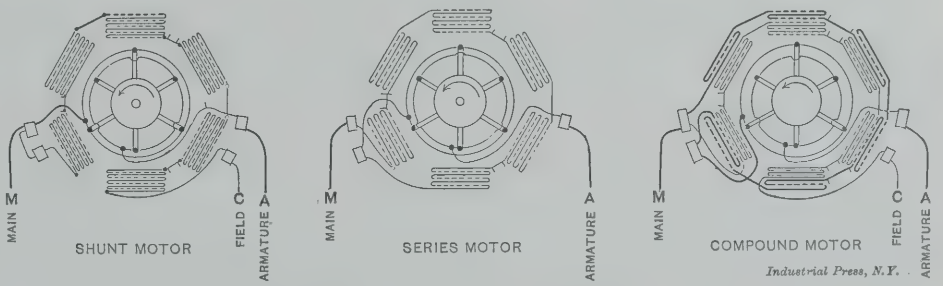
The Hilles & Jones punch, No. 2, has a ¾-inch punch, 12-inch shears, a C. & W. motor, type 5-F, compound-wound, 470 volts, 8.7 amperes, 1,000 revolutions, 5 horse power. The Hilles & Jones horizontal punch, No. 3, has 12-inch gap, 1 x 1-inch punch, a C. & W. motor, compound-wound, type 7.5-F, 470 volts, 13 amperes, 900 revolutions, 7½ horse power. The New York air compressor is a General Electric, 100 horse power, 470 volts, 175 amperes, 600 to 690 revolutions. Air is delivered at 100 pounds pressure; capacity, 500 cubic feet. The Milwaukee motor has a voltage of 470 volts, 195 amperes, 120 horse power, 580 revolutions. In the smith shop are two No. 6 Sturtevant blowers, with 12 horse power Sturtevant motors, 470 volts, 14 amperes and 1,600 revolutions. Exclusive of the Sturtevant blowers, which are in the smith shop, a total H. P. of 416½. With the compressors omitted, there is 196½ for the ship shed tools alone.

Shunt and Compound Motors.

Whereas the ship shed motors are nearly all compound-wound, the motors in the machine shop are both shunt and compound-wound. Those for the ship shed have a variable load with high starting torque and for this it is necessary to have the motor compound-wound. When the load is practically constant, the shunt-wound motor is the best. In a shunt motor system the current is divided, a small portion of the total being used only for exciting the magnets, the main current being led off direct to the external circuit. In a compound motor system, the shunt and series windings are combined. There are two sets of coils on the magnets. The series coils, consisting of comparatively few turns of wire of large section and low resistance, through which all the current of the external circuit passes; and the shunt coils, of many turns of wire of small section and high resistance, through which a small portion of the total current passes. With the shunt winding the motors are practically self-regulating, that is, they maintain a constant counter-electro motive force under varying conditions of load. I give the working principles of these two types of motors for the reason that, although familiar enough to the electrical engineer, they are not at all so to the mechanical designer or machinist, for whom this article is written.

Experiments to Determine Power Required to Drive Machine Tools.

On page 8 are data derived from experiments on three of the machine shop tools, especially prepared for this article. The machines were working under ordinary shop conditions and the data were gathered during the regular work. A 62-inch x 30-foot Putnam lathe, turning a cast-iron cylinder head 36½ inches in diameter, of hard cast iron; the tool of Sanderson self-hardening steel. A motor, Crocker-Wheeler, type 10-I, shunt-wound, 10 horse power, 850 revolutions, 470 volts, 18.5 amperes.



Industrial Press, N.Y.

Fig. 8. Shunt, Series and Compound Motors.

The second experiment was with a Woodward & Powell planer, 36 inches by 12 feet, of the Crocker-Wheeler motor, type 15-I, compound, 15 horse power, 840 revolutions, 470 volts, 28 amperes. The motor is located near the top of the housings, geared to a countershaft, which in turn is belted to the driving pulleys. It is instructive to learn that the reverse to cut consumed (of course for an instant only) from 2.22 to 2.29 times the power required to cut; and the reverse to return from 4.95 to 3.59 the power required to return; or from 5.11 to 3.86 the power required for cutting. There were two tools cutting on cast steel crank webs.

The third experiment was with a 36-inch x 25-foot Putnam lathe, Crocker-Wheeler motor, 7.5 I, shunt-wound, 7.5 horse power, 875 revolutions, 470 volts and 13.5 amperes; cutting shaft nickel steel, oil tempered and annealed, with Sanderson self-hardening steel tool.

The fourth and last experiment was with the same lathe, 36-inch x 25-foot Putnam, cutting nickel steel shaft, cut constant at ¼-inch deep and feed ⅛-inch per revolution. The speed of motor was gradually increased from No. 3 notch to No. 11 notch of the controller, representing an increase of motor revolutions from 220 to 700 per minute. The results are given in the following table and are also plotted in Fig. 10.

It is unfortunate that there was not time to carry these experiments still further, that correct deductions might be made as to the actual power required to cut various metals at varying speeds for different types of machines. Those shown are hardly sufficient in themselves to determine this data with any degree of exactness; still it may complete or add to somebody's information, while they in their turn may supplement ours.

As a general deduction it would seem that the tendency is to place too large motors upon the machines to the sacrifice of efficiency, as they are seldom, if ever, run at their highest speeds. It is, of course, best to have motors of ample size, but we are so fearful of getting them too small that we err on the other side. Necessarily in a shop manufacturing general machinery of all sizes and description, motors for a certain lathe must needs be larger than in a shop manufacturing standard engines, etc. In the first case the lathe may be called upon to turn up work of all diameters, while in the second instance the diameter of the work will vary within the same limits, year in and year out. These factors must be taken into account in designing an economical plant. We hope to have the pleasure of putting before our readers in

Power Required to Drive Shafting.

A paper read at the International Engineering Congress at Glasgow in 1901 by Messrs. James Crighton and W. R. Riddel contains some figures that are interesting in connection with our desire to learn the amount of friction and power necessary to drive line and countershafting. There were two main lines of shafting in the case under discussion. At the first trial, only the line shafting and loose pulleys were run. The machines and countershafts were run along with the shafting at the second trial and the final trial was made with the machines cutting at their normal rate. The average diameter of shafting was 3¼ inches; the average number of revolutions 140 to 150; the bearings were of white metal, self-oiling. The machine was 12 feet between centers. The total length of shafting in the works was 2,300 feet and its weight 37.42 tons of 2,240 pounds.

The engine indicated 61.75 I. H. P. on the first trial; 141 I. H. P. on the second trial, and 310 I. H. P. on the third trial. From these powers it will be seen that the line shafting absorbed 29.3 per cent. of the total power; the machine and shafting 67 per cent, and that only 33 per cent. was applied to the removal of the material by cutting, planing, shaping, etc. These figures show the large proportion of power that is lost in keeping the system in motion and the absolute need of individual motor drives; for if but one or two machines are being used, this percentage of loss would be much greater, as this main line shaft friction is a constant quantity whether one machine or the machinery of the entire plant is being operated.

It will be understood that every machine need not be separately driven, as in many cases it is preferable to use the group system—that is, the use of a 15 or 20 horse power motor, driving several medium or small tools. This necessitates a short length of line shafting, but the friction is so small and the convenience so great that it is by far the best way. Another reason is that we have the advantage of the better efficiency of the large motor as compared with the lesser efficiency of the small ones. The cost is much less also, as we have one motor against five or six small ones.

* * *

EFFECTS OF ALUMINUM ON IRON AND STEEL.

The effects that small amounts of aluminum have on the different forms of iron are of great importance. It was discovered by Wittenstrom in the 80's that, if 0.05 to 0.1 per cent of aluminum was added to a charge of wrought iron heated to pastiness, the iron liquefied so that it could be poured. The castings called Mitis castings have properties similar to wrought iron, excepting that they lack the fibrous structure.

In making steel castings, an addition of 0.03 to 0.05 per cent. of aluminum has a very beneficial effect in reducing the small amounts of iron oxide that are formed, especially in pouring. The elimination of oxides makes the steel more tough, and by preventing the oxides from oxidizing some of the carbon of the steel, it hinders the evolution of carbon monoxide, which, stirring up the steel, causes the expulsion of occluded gases. It thus diminishes, if it does not prevent, the formation of blow-holes.

The effect of 0.01 to 0.05 per cent. of aluminum upon cast iron is to convert some of the combined carbon into graphitic carbon. It is mentioned here in connection with wrought iron and steel as the third form of industrial iron. A satisfactory explanation has so far not been offered.—F. O. Hofman in *Technology Quarterly.*

STEEL AND ITS TREATMENT.—1.

HEATING FOR HARDENING.

E. R. Markham.

If men engaged in the different branches of shop work would perfect themselves in their particular lines, and in this way convince those who employ them that they are proficient workmen, they would, by so doing, make themselves indispensable.

"But," said one young man to whom I was talking about taking up a course of evening study, "I work hard all day and I don't care to study all night. When I get out at six o'clock I want a little recreation; so I go down town with the boys. I shan't be young but once you know." I told him he would be old once, and asked him to seriously consider this fact and that the money he spent evenings with the boys would purchase the necessary books to study; or would pay for a course of study in some correspondence school. His answer was: "I never spend more than 10 or 15 cents of an evening, and that is little enough. Why, Smith spends from 25 to 50 cents every night, and I could tell you of lots of boys in our crowd who spend *more* than that." And he tries to justify his own actions by mentioning others worse than himself.

An experience of years in charge of large numbers of men has convinced me that it is not of much use to talk to the "*old fellows*" whose habits are fixed. I wish to say a few words to the *young man* just starting to learn the trade that is to fit him to fight life's battle; and to the man—be he young or middle aged—who has an ambition to be somebody, and realizes that he depends on his own efforts to reach the goal. And by the way, when it is apparent that a man is trying to help himself, some one is generally found who will take an interest in him and try to help him. I hear young men say: "What is the use of studying and working every minute trying to reach the top of the ladder? If everyone did that, the top wouldn't be large enough to hold them all." As long as a great proportion of our young men feel and talk that way, however, there is no great danger that the top rounds of the ladder will be seriously affected by the weight they have to sustain. And the chances are good for the man who is willing to sacrifice a little time each week in order to broaden his mind and learn things that will be of benefit to him in the future.

At the present time when libraries are accessible to nearly everyone, and when books and mechanical journals treating on nearly every branch of the machine business can be obtained so cheaply, there is really no excuse for the man who does not better his condition. And in no branch of machine shop work is there a greater field for study and advancement than in that of hardening and tempering steel.

The past twenty-five years has witnessed great changes in the designing of machinery. Lathes, planers and milling machines have been changed not only in design but by the addition of metal to so strengthen them that heavier cuts can be taken and faster feeds used than were dreamed of thirty years ago. Now in order to have these machines do the maximum amount of work it has been necessary to make stronger and heavier fixtures. Cutting tools have also been changed and made much stronger. But if these tools are to do the amount of work the machines are capable of producing, it is very essential that they be hardened *properly*. I am convinced that very few manufacturers realize the amount of money lost in their establishments every month because cutting tools are not properly hardened, and are thus incapable of turning out as much work as they otherwise might. Some manufacturers are looking for men who can do this class of work in a *satisfactory* manner; and their number will increase as they realize the enormous leak through this one source, and the demand for competent hardeners will be greater than the supply.

In order to become a successful hardener, one must understand the characteristics and the nature and peculiarities of steel. These can best be learned by an intelligent study of works treating on these subjects. Tool steel is manufactured with the idea in view that it is to be used to make tools that must be hardened in order to do the work expected of them. All makes of tool steel are not adapted to the same class of tools. Many times a mistake is made in buying steel, say, to make fine-edge tools, because some one had good success with this particular make when using it for railroad track chisels. As the man using the steel has very little to say about the buying of it, I shall not say what particular brand of steel is best for this or that purpose; but I shall endeavor to give the reader such advice as should enable him with a little practice to get good results from almost any make of steel.

Any tool steel commonly used in machine shop work has a surface which is somewhat decarbonized from the action of the oxygen in the air acting on the carbon near the surface of the bar, during the various processes through which it goes, in the rolling mill and forge shop. Consequently it is necessary to select steel enough larger than finish size of the tool to be made, to allow of the removal of sufficient stock to get below this portion, or the piece when hardened will have a *soft* surface. Or if not soft the surface will not be as hard as the balance of the piece. When centering tool steel it is necessary to have the centerpunch mark in the *center* of the piece, as indicated in Fig. 1. If centered as shown in Fig. 2 a larger portion of the decarbonized surface will be removed at *a* than at *b*. As a result the side from which the greater amount of stock was removed will be the hardest; and as steel contracts when hardening, if one side is harder than the opposite side, the contraction of the two opposite sides will be unequal, consequently the piece must spring.

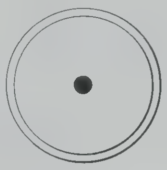

Fig. 1.

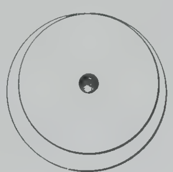

Fig. 2.

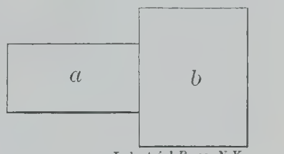


Industrial Press, N.Y.

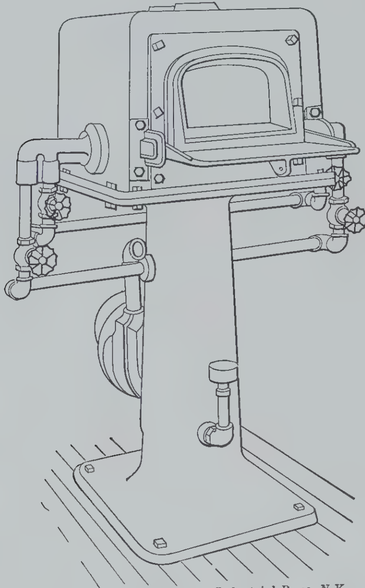
Fig. 3.

Every man and boy working in a machine shop knows that tool steel is hardened by heating until red hot and then plunging in some cooling bath. But a great many are not thoroughly posted as to the best methods of procedure to get the best results. In order to heat steel properly one must understand the peculiarities of the particular steel he is using. All steels are not affected alike by the action of heat. Some makes of steel will harden at an extremely *low* red heat, and give the best results if heated in this manner; while others require a higher heat in order to harden at all. One brand of steel I have in mind gives excellent results if heated for hardening in some manner that excludes the air from the steel; but if a tool which cannot be ground on its outer surface—as a tap or formed milling cutter—be made of this steel and exposed to the action of the air when heating, the surface carbon will be given off to such an extent that the outer surface will be soft, rendering the tool unfit for use. Yet these same tools if heated in a muffler furnace, or in a piece of gas pipe, or tube, in the open fire would be very satisfactory. In fact, *any* steel is better if heated for hardening as described above; but all steels are not so sensitive to the action of the air as the one mentioned.

I remember having in my employ in a large tool room at one time, a young man who, when he had a tool to make whose shape betokened trouble in hardening, would ask permission to harden the tool himself. This privilege was always granted, as he showed a desire to learn. While the machine at which he was working was running, he would cut a thin piece of steel from the end of the bar from which he had cut the piece for the tool. This he would heat in a furnace in the tool room and then harden, being very careful in heating not to get it any hotter than was necessary, according to his judgment. After drying thoroughly he would examine it for hardness. If he considered it hard enough he would break it and examine the fracture.

He would then bring it to me and tell me his opinion of the steel and of his heat, asking me to give him any information possible on the subject. Is it necessary for me to say that to-day that young man is holding a responsible position in a large manufacturing establishment? The desire he had to know the *whys* and *wherefores* of every job he had anything to do with, gave him an impetus to study and work, and it was a positive pleasure to give him any information possible.

But to return to the heating of steel for hardening. Although steel should never be given a higher heat than is necessary to produce a desired result, an uneven heat is much more detrimental to steel than an even heat which is a trifle too high. In order to get good results when hardening, the piece must be heated uniformly throughout, the corners and edges must not be hotter than the center, and the interior of the piece must be of the same temperature as the outside; otherwise the piece will be almost sure to crack when dipped in the hardening bath. If a piece of steel is heated hotter than is advisable for hardening—yet not hot enough to burn it—lay it one side, and allow it to cool. Then it may be reheated to the proper temperature and plunged in the bath. The effect of a high heat is to open the *grain* of the steel, making it porous. In this condition it is very brittle, and on account of the separation of the atoms that go to make up the piece of steel, it will be incapable of doing the amount of work it would if the grain were compact, as the minute holes or pores between the atoms of steel allow the surface of the tool to break away. The reheating of the piece has the effect of closing the pores and of making the grain compact, thereby furnishing a solid backing for the cutting edge.



Industrial Press, N.Y.

Fig. 4.

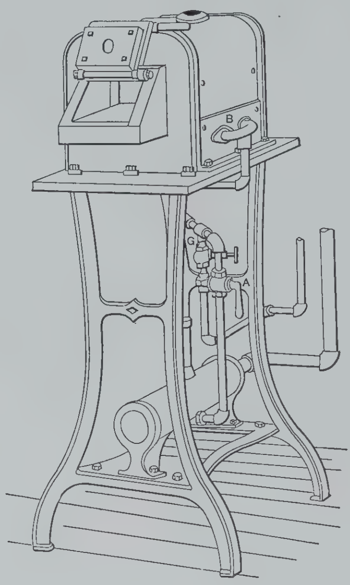


Fig. 5.

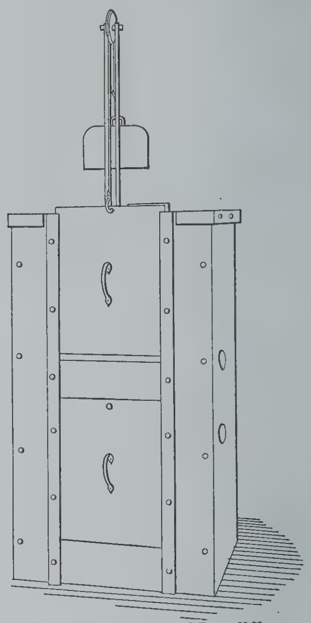
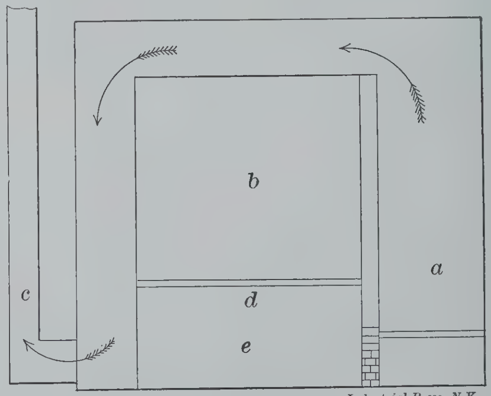


Industrial Press, N.Y.

Fig. 6.

A method that is wrong, but nevertheless often adopted by shop men when a tool is heated too high, is to allow it to cool in the air until it appears "about right" and then to dip it. The grain is then as open as if dipped at the high heat, and the unequal heat—too hot inside and cooler at the surface—would cause unequal contraction of the outer and inner portions of the piece, thereby causing it to crack. It is *unequal* contraction when cooling that causes a tool of the shape shown in Fig. 3 to crack at the shoulder when hardened. Heat has the effect of expanding steel, while cooling contracts it. A piece of steel which is expanded by heating, if suddenly cooled (and thereby contracted) is subjected to a very great strain. Now if one portion of Fig. 2, as *a*, is smaller than *b*, then *a* will, of course, contract faster than *b*. And if *a* hardens way into the corner or to the shoulder before the larger portion was through contracting a crack must be the result. This would be especially true if the two diameters were unevenly heated. But the larger shoulder containing more heat than the smaller diameter communicates *its* heat to the corner, keeping that from cooling as rapidly as the balance of the smaller portion and preventing cracking at that point. Uneven heating is probably the cause of more steel being ruined than any other one thing. While it is advisable to heat steel as quickly as possible consistent with uniform heating, yet it should never be heated so fast as to produce uneven heats.



Industrial Press, N.Y.

Fig. 7.

It is, of course, very desirable to have in a hardening room the best equipment obtainable. Generally speaking, however, men are obliged to use the equipment furnished by the concern employing them. Everything being equal, a man having access to a good muffler gas furnace, and the most approved baths can do better work than one who is obliged to use an ordinary blacksmiths' forge having a leaky tuyere, and whose only bath is a greasy pail filled with water of an uncertain quality. Yet it is a fact that the *successful* men in our shops are men who make the best of conditions as they find them. Now, if a man finds the conditions as stated, he can build a large, high fire, and by placing the article to be hardened in a piece of pipe or other receptacle, so that the fire and air from the blast cannot strike it, he can by frequently turning and moving the piece, get a very uniform heat. He can also empty the pail, wash it out and fill it with clear water. Years ago I was making tools in a small shop that had just been started, where there was no furnace of any description and no means of heating a piece of steel. I made six sets of small form milling cutters. The proprietor proposed sending them to a blacksmith to be hardened, but I asked the privilege of hardening them, which he granted. I took them home, and heated them in the kitchen range, putting them one at a time in a small iron box I had in the house. I placed about ½ inch of powdered charcoal in the box before putting in the cutter and while the cutter was heating I covered the box with a piece of sheet iron. When the cutter had reached an even low red heat, I took it from the box with a hook and plunged it in a pail of water containing a small quantity of salt. After hardening the entire lot they were brightened and the temper drawn. In order to do this I inverted the box in the fire, placed the cutters on the bottom of the box, and by frequently turning them I got a very satisfactory temper, as they were not very thick. I mention this incident to show that under trying circumstances a man may, by using his wits, do a very satisfactory job. Although I have since then hardened many pieces worth hundreds of dollars each, I do not think I have ever done a job of hardening that was a source of greater pride than those milling cutters, hardened under the difficulties mentioned.

The heating of steel is very important and a great deal depends on the facilities for doing a good job in a reasonable amount of time. There are several forms of hardening furnaces in the market which give excellent results. Figs. 4 and 5 show two kinds using illuminating gas as fuel, which are both of the form known as muffler furnaces, because the work is heated in an oven, or muffler. The flame circulating around the muffler does not come in contact with the steel and one obtains much better results than if the work were exposed to the action of the products of combustion in the fire. But if so situated that one cannot have a furnace of the kind shown, it is possible to make one that will do excellent work. Still I doubt the economy of making one when it may be bought so cheaply of some reliable maker.

If the gas rates are reasonable in the city in which the shop is located, a gas hardening furnace will be found the cheapest form to use. They are certainly the most satisfactory. But if the gas rates are so high as to make this sort of furnace impracticable, a very excellent form of coal-burning furnace, of the form shown in Fig. 6, may be procured, or one as shown in Fig. 7 may be used. This furnace will burn either charcoal or hard coal. It consists of a firebox *a* and a muffler *b*, the flame and heat passing up the side and across the top of the muffler in the direction of the arrow. It then passes down the opposite side of the muffler to the smoke pipe *c*. The grate *d* should be made of a form that allows of the easy removal of clinkers and ashes. The ash box *e* should be provided with a door having draft holes, which may be closed or opened to furnish the desired amount of draft. There should also be a damper in the smoke pipe in order that the draft may be checked at will. The muffler should have a door, through which should be drilled one or two holes. These should be covered with isinglass, in order to exclude the outside air, yet furnish a means whereby the condition of the work may be seen when the door is shut.

It should be borne in mind that it is not advisable to heat tool steel in an ordinary *coal* fire unless some means is provided whereby the fire will not come in contact with the steel, as the sulphur in the coal has a very injurious effect on the steel. In the furnace described above, the work being in the muffler is entirely removed from the action of the fire, the heating being done by radiation.

A piece of tool steel that is to be hardened should never be straightened *cold*. If the piece is bent too much to turn out and allow of removing all the decarbonized portion at all points, it should be brought to a red heat and straightened. If a piece of stock should spring in annealing it should not be straightened *cold*, that is, if it is to be hardened afterward.

When making costly tools from a bar of steel that has not been tested, it is advisable to cut a small piece of stock from the bar, heat it very carefully, dip in the bath, and then test it with a file for hardness. After drying thoroughly it should be broken as nearly across the center as possible, the grain examined, and by aid of a magnifying glass it should be examined also for traces of piping. If the steel is piped the bar should be returned to the steel mill before there is any chance of an expensive tool being made from it.

"A pipe," according to Metcalf, "is the cavity formed in an ingot when it cools; the walls chill first and nearly to the full size of the mold, then the shrinking mass separates in the middle, forming a pipe. A pipe should be at the top of the ingot; it may occur anywhere by bad teeming. This cavity, or pipe, may extend through the entire length of the bar, rendering it unfit for general use. A make of steel should not be condemned, however, because a bar containing a pipe is discovered. This is liable to happen to any steel. It is closely inspected at the mill, but sometimes escapes even the closest inspection, and the steel maker will willingly replace the piped steel with a sound bar.

BLANKING DIES.

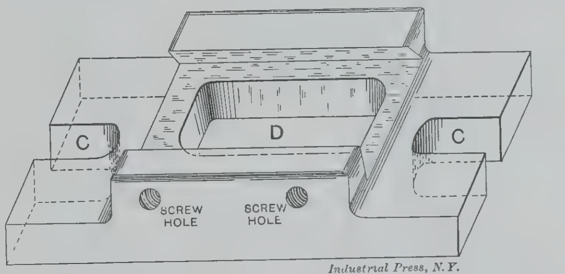
MAKING AND USING "DOUBLE" OR PIERCING AND BLANKING DIES.

Joseph V. Woodworth.

When ordering steel for dies, annealed steel should be specified, as the saving of time and labor and the superior results that will be obtained in hardening and tempering the finished tools will be a source of gratification to the diemaker. When these results are taken into account the slight extra cost of annealed steel is insignificant. As to the grade or brand of steel to use, be sure to get a good grade, and as there are several brands of steel on the market which are used principally for dies, no difficulty should be experienced in procuring a grade which will prove suitable for any special class of work. When steel forgings are required the job should be given to a smith who understands this branch of his art, for, in order that the forgings shall machine well and be hardened and tempered so that the finished tools will work satisfactorily, the smith must understand such work.

Die Block or Bolster.

Before taking up the description of the die we will devote a short space to the die block or bolster. Although these bolsters are made in a variety of shapes and sizes, the one shown in Fig. 1 is of the type most generally used for fastening and locating the class of dies indicated, while in Fig. 2 are shown a number of other styles used for dies of the same class. A large number of shops make a bolster for each die, so as to leave the tool permanently within it, but for economy, where dies for producing blanks of an average shape and size are used, two or three are all that are required.



Industrial Press, N.Y.

Fig. 1. Bolster for Holding the Die.

In machining the bolster a cut should first be taken off the bottom and then the face planed dovetail to an angle of 10 degrees, this being a standard among diemakers. The slots *C C*, Fig. 1, are cast in width sufficient to allow of clearance sideways for the fastening bolts, with which it is afterward secured to the press bolster. The hole *D*, in the center, should be made large enough for the largest blank—from the set of dies which are to be used in this bolster—to drop through after being punched.

Double Punch and Die.

In Figs. 3, 4 and 5 are shown a double punch and die used for the production of blanks like Fig. 6. The punch and die consist of the following parts: The punch holder or stem *A*, Fig. 4, of cast iron, the punch plate or pad *B* of mild steel, the blanking punch *C* of tool steel, the piercing punches *D* of the same, the stripper and gage plate *E*, the die *F* of tool steel and the pilot pin *G*. The shape of the piece to be produced in a die of this type may be any circular or irregular shape desired, as the method of construction here described is applicable to all, excepting when the blank to be produced is very large in size or when the metal punched is very thick. Fig. 8 shows different shaped blanks produced in dies of the above construction.

As most presses in which punches and dies of this class are used require a punch-holder with a round stem, one of this sort is here shown. When machining the holder great care must be taken to get the working surfaces square with the stem; also the faces of the punch plate and stripper plate must be perfectly parallel. When planing the die no great care is required, as it has to be ground after hardening. It should be finished with beveled sides to fit the bolster, with the edges of the face smooth, so as to have a square edge from which to lay out the die. Lay the punch plate, punch-holder and stripper plate aside, as they will not be touched until the die proper has been finished.

The Use of Templets.

Now in order to lay out the die a templet or master blank is required. It should be made from sheet steel about 3-32 inch thick, and should be filed and finished all over to the exact shape of the blank and be the size required. The two holes should then be laid out in the exact location desired, and then drilled and reamed to size. Care and accuracy in the preparation of the templet are necessary, as the quality of the work to be produced depends on it. Now take a piece of, say, ⅛-inch brass rod about 2 inches long and solder one end of it to the back of the templet as shown in Fig. 6. The templet is now complete and there is no possibility of getting the wrong side up.

Take a piece of soft sheet brass, of the same thickness as the male templet, and bend it to the shape shown in Fig. 7; that is, to fit across and over the face of the die, with the bent ends projecting down the inclined sides of the die about 5-16 inch. This is the female templet, and it should be worked out in the center to fit the male templet. After this has been done the face of the die should be polished with rough emery cloth and "blue-stoned," the female templet placed upon it, in the proper position, and an outline of the blank marked through it on the face of the die with a sharp scriber. Now remove the templet and proceed to finish the blanking die, which is accomplished by working the blank through it.

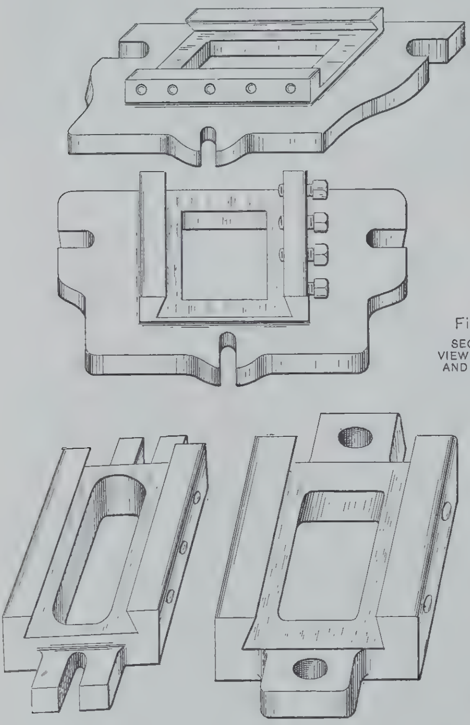


Fig. 2. Different Types of Bolsters.

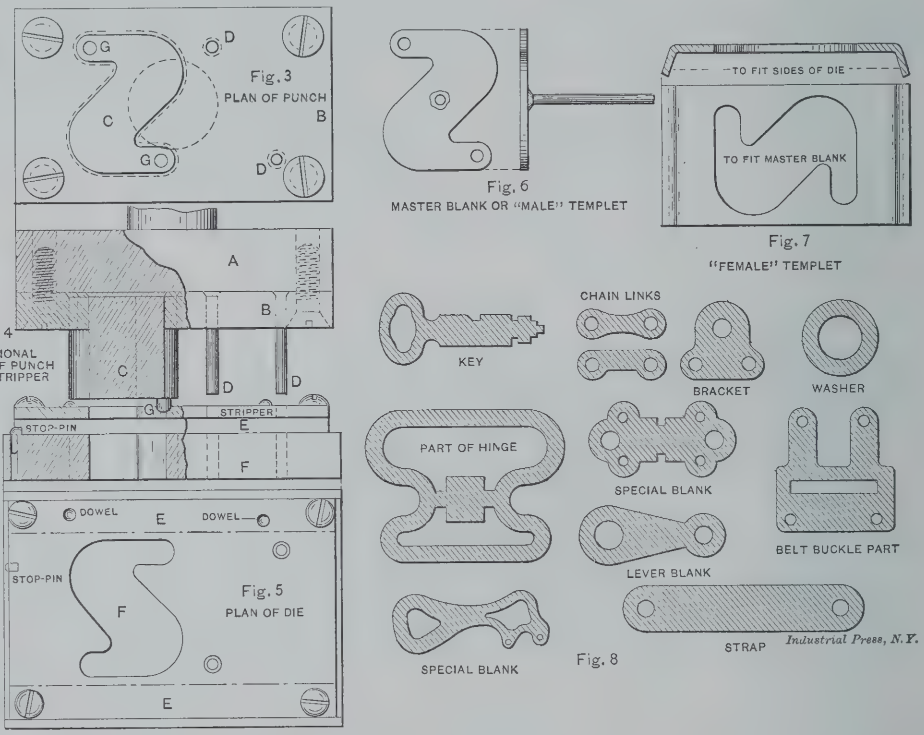

Figs. 3 to 8. Double Punch and Die, Templets and Characteristic Blanks.

To work a templet through a die proceed as follows: After the surplus stock has been removed by drilling holes about 1-32 inch apart around the inside of the outline and then drifting it out, file through from the back to within a shade of the line. Now take the male templet and, holding it by the end of the brass rod, enter it into the die from the back, holding it as parallel as possible with the face of the die. By holding a piece of white paper in front of the die it will be seen that the die touches the templet at only a few narrow spots. Take a lead pencil and mark these spots, making a line at each spot as long as the surface touched. Now remove the templet and file where the marks appear. Keep inserting the templet, marking the spots, and filing them away, and in a surprisingly short time the templet will be at the top of the die, which will then be the exact shape and size desired, fitting the templet perfectly.

Clearance.

There are a great many dies of this type used (for blanking out stock which is not required to have smooth sides) in which it is not necessary to finish the insides smoothly; but there are a greater number in which the finish of blanks with smooth sides is one of the objects sought. In dies for producing smooth and well-finished blanks the insides should be finished highly, either with a dead smooth file or a scraper.

In giving clearance to a die a few things must be considered in order to decide upon the proper amount to give. For a die which will only be used to produce a few thousand blanks excessive clearance should be given, say, 5 degrees, as this will allow of the die being finished quickly. In dies which are required to produce large quantities of blanks, and in which the blanks produced are desired to be approximately the same shape and size, 1 degree is plenty. As the die will have 1 degree of clearance all the way through, the holes drilled in the process of removing the stock should be reamed from the back with a reamer tapered to from about 1-32 inch to 1 inch of length. The reaming of the holes when constructing a blanking die will save a vast amount of filing, and the giving of the 1 degree of clearance will not be difficult.

The next step in the construction of the die is the locating of the two piercing holes. To accomplish this, place the male templet within the female and clamp it to the face of the die in the correct position, allowing for a thickness of metal between the blanks. Now take a center drill which fits the holes in the male templet and transfer the two holes through it to the face of the die. Drill these holes and then ream them from the back with a reamer of the same taper as the one used for the blanking die. After the holes for the dowel pins and screws, with which the stripper and gage plate are to be located and fastened on the die face, have been drilled and tapped and the hole for the stop pin located and drilled the die is ready to be hardened and tempered.

Hardening a Blanking Die.

In order to harden a blanking die properly great care should be taken, first, in the heating of the steel, and, second, in the quenching. In all shops where dies or other tools that require hardening are constructed a gas furnace or "muffler" should be used for heating them. But when a "muffler" is not handy charcoal should be used. After a good clean fire has been built all screw and dowel holes should be plugged with fire clay or asbestos. By taking these precautions the tendency of the steel to crack around the holes is, as far as possible, eliminated. The steel is now heated to an even cherry red, so that the entire surface will be the same heat. Then it is removed from the fire and dipped straight down, endwise, into the water, which should first be warmed slightly to take off the chill. Care should be taken to dip straight and not to move it or shake it around, as that will increase the possibility of the die warping or shrinking excessively. After removing the die from the water it should be immediately warmed. Now grind the face of the die, heat a piece of heavy cast iron red hot, place the die upon it, and it can then be drawn evenly to the temper desired. By taking a piece of oily waste and wiping the face of the die as it is heating the different colors will show up clearly. When the color denoting the temper required appears remove the die and allow it to cool off slowly.

Finishing the Punch.

Now for the blanking punch. Take the blank, or male templet, remove the wire rod and mark the spot where it was attached so as to know the back from the front of the blank. Then solder the blank, front out, to one end of the piece of steel which is to be used for the blanking punch. The punch can now be machined, either in the shaper or in the milling machine, so that its entire length will be the shape of the blank, finishing it as close to the edges of the templet as possible. Now heat the punch slightly and the templet will drop off. Clean the blank, lay it aside, and proceed to fit the punch. If it is to punch very thin stock make it a tight fit within the die; if for heavy stock, a trifle loose. In order to make a punch a perfect fit, so as to punch thin stock cleanly, the edges of the cutting face should be beveled with a file and the punch should then be sheared through the die in the press, in much the same manner as a broach is used, being careful to have it in perfect alignment with the die. This shearing of the punch should be accomplished progressively, first forcing it in about 1/8 inch, then removing it and filing away the curled up metal, and repeating this until the punch has been forced completely through the die. While doing this use plenty of oil on the parts.

Before hardening the punch—that is, if it is to produce accurate work, for in most cases it should be left soft—it is necessary to locate the holes for the pilot pins *G*. These pins are necessary in order to produce pierced blanks that will be interchangeable. Take the male templet and enter it into the die from the back, with the front up. It will fit the die tightly because of the shrinkage in hardening. Now enter the blanking punch from the top and locate the holes for the pilot pins through the holes in the blank with the same center drill used for locating the piercing dies. Drill the holes to size and then harden and draw the punch to the temper desired, which in most cases should be a dark blue. In tempering the punch draw it from the back, allowing the temper to run out to the face, and thus the back will be soft while the remainder will be as hard as required. The drawing of the punch so that the back will be soft is done to strengthen it and also to allow of upsetting it when locating it within the punch plate.

Aligning the Parts.

To locate the blanking punch in the punch plate, take the plate and clamp it true on the face of the die and then transfer the outline of the blanking die to the punch face. Then work a hole of the shape of this outline through the plate so that the punch can be entered face first through from the back. Place both punch and punch plate under the ram of the press, set the punch dead square with the face of the pad and proceed to force it through, using the punch as a broach to finish the hole. It will be found necessary to repeat this operation several times in order to get the punch through the plate, as the surplus stock curled up by the punch will have to be removed. After having forced the punch into the pad until the face is through, force it back and out again. Now chamfer the edges of the hole at the back of the plate and force the punch in again, until the back is a shade above the plate; then upset or rivet as shown and finish flat with the plate, and there will be no danger of the punch pulling out when in action.

To locate the holes for the piercing punches, enter the blanking punch into the die until the faces of the punch plate and the die are within 3-16 inch of each other, with a pair of parallels between them. Then use the die as a jig and locate holes for the piercing punches, spotting these deeply. With a drill about two sizes smaller than the piercing dies, drill entirely through the punch plate and then ream the holes to size. Use the die as a jig for all three operations. For the two piercing punches use drill rod or Stubbs wire and upset the heads before hardening, as all small piercing punches should be hardened for their entire length, otherwise they will bend or break when passing through the stock. If, after hardening, the punches are found to have sprung, they must be carefully straightened before forcing them into the punch plate. Fasten the punch plate to the cast-iron holder *A* with four flat-head screws, as shown in Fig. 4.

All holes for screws and dowels in the stripper plate should be transferred through the die. The holes for the two piercing punches should be the same size as the dies, and must be transferred, drilled and reamed through the dies after the plate has been located and fastened. By having the piercing punches fit tightly within the stripper they will be strengthened and supported while piercing the metal. The hole for the blanking punch may be a loose fit for the punch. After the gage plates and stripper have been located and fastened upon the die, as shown, with the stop pin located so that its locating face is the same distance from the edge of the blanking die as the width of surplus stock allowed between the blanks, the die will be complete.

The practical points to be kept in mind when constructing a die of the above type are: Be sure to make an accurate pair of templets. Machine the punch-holder, the pad and stripper plate accurately. Work the blank through the die and use it in locating all the holes for pilot pins and piercing dies. Finish the die before starting on any of the other parts. Transfer all holes in the punch plate through the die, and, lastly, be sure to have the front of the male templet up during all operations in which it is used. By keeping these practical points in mind you will have a punch and die in which the alignment between all parts will be perfect.

Setting the Die and Using it.

To operate the die drive it into the die block or bolster, Fig. 1, and then set it up in the press. The proper way to set a die of this kind is to first place the punch within the ram of the press and fasten it there. The punch should then be brought down until its face is within 3-16 inch of the die face. Then, using the left hand through the press bolster, the die should be raised up until all punches have entered it. The punch should then be brought down, by moving the press flywheel with the right hand, about 5-16 inch, and the die will rest squarely on the press bolster in perfect alignment with the punch. Now fasten the die to the press, give it a rap with a hammer at each end and go ahead.

The stock to be punched should be entered beneath the stripper and pushed up against the stop pin. At the first stroke of the press the two holes will be pierced and a "scrap" blank punched out. Now feed the stock forward until the back edge of the punched hole rests against the stop pin, and at the next stroke, as the punch descends, the pilot pins in the blanking punch will enter the holes pierced at the first stroke and a blank will be produced which will be an exact duplicate of the male templet. The stock may then be fed along until the entire strip has been worked up.

* * *

In astronomical work it is of the greatest importance to be able to read the graduated circles with the attached microscopes without bringing near the circles the source of light. Any light that we are now able to produce is accompanied by heat, and heat even of small degree locally applied, will quickly distort the circles so that accurate readings are impossible. To overcome this difficulty, Professor Becker, of Glasgow University, has recourse to solid glass rods to convey light to the graduated circles. Light projected into one end of a glass rod such as he uses, is delivered at the other end, even if the rod is curved. The light cannot escape from the sides on account of the internal reflection from the sides. The heat conveyed with the light, is, of course, of little proportions. To illustrate the sensibility of such graduated circles it may be mentioned that the radiation of heat from the human body has been found to exert a most sensible effect. So if it is necessary for an attendant to be near a circle, he or some one to take his place must remain in the same approximate position constantly throughout an observation.

PHILADELPHIA—MACHINERY FLOOR, THE BOURSE.

SUBSCRIPTIONS.
SHOP EDITION, $1.00 A YEAR. TEN CENTS A COPY.
ENGINEERING EDITION, $2.00 A YEAR. TWENTY CENTS A COPY.
FOREIGN EDITION, $3.00 A YEAR PREPAID.

LESTER G. FRENCH, Editor.
FRED E. ROGERS and GEO. H. HALL, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

SEPTEMBER, 1902.

NET CIRCULATION FOR AUGUST, 1902,—25,724 COPIES.

Mr. George H. Hall has been engaged as Associate Editor on the staff of MACHINERY, his work beginning with the October number. This addition to the editorial force will enable us to materially strengthen the machine shop features of the paper and we shall make the dollar or shop edition more valuable to the practical machinist than ever before. Mr. Hall is well equipped for his position by technical training and some eight years' varied experience in machine shop and drafting room, as well as by occasional work which he has already done on MACHINERY.

* * *

EIGHT YEARS.

The eight years which comprise the life of MACHINERY cover a period of unexampled prosperity to manufacturers; and while the growth of the paper has been unusual in the history of trade publications, it has not more than kept pace with the progress of the trade it represents.

Firms that were not in existence eight years ago, to-day own and operate plants employing hundreds of men, the establishment of which heretofore represented the toil and saving of a generation, and the extension of existing plants has progressed in a like degree. One entire section of Cincinnati—a city in itself—devoted almost entirely to the manufacture of machine tools and comprising twenty-one plants, some of the largest in the country, has sprung up in the period referred to. And it is also true that the rewards of skill and energy during that period have not been limited to the employer; for among the writer's personal acquaintance are many instances of mechanics who were earning day's wages less than eight years ago, who now control enterprises which represent the investment of good-sized fortunes. Yet the development in machine tools and kindred lines in this country has hardly more than begun, for the multiplicity of enterprises which rely for their progress and profits on the use of improved machinery offer rewards that will continue to spur on the ambitious mechanic; and although the present period of prosperity cannot continue without interruption, it is not probable that any one now living will witness the surrender by this country of the lead it has acquired in the design and manufacture of labor-saving appliances.

This is not a special number of MACHINERY, although it contains more advertising than usual. No canvass was made to obtain additional business for the September number, because we wished it to be a fair specimen, both as to reading and advertising, of what the paper will be during the coming year—except that we shall try to improve it each succeeding month. L.

THE ENGINEERING EDITION OF "MACHINERY."

The dollar edition of MACHINERY has attained the largest paid circulation ever reached by a mechanical paper and will be continued at the present price, as the Shop Edition.

There is no monthly in this country devoted to constructive mechanical engineering, although there are several valuable publications which cover the general engineering field with matter of a descriptive and popular character; and the Engineering Edition of MACHINERY has been published in response to a demand for a technical monthly for mechanical and consulting engineers, superintendents and others engaged in actual constructive work, who desire to keep closely in touch with mechanical progress without taking the time necessary to read several publications.

A number of important features will be introduced in the Engineering Edition, beginning this month, of which the following is a brief summary:

FIRST—The articles will be mainly technical, rather than descriptive or popular. They will contain specific information relating to the design, construction and operation of machinery and kindred subjects; and will thus be valuable for future as well as present reference.

SECOND—No write-ups or matter for advertising or other considerations except the merit of the article illustrated have ever been inserted in MACHINERY; but in their place a very complete summary has lately been given, containing short descriptive articles on new tools or machines that have just been placed on the market. Information concerning these is obtained systematically, and although MACHINERY already publishes more descriptions of such machines than all the other papers combined, this department will be further extended.

THIRD—It is intended that the Engineering Edition shall cover its field so thoroughly that even if no other paper is seen the reader will obtain all the important mechanical news of the month, and to this end there will be editorial note and comment on all noteworthy mechanical events in each number. This matter will be systematically gathered and will be so complete that the readers will be kept in close touch with mechanical progress. In many respects this will be the most valuable feature of the paper.

FOURTH—A digest of leading articles in the engineering papers will be given in each number, together with a list of other articles which do not receive extended mention. The digest will be edited with a view to giving the substance of items that are of the most interest to constructive engineers.

FIFTH—A data sheet will be published each month containing tables, diagrams and other information of practical value, in condensed form, most of which will be taken from the proceedings of the various engineering societies. As these proceedings are usually seen only by the members of the societies issuing them, much valuable matter is lost to professional men. The data sheets will represent this material in the most condensed possible form without sacrificing any part that is of value.

SIXTH—The collection and publication of data from the proceedings of engineering societies will be extended so as to include information covering important laboratory work conducted either by the technical colleges or private testing laboratories. The results of many important tests are now not published at all, and it is believed that their preservation in permanent form will be of great value to all who are interested therein.

The price of the Engineering Edition will be $2.00 a year, and we shall make the paper worth that to its subscribers.

* * *

The uses of aluminum are manifold and new ones are constantly discovered. It is found to have a very favorable effect upon zinc used in galvanizing. In the process of galvanizing suitable prepared sheets are drawn through a bath of melted zinc which ordinarily goes through a slow oxidation process, forms drosses, and finally loses its power to coat iron. By adding one pound of an alloy of zinc with 2 per cent of aluminum to the zinc bath, this becomes more fluid; a given weight of zinc, thus charged, coats 20 per cent more surface, the sheets are brighter and keep their color better. The amount of aluminum added is only 0.001 per cent, but it has this remarkable effect.

IMPORTANT STEAM TURBINE DEVELOPMENT.

The advent of the General Electric Co. in the steam turbine field gives renewed pertinence to the question of whether the turbine is to become a formidable rival of the steam engine, or possibly, even, to become its successor. There was great interest shown when the Westinghouse Machine Co. took up the manufacture of the Parsons steam turbine in connection with their engine business. That the General Electric Co., however, should have decided to seriously enter the steam engine field and that the type of engine they have adopted is the turbine, is even more significant. The wheel which they are preparing to manufacture is the invention of Charles G. Curtis, assignor to the Curtis Steam Turbine Co., New York City.

In 1896 experiments were made on a Curtis turbine of about 150 horse power at Stevens Institute. Its economy was about that of a simple high-speed steam engine of corresponding power, but somewhat inferior to that of a compound engine. This turbine, however, was built for experimental purposes before it had been determined what the exact requirements were, and was faulty in construction.

A Curtis turbine of 500 horse power has been in operation in the power house of the General Electric Co. at Schenectady for over a year, giving good results. Although rated at 500 horse power it has carried a load of 1,000 horse power for several hours at different times and has also established a record for continuous service by running for a period of ten days without shutting down. Oil is pumped on the bearings continuously. In common with other steam turbines the condensation is free from oil and can be used over again without injury to the boilers, while the cost for attendance is exceedingly low.

The General Electric Co. are making preparations as rapidly as possible for building turbine units in larger sizes. One of 1,500 horse power for the works of the Michigan Construction Co., Jackson, Mich., will soon be completed. This is to be direct-connected with an alternating current generator and is the first wheel which they have built to be installed outside their works. They will soon build two more 1,500 horse power turbines, for their power house at Schenectady. It is understood also that they have orders for several wheels of a larger size. One of these is for installation in the new station of the Commonwealth Electric Co., at Chicago, and there is the possibility that if the results compare favorably with those from reciprocating engines, more turbine units will follow. The design adopted for this station is novel, in that the turbine is placed horizontally, with its shaft running in a step bearing in a vertical position and the generator located directly over the wheel. The experience of the General Electric Co. in designing the step bearings for the generator shafts of the Niagara Falls Power Co. has enabled them to adopt this type of construction for the steam turbine, with a reasonable assurance of success.

Last April the steam yacht Revolution, about 140 feet long, and equipped with Curtis turbines, was launched from the yard of Chas. L. Seabury & Co., Morris Heights, N. Y. The boat has twin screws with a turbine on each shaft, and the engines have developed 2,500 horse power. While no figures have been given of the performance of the engines and the speed attained by the boat, it is known, by comparison with other vessels, that she has traveled in the vicinity of 20 knots an hour.

The first Curtis patents were issued about 1896, and it is evident from the successful progress made in the application of this wheel that it is to assume a prominent place among high-speed steam motors. Next month we shall outline briefly the characteristics of the Curtis, De Laval and Parsons turbines.

THE DAVIS ARMOR PLATE.

Lieutenant Cleland Davis, of the Navy, has discovered a process for making armor plate that promises to be vastly superior to the Krupp plate, which up to the present time has been the most effective. The method employed by the great German gunmaker consists in using a highly carbonated gas directed by many gas jets upon the face to be hardened. At a red heat the plate absorbs the excess carbon from the gas and at the end of two or three weeks of the hardening process its face becomes sufficiently carbonized to produce an extremely hard composition. Lieutenant Davis in his experiments discovered that a current of electricity directed on the armor plate by large carbon anodes would carry with it a portion of the carbon of the anode and transfer it to the body of the metal. The spot so treated became intensely hard and the depth of hardening was found to be dependent upon the time that the current was applied. Usually only a few hours were necessary to produce results equal to the Krupp process.

The contest between armor and artillery becomes wearisome at times, but the recent improvements in regard to both are of perhaps greater interest than usual. Last December it was demonstrated at the Sandy Hook proving ground that it was possible to penetrate the heaviest Krupp armor with a 12-inch shell and completely wreck the armor. This is done by employing a powerful explosive agent in the shell, which, however, is desensitized, so that it will not explode in the gun. The explosive is fired when the shell has entered the plate by means of a delay-action fuse which can be arranged to act at any given time within very narrow limits. This achievement is responsible for the refusal of the government to experiment further with guns of the Gathmann or Zalinski types. The first of these fired a high explosive by means of powder, and the second by means of compressed air, and in both cases the charge exploded against the face of the armor without penetrating it.

The armor-piercing shell now used by the government is considered one of the most important improvements in modern artillery. If the Davis armor proves to be as great an advance in armament we shall be well equipped to battle with the foes of the future. The fortunate part of it all is, however, that the improvements in artillery and armor may more frequently than not be applied in industrial work, where they are of greater utility to mankind in general than when applied simply to implements of war.

* * *

NOTES AND COMMENT.

REVIEW OF CURRENT EVENTS, TECHNICAL AND MECHANICAL.

Work has been begun upon the buildings for the new National Bureau of Standards, Washington, D. C., and if present plans are carried out the completed buildings will represent an outlay of over $1,000,000. The first building to be erected will be the mechanical laboratory, which will be followed by a main building to include the office of the director of the bureau.

What is said to be the largest steel tank in the world has been completed at Boston for the Atlantic Refining Co. It stands 36 feet high, its diameter is 90 feet, and its capacity 36,000 barrels. In the construction of the sides 144 plates of iron were used, and in the bottom 102 plates. The weight of each plate is 900 pounds. Lighter plates were used on the roof, and it required 202 of them. In the joining of the plates two tons of steel rivets were utilized.

Dr. Auer Von Welsbach, of incandescent mantle fame, is following Edison's lead in the invention of an improved storage battery. He claims much greater capacity and endurance for his battery than can be secured with the commercial lead battery now so extensively used. Important elements in the battery are certain of the rare earths, with the characteristics of which he became very familiar when developing the Welsbach mantle.

Last month we referred editorially to the Blickensderfer electrical typewriter, in which a slight depression of the keys causes the typewheel to be operated electrically and so print with uniform stroke at whatever speed the operator may manipulate the keys. An exhibition was recently given in the office of the Baltimore *Sun* of another electrical typewriter invented by J. H. W. Marriott, of Baltimore. Mr. Marriott has been personally identified with the typewriter business for many years, being formerly with the Remingtons. A feature of the new machine is its manifolding qualities, as the electrical blow can be so regulated as to strike with a force as great as 10 pounds or even more.

The largest steel freight cars yet designed are to be built by the Pressed Steel Car Co. for the Monongahela Connecting Railroad, a line having thirty miles of track, twenty locomotives and nearly three hundred cars, all owned by the Jones & Laughlins Steel Co. It connects with the Pittsburg & Lake Erie, with the Baltimore & Ohio and the Pennsylvania Railroad and crosses the Monongahela River between the Soho and Southside plants. It is used entirely for switching freight and supplies for the steel mills and other industries on its route. The cars in question will have a capacity of 200,000 pounds, just double that of the largest steel cars now in common use. These cars will be so heavy that the bridge across the Monongahela River will have to be entirely rebuilt. The cars cannot go off the home line as they are too wide and heavy to cross bridges on other railroads.

It is a dull month when we are unable to publish an item about "A Solder for Aluminium," yet the field is still open for such a solder, adapted for ordinary use by ordinary mechanics. This month our item comes from a press dispatch from Worcester, Mass., to the effect that W. H. Whitney, of Clark University, has invented a solder for aluminium that can be applied with a soldering iron, and appears to produce good results. Mr. Whitney is not ready to give any information about his invention further than to say that he has employed it with success in instrument making. The use of aluminium, "the metal of the future," has been greatly restricted by the fact that it cannot be successfully soldered or brazed by ordinary methods, and articles must either be of one piece or else riveted, pressed or otherwise fastened together by mechanical means. It is to be hoped that Mr. Whitney's invention will fully meet his expectations.

A gigantic project which is "in the air," and yet appears to be given some credence is the proposition to establish an electrical power plant at Victoria Falls, on the Zambesi River, Africa, that will equal or eclipse the Niagara plant. These falls surpass the cataract of Niagara in magnitude; but they are in the heart of the Dark Continent, and it would be necessary to transmit the power long distances to reach the important cities on the coast. The question of utilizing this power has been carefully canvassed by prominent engineers, and it is reported that a commission is to set out from London to make an investigation within a few weeks. It is improbable that the immediate future will see an actual beginning of the work, because its successful completion must depend upon railroad communications, requiring about 300 miles of track through the most difficult country for railroad building. The land is swampy and malarial, and the natives are not friendly.

A typewriter is now being manufactured at the Remington shops, Ilion, N. Y., with an attachment by which a message, mechanically correct, can be sent over a telegraph wire through the manipulation of the typewriter keys, as in typewriting. It is the invention of Charles E. Yetman, formerly a Western telegraph operator. The machine enables the operator to make the dash and dot symbols of the Morse alphabet at a high rate of speed and with little chance of an error. The typewriter has a series of rings arranged side by side on a shaft with edges serrated to correspond with the dashes and dots of the telegraphic code. The depression of a key causes its ring to rotate and make and break the circuit for the Morse letter corresponding. The machine makes no record or reproduction at the distant end of the line, and an experienced operator is required to read and receive the message; but anyone who can operate a typewriter can send a message much more accurately and at a higher rate of speed than is possible by the use of the ordinary telegraphic keys. The machine has been tried with success in various newspaper offices and in the offices of the Associated Press.

One of the applications to which the steam turbine is eminently fitted is for the operation of centrifugal pumps for fire service or any other purpose. The centrifugal pump is a fairly efficient machine when driven at the proper speeds, which are always high, and that is just what the steam turbine can do without belting up. It has decided advantages over the reciprocating pump, since there are no cylinders, pistons or valves to be cut and abraded by foreign substances in the water, so it makes no difference how dirty or gritty the water may be, it can be handled with impunity. This is a prime advantage for a fire pump, and especially for the portable fire engine, which often has to pump very bad water at high speeds. The Parsons Co., the builders of the steam turbine in England, have in operation in one English mill a centrifugal pump driven by a Parsons steam turbine at a normal speed of 2,000 turns per minute. At this speed it delivers 25,000 gallons against a head of 40 feet. In case of fire it can be speeded up to 4,000 turns per minute, when it will deliver a somewhat larger column against a head of 160 feet.

One of the interesting, not to say amazing, features of modern engineering construction is the varied and extensive uses to which concrete is being put. A grain elevator has recently been built in Buffalo having a storage capacity of 650,000 bushels, of which the foundation is of concrete up to and including the basement, ten feet high. On this foundation stand 90 steel storage bins 65 feet in depth and of various diameters up to 15 feet. Concrete is being used exclusively on the Lackawanna Railroad for retaining walls, culverts and other construction, which a few years ago would have been made of cut stone. Concrete is largely used in the construction of the new shops of the Central Railroad of New Jersey at Elizabeth, N. J., all foundations for shop walls and machine tools being made of it; also the floors. The roundhouse walls are concrete, as are the pits and wall for the turntable pit. The time-honored wooden pile has also been displaced by the concrete pile. In this case a steel tube is driven containing a steel core. The core is composed of two longitudinal sections which are removed after the tube is driven and the space is filled with concrete. This in effect makes a concrete pile with a thin outer steel shell. The inevitable disintegration of the steel shell, of course, does not affect the integrity of the pile.

THE LIGHTEST AUTOMOBILE.

Elsewhere in this number is an article upon the heavy motor trucks made by the Morgan Motor Co., Worcester, Mass., which are among the heaviest and possibly are the heaviest made in the United States. By way of contrast it is interesting to note that what will be the lightest automobile made in this country is to be manufactured at Hartford, Conn.; or, more properly, the motors for such automobiles. Part of the Acme shops, recently vacated by the Acme Machine Screw Co., have been leased for the purpose, and the motor to be built is very light in weight and is intended to be attached to ordinary bicycles. It is of French design, weighs only 20 pounds, and is capable of developing 1¼ horse power. It is known as the French Clement motor. A wheel equipped with one of them has been known to make a trip of 1,500 miles without serious breakdown; but most readers of this will probably question whether a common bicycle will be capable of long standing the strain of so powerful a propelling force, although provision is made for strengthening the front forks of wheels that are to be motor propelled. Gasoline is fed to the motor from a tank situated in front of the handle-bars, and the motor itself is clamped to the lower member of the frame in front of the rider.

ELECTRICALLY-WELDED AUTOMOBILE PARTS.

The marked increase in the number of automobiles manufactured has led the Standard Welding Co., Cleveland, O., to adapt their electric welding process to the production of several important parts for automobiles. This action, together with the influence of firms making drop forgings, is likely to be the beginning of a tendency to standardize certain parts of automobiles in the same way that bicycle parts have come to be regarded as standard. The initial effort of the Standard Welding Co. in automobile work was the manufacture of the seamless rim in various styles and diameters for wood and wire wheels. The advantages of these rims come from the high-grade material that it is possible to use and the accuracy of dimensions. This latter is especially valuable in connection with wood wheels, as it enables the maker to adopt a standard of size without special attention being given to sizing each wheel for each individual rim. As drop forgings have been used advantageously in the manufacture of automobile parts, especially axles, levers, etc., a considerable amount of special work is carried on by this company in electrically welding these special forgings to commercial iron or steel, to produce the finished product. This obviates the necessity of making long and expensive forging dies and gives great flexibility in the manufacture of articles of this class, as small articles can be readily drop-forged and welded to meet the various conditions.

ANOTHER ATTEMPT AT ELECTRICITY DIRECT FROM HEAT.

Prof. C. B. Thwing, of Syracuse (N. Y.) University, has invented a thermo-electric generator for the direct conversion of heat into electricity. The principle of the apparatus is the old one that a current may be produced in a closed circuit by heating the point of contact of two dissimilar metals. For example, if a piece of bismuth and a piece of antimony be soldered together, their free ends connected by a wire and the place where the pieces join be heated, there will be a slight current flowing across the heated point from the bismuth to the antimony. The improvement in Prof. Thwing's apparatus is that a more powerful current may be generated, and greater durability obtained than in any previous device operating on this principle. We have not been able to obtain authentic information regarding the invention, but understand that a small machine has been experimented with which has generated a 20-volt current and is applicable to light power, such as required for dental tools, etc. The metals employed are said to be alloys of iron and nickel, one of the metals being cooled with air currents at the same time that the other is heated. Prof. Thwing is at the head of the Department of Physics at Syracuse University, is in good standing among physicists, and it is not improbable that his invention may be an important step, even if a short one, toward the goal of "electricity direct from coal."

NEW METHOD OF COVERING HULLS OF VESSELS WITH COPPER.

Copper sheathing has been employed for covering the hulls of wooden sailing vessels for a great many years and is used to some extent on the hulls of steel and iron vessels, in order to reduce the quantity of barnacles and other sea growths that accumulate. When used on iron or steel hulls the latter are first sheathed with wood and then the sheet copper is applied, to prevent the electrolytic action that would occur between the copper and plating of the hull. The objection to copper sheathing is that it is almost impossible to entirely prevent electrolysis, and portions of the hull, or even valves and fittings below the water line, are almost certain to become damaged to a greater or less extent. This is especially the case if the vessel grounds or encounters an obstacle, causing part of the sheathing to be scraped off. Under such circumstances the exposed portion of the hull forms one pole of a battery, of which the copper sheathing is the other pole. At the Atlantic Iron Works, South Boston, Mass., a large steam yacht has recently been coated by an entirely new process, which, it is claimed, will produce as good results as copper sheathing and will entirely prevent electrolysis. The hull is first painted and then a coating of powdered quartz is sprayed over the painted surface. Upon this a coating of copper in powder form is then sprayed with an air brush and finally there is another coat of powdered quartz. It is claimed that the quartz serves to isolate the copper from the hull and also the particles of copper from one another; and that, if part of the coating should be rubbed off, exposing the bare hull, there would be no electrolytic action.

THE MEDAL IN HONOR OF JOHN FRITZ.

The celebration of the eightieth birthday of John Fritz, the American engineer, whose most distinguished services have been rendered in the iron and steel industry, will take place the last of next month at the Waldorf-Astoria, New York City. Last winter representative members of the four great engineering societies of America organized for the purpose of planning a suitable recognition of Mr. Fritz' career at the time of his eightieth anniversary. It was decided to establish a John Fritz medal, to be awarded every year "to the originators of the most useful scientific or industrial achievements, in perpetual honor of John Fritz and to the glory of engineering." Subscriptions were called for, and the responses have been so numerous that the success of the project is insured, several thousand dollars having been received. It is intended that the medal shall be awarded by a perpetual committee of sixteen, to be appointed or chosen in equal numbers from the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers and the American Institute of Electrical Engineers. The committee may select any person of any nationality. No award shall be made until after at least one year of consideration, and it must have the affirmative vote of at least three-fourths of the board. The belief is that this medal will be a distinction not second to the Bessemer Gold Medal, awarded by the Iron and Steel Institute of Great Britain.

"PERMANENT" MOLDS FOR CASTING IRON.

A company known as the International Foundry Co. has been incorporated in New Jersey with a large capital, to exploit a new process invented by Charles Szekely, of New York. The idea is to make "permanent" molds for iron castings, the inventor having discovered a preparation which is smeared on the insides of sand molds and which renders unnecessary breaking them up when one casting has been made. The plan is, of course, to make several castings from the same mold. This will probably make the average molder smile with contempt, but then there may be something in it. Another scheme to beat the molder has been developed by Frederick Baldt, Chester, Pa. In this process a fusible pattern is used which is embedded in sand by a suitable molding machine. The mold is then heated and the fusible pattern melted out, leaving the mold ready to receive the molten iron, or other metal. The chief novelty of this invention is the means employed to pack the sand around the pattern since the idea of a fusible pattern is a very old one and one often used by model makers and others having need for only one casting from a pattern. In such cases the pattern is commonly made from impression wax shaped to the desired form. The pattern is molded and then, if of complicated form having cores, etc., that make it impossible to pull it when made in one piece, it is melted out. Plaster of Paris is often used for the mold when the casting is to be made of a metal having a low melting temperature.

COMPOUND LOCOMOTIVES ARE TWENTY-FIVE YEARS OLD.

It is now the 25th anniversary of the application of the compound system to locomotives in France. The first compound locomotives were designed by A. Mallet and operated on the railway between Bayonne and Biarritz, France. They were built at the Creusot works and had one high-pressure and one low-pressure cylinder, with provisions for working either simple or compound. In that year the Institute of France awarded to Mallet the Fourneyron prize for mechanics, in consideration of his achievement. The use of the compound locomotive has extended throughout Europe since its introduction by Mallet and it is estimated that nearly 15,000 are now in operation on various European roads, of which two-thirds are of the Mallet type. In marked contrast to the development of the compound system abroad is the growth of compounding in this country. The first compound engine of any consequence to be tried in the United States was Dunbar's five-cylinder compound, which first ran on the Boston & Albany Road in 1883, or six years after the successful introduction of Mallet's locomotives in France. Dunbar's engine was a failure and compounding made no progress here until 1888-9. In these years Webb's three-cylinder compound was tried on the Pennsylvania R.R.; the first Baldwin-Vauclain compound was built for the Baltimore & Ohio R.R., and the first Schenectady compound having an intercepting valve to allow high-pressure steam to be used in the low-pressure cylinder was introduced.

ANOTHER GIGANTIC SUSQUEHANNA POWER PLANT.

Vast in scope is the Susquehanna power plant which is to be constructed for supplying Baltimore, Wilmington, Chester and Philadelphia with electric power. That part of the Susquehanna River where it is proposed to locate the plant is about 35 miles from Baltimore, near Peach Bottom, and almost on the boundary line between Maryland and Pennsylvania. At this point there is a fall of 120 feet within a short distance, and there are numerous islands which facilitate the location of the power house and the construction of dams. It is proposed to utilize this power for three plants, so located that each will have a fall of 40 feet and will be capable of generating 50,000 horse power. There will be about 10 per cent loss in the transmission to Baltimore. The consummation of this enterprise came last month through the consolidation of the lighting and electric railway interests of Baltimore; and the syndicate which controls these interests is also represented in the Susquehanna Electric Power Co., which will build the new power stations and supply the current. The plans as now announced contemplate one power plant of 40,000 horse power to supply the present needs of Baltimore for electric railway work and lighting; but as the demands for manufacturing and other purposes increase, the plant will be developed to as great a capacity as necessary, up to the limit of 150,000 horse power. The complete equipment for each station will include ten 5,000 horse power electrical units, for each of which there will be three pairs of 48-inch turbine wheels.

This is the fourth instance of the utilization of water power for electrical transmission on a large scale in the East, although there have been many in the Western section of the country, particularly in California. The other three Eastern plants are the Niagara Falls, the St. Lawrence plant at Massena, N. Y., and the Susquehanna plant now being constructed at Yorkhaven, Pa., near Harrisburg. It will completely eclipse its Yorkhaven rival, however, which is to have 40 units of 600 horse power each, or a total of 24,000 horse power.

WIRELESS TELEGRAPHY ON THE PACIFIC COAST.

The Fessenden system of wireless telegraphy is to be used by the government to communicate between San Francisco and the Farallone islands, which are about 30 miles from the coast. The last Congress appropriated $40,000 for a system at this point, as an aid in weather predictions, and Chief Moore of the Weather Bureau has already let part of the contract.

It is not generally known that the first practical use in this country of a wireless telegraph system was near the scene of this installation by the daily *Call* of San Francisco. In the stirring times of the Spanish war Marconi lay claim to having discovered a method of transmitting messages by electric current, without the use of wires, but for the most part was looked upon as a dreamer or a fakir. The *Call*, however, with a mingled interest in the development of science and the promotion of a good advertising scheme determined to give the apparatus a test. The instruments were procured in London and after experimenting with them more powerful apparatus was found to be necessary if messages were to be conveyed considerable distances.

More apparatus was cabled for and upon arrival was installed with a view to giving advance information from the expected transport Sherman, which was bringing a California regiment from the Philippines. With the sanction of the government the sea end of the aerial line was established on board a lightship anchored some nine miles from the entrance to the Golden Gate. The lightship dynamo supplied the electric current and her masts offered a suitable altitude for the pendant wire, while the land station was fixed at the famous Cliff House. From a mast on the top of the building on the seaward side a long wire hung with a free end down 80 feet to near the water. The Sherman was sighted on the morning of August 23, 1899, the wireless message was successfully transmitted to the shore and within thirty seconds a signal gun was fired from the dome of the *Call* building, announcing her arrival.

AIR RESISTANCE ENCOUNTERED BY MOVING TRAINS.

The results of the high-speed tests made last year on the Berlin-Zossen line have recently been made public in part. Two cars were used in these tests which were built by German manufacturers. Both had a seating capacity of fifty persons, and were of the same width and height as the standard Prussian State Railway cars. Three-phase current was transmitted from overhead conductors at a tension of 10,000 to 12,000 volts. The current was delivered to the motors at a lower voltage by static transformers on the cars. The armatures of the motors were carried on a hollow sleeve surrounding the axle which was connected to the axle by a set of springs at each end. The motors were thus connected to the axle without the interposition of reduction gearing. Each car had four motors of 250 normal horse power and 750 horse power in starting, making a total of 1,000 horse power when running and 3,000 horse power when starting.

To measure the air resistance pipes of different diameters were attached at various angles to the front of the cars and led to pressure gages from which readings were taken at different speeds. One pipe was so arranged that it could be extended to various positions in front. The readings from this pipe show that a uniform cone of compressed air about 11 feet in length was pushed ahead of the car. At a speed of 32 miles per hour the air pressure was about 2.7 pounds per square foot; at 37 miles, 4.1 pounds; at 43 miles, 5 pounds; at 50 miles, 6.2 pounds; at 62 miles, 10.4 pounds; at 75 miles, 15 pounds; at 81 miles, 17.5 pounds; at 93 miles, 23 pounds; and at 96 miles, 24.6 pounds. These results appear to show that for the speeds tested air resistance varies according to the square of the velocity as has heretofore been held, but that the coefficients of resistance have uniformly been too high. From these experiments it is deduced that air resistance per square foot of impinging surface may be found by the formula $P = .0027\ V^2$. This gives results a little over one-half that given by old air resistance table based on the coefficient .0049.

AUTOMATIC TELEPHONE EXCHANGES.

The general extension of telephone service in cities and towns to other than business places is retarded by its cost. In many cities the telephone rates seem unreasonably high and this condition is quite popularly attributed to the monopolistic privileges enjoyed by the telephone companies. While there is undoubtedly much truth in this contention, we are assured that in many places the rates are not higher than a reasonable profit on the investment demands. The one great expense of telephone service is the central exchange. The cost of installation of large exchanges and the wages of the operators are the chief sources of operation cost. The central exchange is an exception to the general rule in other lines of business that the greater the business done the less the proportionate operation cost. In the telephone business the cost of an exchange increases not in direct ratio to the number of subscribers, but rather as some power of the number. The opportunity for the cheapening of telephone service seems to be in the direction of the automatic telephone exchange. Already these remarkable machines, seemingly endowed with almost human intelligence, have been installed in some towns with very satisfactory results. The subscriber calls any number desired by rotating a disk on his instrument so as to select the number required. The machine at the central exchange automatically calls up the number, or in case the number is "busy" it warns the subscriber of that condition by a loud buzzing. Only a few attendants are required in a large exchange to see that the machinery runs without interruptions, and on Sundays and the latter part of the nights the exchanges work automatically without any attention. Complete privacy is also insured by the automatic exchange.

STEAM STEERING GEAR.

THE ADVANTAGE OF STEAM OVER HAND GEAR—TYPES OF STEAM STEERING GEAR AND METHODS OF TRANSMISSION.

ARTHUR MASTERS.

The first thing to be done upon getting a ship under way, or after releasing her from her moorings, is to guide and control her on her course, and here it is necessary in the large and swift battleships and cruisers, and vessels of the merchant marine, to provide more powerful and effective appliances than can be obtained by manual labor alone, for moving the rudder and directing the path of the ship. It is with this object that the steam steering engine is fitted.

This engine is sometimes placed in the main engine room of the vessel, as in the case of steam yachts; but more often in a special compartment of its own, near the rudder or tiller, as may be found most convenient, and as it is such a vital portion of the ship's auxiliary machinery that of the battleship or cruiser is always placed under protection of the side armor, the protective deck, or below the water line, and out of the reach of the enemy's shell. Lord Brassey's "Naval Annual" for 1892 reflects somewhat on the reliability of the steam steering gear in the following: "The man who shall invent a system of steam steering that should be as trustworthy as, say, the propelling engines of an average man-of-war, will deserve well of his country. At present no such system exists." It is now ten years since the above words were written, but in that time a wonderful improvement has taken place.

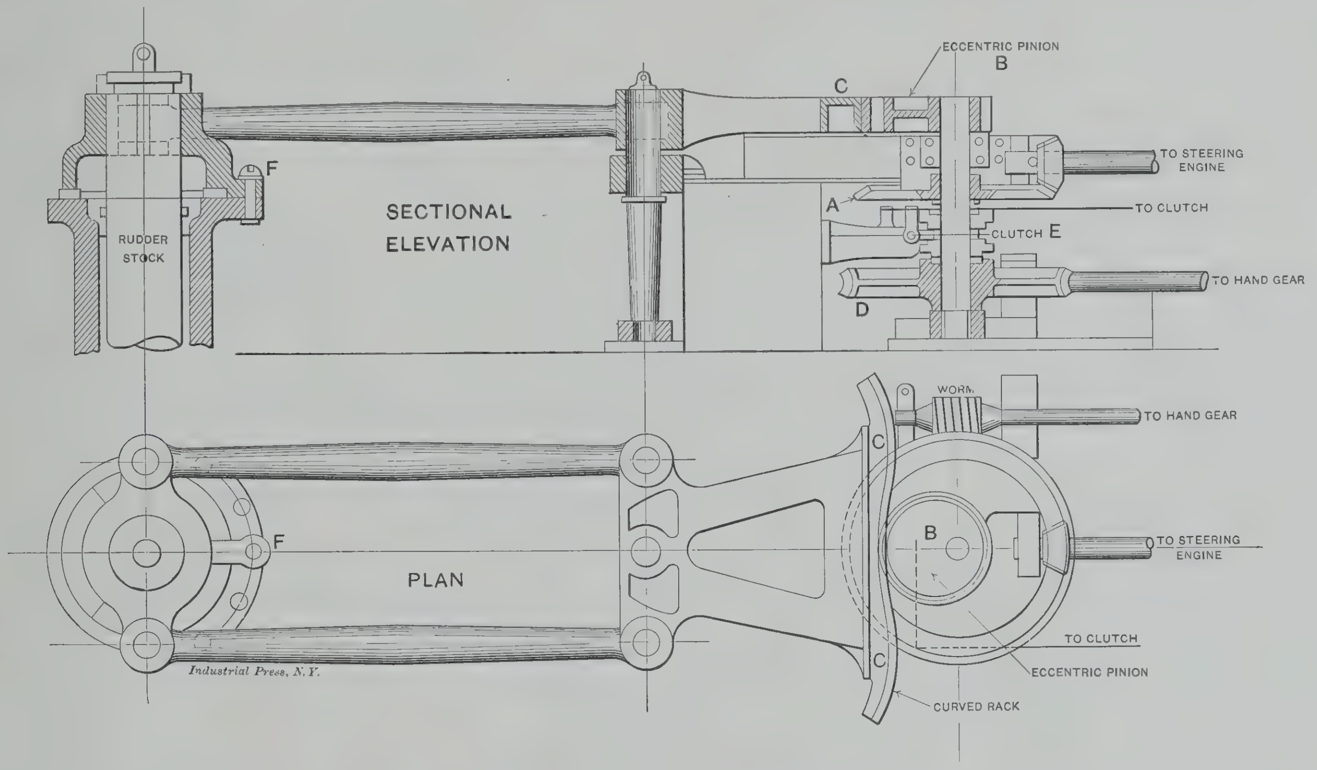

Fig. 1. Harfield's Compensating Steering Gear.

Seldom now does one hear of steam steering gear giving way, and during the recent naval war between the United States and Spain, I do not call to mind a single instance where either the steering gear or the main machinery was damaged in action.

It is usually the custom to steer the ship from the bridges, the pilot house, or the conning tower, whence a good lookout can always be kept, and where the helmsman is within easy access, and under the eye of the navigating officer. But it is possible to steer the ship by a helmsman stationed below in close proximity to the steering engine itself, to whom the necessary directions can be transmitted either by electric or mechanical telegraphs, or voice tubes. This arrangement would, of course, be adopted in the event of the mechanical connections between bridges or pilot house—which are all in more or less exposed situations—and the steering engine being disabled or shot away.

The controlling gear, which is simply the gear by which the steering engine is worked from the bridges, or any other steering station, may be composed of any one of the three following systems most commonly employed, namely, shafting and bevel wheel gearing, wire rope transmission, or hydraulic or electric telemotor. On the bridges, in the pilot house, and conning tower, is a small hand-wheel mounted on a pedestal, and to this hand-wheel the steering engine valve, known as the "controlling valve," is attached by any of the above systems reaching from the pilot house or bridge down to the main or protective deck, thence aft to where the steering engine may be situated. This is shown in Fig. 2. The motion of the hand steering wheel on the bridge, or wherever it may be worked from, is conveyed to the engine by one of the above-mentioned systems, and the controlling valve and the whole of the gear are so arranged that the rudder, which is being moved by the engine, follows the motions of the hand steering wheel exactly.

The "Great Eastern" was one of the first vessels furnished with a steering engine. This engine was designed by Mr. McFarlane Gray, and from that time up to the present large merchant steamers have been similarly fitted. Steam has been generally preferred to hydraulic power, after numerous trials, although some arrangements on the hydraulic principle have been very satisfactory. The latter gear has certain advantages, but it is heavier and more costly than steam gear; hence steam is now generally used for the purpose in warships of all classes, in torpedo boats, and merchant steamers.

The advantages of the steam steering gear are obvious, as for manœuvring purposes it is requisite to have the power of moving the rudder rapidly through large angles. In the case of hand steering, with such a multiplication of tackles between the steering wheels and tillers, it makes the loss of power in friction very considerable, and the time of putting the rudder over very long. Again it will be evident that a ship whose rudder can be put over quickly to its extreme angle will acquire angular velocity more rapidly than she would with the same rudder put over slowly. Furthermore, it has the further and important advantage of placing the control of the largest ship in the hands of one or two men—possibly in those of the commanding officer himself.

As another example of the advantage to be obtained by using steam steering engines, the British battleship "Minotaur" may be mentioned. "With manual power 78 men were required to steer her, and the helm was only got over to 23 degrees in 1½ minutes, while turning the circle occupied about 7½ minutes. With steam gear on the same vessel two men put the helm over to 35 degrees in 16 seconds, the circle was turned in about 5½ minutes, and its diameter was less than two-thirds that on the former trial."

Another instance of the superiority of steam steering over hand steering may be shown in connection with the steam trials of H. M. S. "Hermione," second-class cruiser of 4,360 tons. In moving the rudder, with steam gear (Harfield type): "From amidships to hard a-starboard, took 7 seconds; from hard a-starboard to hard a-port, 16 seconds; from hard a-port to amidships, 6 seconds, one man working the wheel. With hand gear, and with six men at the wheels, the rudder was put hard over in 55 seconds."

This gear, which is on the compensating principle, has the advantage of acting with increased power in proportion as the load increases. It is illustrated in Fig. 1. In this rigid arrangement the engine drives a horizontal bevel wheel, *A*, loose on the vertical spindle, but which, by means of a clutch keyed to the vertical shaft, rotates an eccentric pinion *B* on same shaft. This eccentric pinion gears with a rack *C*, so shaped as to always engage with the eccentric pinion while moving about a fixed center. The force is transmitted to the rudder by means of double rods, which simply transmit the force from the fixed axis to the rudder head, but do not alter it. So the fixed center may be considered to be the rudder head. Assuming the engine to exert a constant turning movement on the vertical shaft, it will be noticed that when the rudder is central the longer radius of the eccentric pinion acts on the rack, and the motion is comparatively rapid, and the force exerted is small. As the rudder increases its angle, and therefore its resistance to motion, the small radius of the eccentric pinion comes into operation and the force exerted is correspondingly increased. A worm on the hand-steering shaft and gearing with a worm wheel *D*, also loose on the vertical spindle, is provided, to enable hand power to be used, the clutch *E* being the means of transference from steam to hand power. In order to prevent any possible risk of accident when this transference occurs it may be necessary to ship the rudder pins *F* so as to secure the rudder. Sometimes a brake wheel and band is fitted for this purpose.

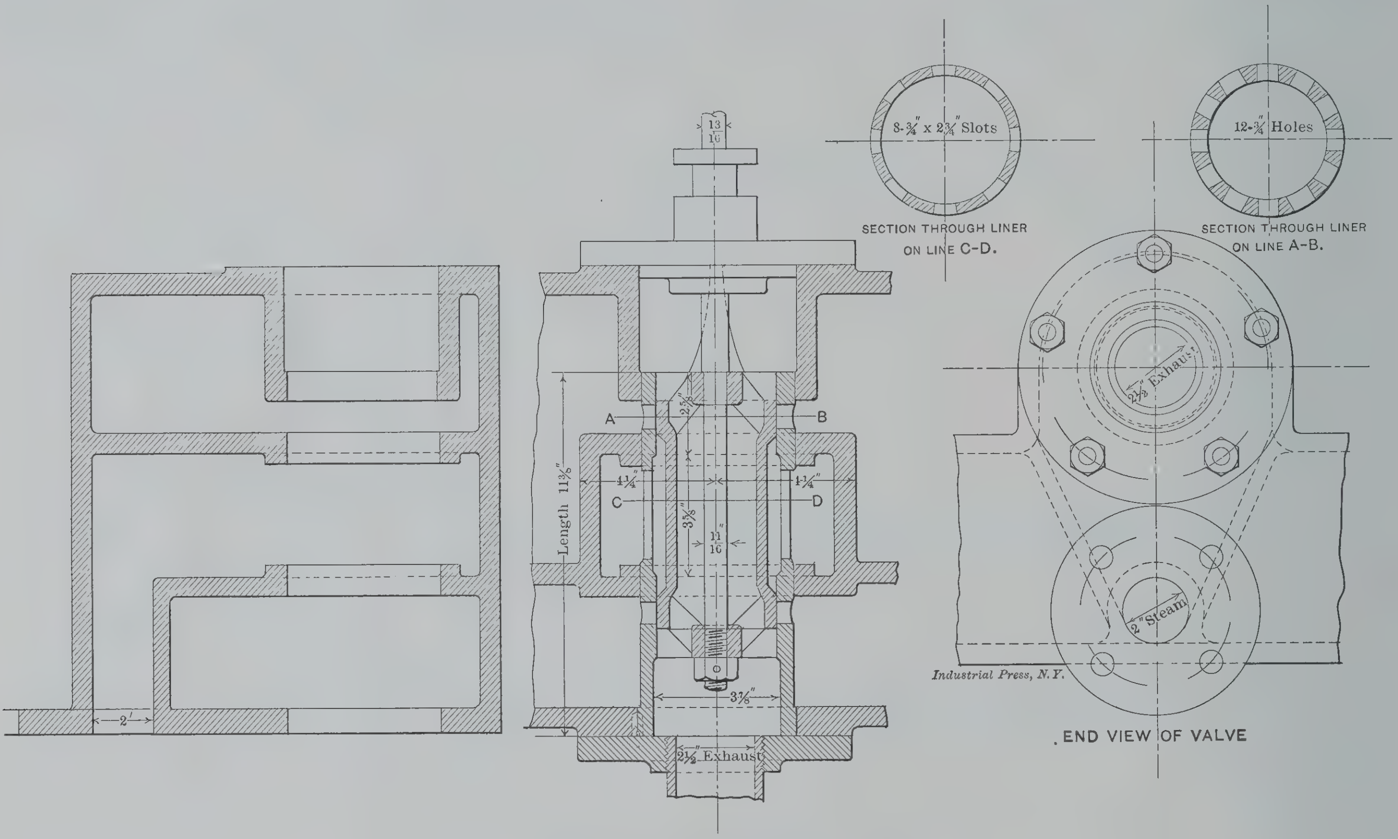

Fig. 4. Controlling Valve of Steam Steering Engine.

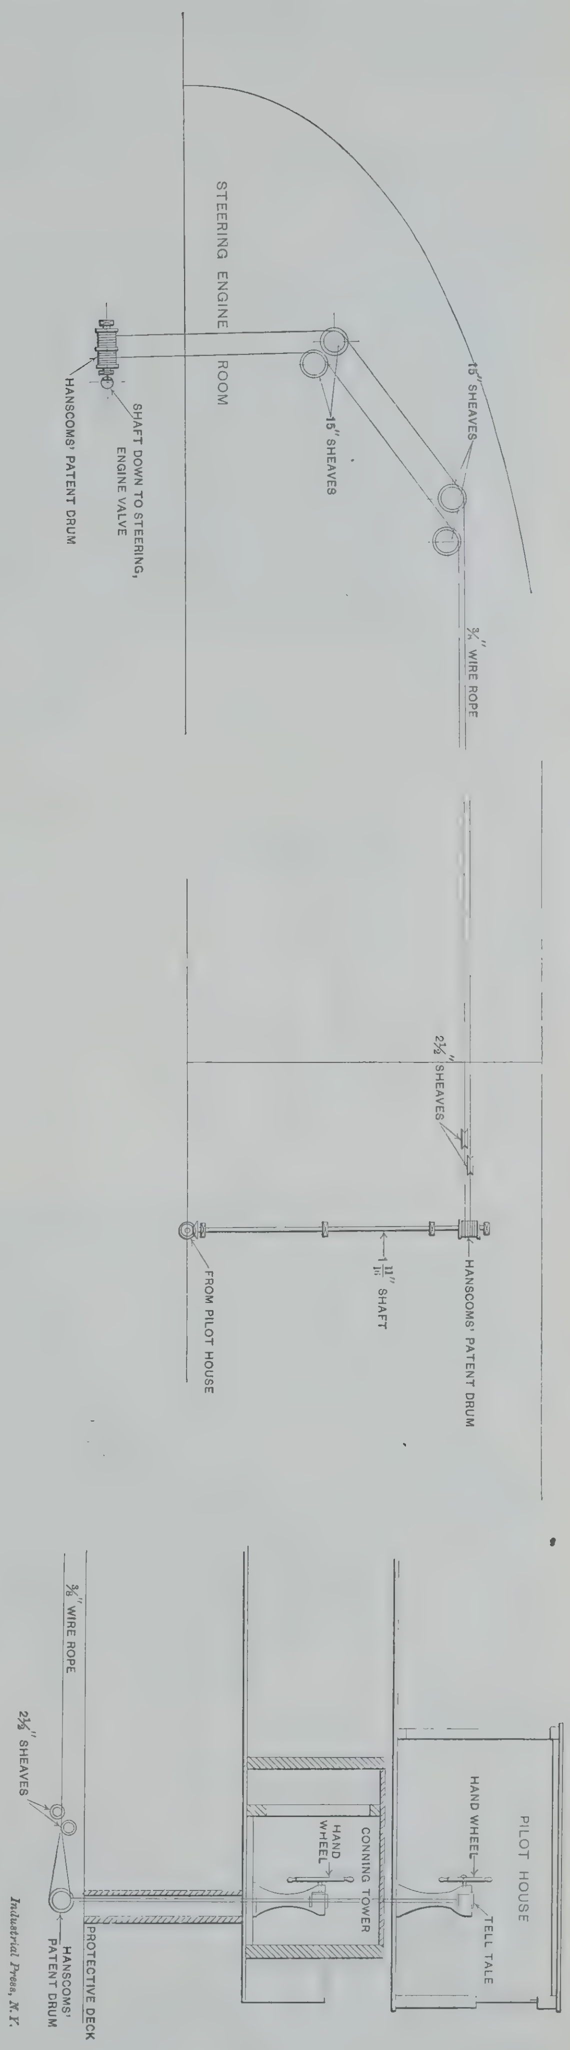
The requirements of steam steering engines for vessels in the United States Navy are that they shall be capable of putting the rudder from hard a-port to hard a-starboard, or *vice versa*, in at least 20 seconds when the vessel is moving at full speed. Fig. 3, plan view, shows the general arrangement of a steering engine as used on vessels of the United States navy, and is of the Williamson pattern. In proportioning the several parts of the engine, the strength of the rudder stock is taken as the basis of design; and into this calculation (size of rudder stock) enter the requirements of speed, maximum angle of rudder and area of rudder. It may be interesting to note here the result of experiment, namely, "One square foot drawn 10 feet per second through water, with surface normal to line of direction, gives a pressure of 112 pounds." Taking this as a basis for pressure which, in the case of a ship's rudder, varies as the square of the velocity, and is proportional to the sine of the angle, we have:

$$D = \sqrt[3]{\frac{A \times 112 \times \sin a \times V^2 \times l \times 10}{10^2 \times M}}$$

A = Area;
V = Velocity of feet per second;
l = lever in inches;
M = Moment torsion diameter of rudder head in inches.

Referring again to the Williamson engine in Fig. 3, it will be noticed that the power of the engine is transmitted through double-spur gears *A*, off crank shaft, through double helical gears *B*, which operates a right-and-left handed screw *C*, on which travel right and left-handed driving nuts *D* (that is, one nut at each end of the screw), which also slide on guide rods *E*. To each driving nut is attached a side rod *F*, which is also attached to the yoke *G*, on the rudder head, and as the driving nuts approach or recede from each other, according as the rotating screw *C* revolves in one direction or the other, the necessary motion to port or starboard is communicated to the rudder. The engine is arranged so that it can be used for either steam or hand steering by changing suitable clutch *H*. The great point to be gained by this engine is to keep the wearing surfaces as large as possible so as to reduce the wear and tear. It is also essential that the steering apparatus should be simple in construction and arrangement and safe and reliable in operation; so that much skill and care are required in the details of the gear, to reduce complexity and promote efficiency.

The "controlling valve," Fig. 4, is a special feature of the steam steering engine. It not only admits steam to the engine, so that the rudder is moved to port or starboard as desired, but is so fitted that while the rudder is attaining the wished-for degree, the steering engine itself which causes the



Industrial Press, N.Y.

Fig. 3. Williamson Pattern Steering Gear used in the United States Navy.

rudder to move is also actuating and closing the controlling valve. So that as soon as the helmsman on the bridge ceases to operate the hand wheel, and the rudder has been placed to the desired degree, the controlling valve shuts off the steam, and the steering engine stops, remaining so until the rudder is to be moved again, when the controlling gear and steering engine are again brought into operation.

A more detailed description of the controlling valve gear may be interesting. As shown in Fig. 3, the automatic attachment is fitted on the engine and has stops for steam movement, so that the engine cannot run farther than the hard-over point, which prevents pulling against the rudder stops. The screw *J* is caused to revolve by the action of the bevel wheels *K*, which are operated by an upright shaft from the steering wheel in the pilot house. This screw operates on the bell-crank lever working on the fulcrum *L*, thus giving motion to shaft *M*, which terminates in lever *O*, working about its fulcrum *P*. On end of lever *O* is attached a valve rod.

On the main crankshaft a worm *R* is fixed, which, as the shaft revolves, works the wormwheel *S*, to which is attached sleeve *T*. As the valve is opened and the engine is started in either direction, the tendency of the latter is to follow up the motion given the shaft *M*, and the moment the hand steering wheel ceases to move the starting valve moves back to its central position, and thus stops the engine.

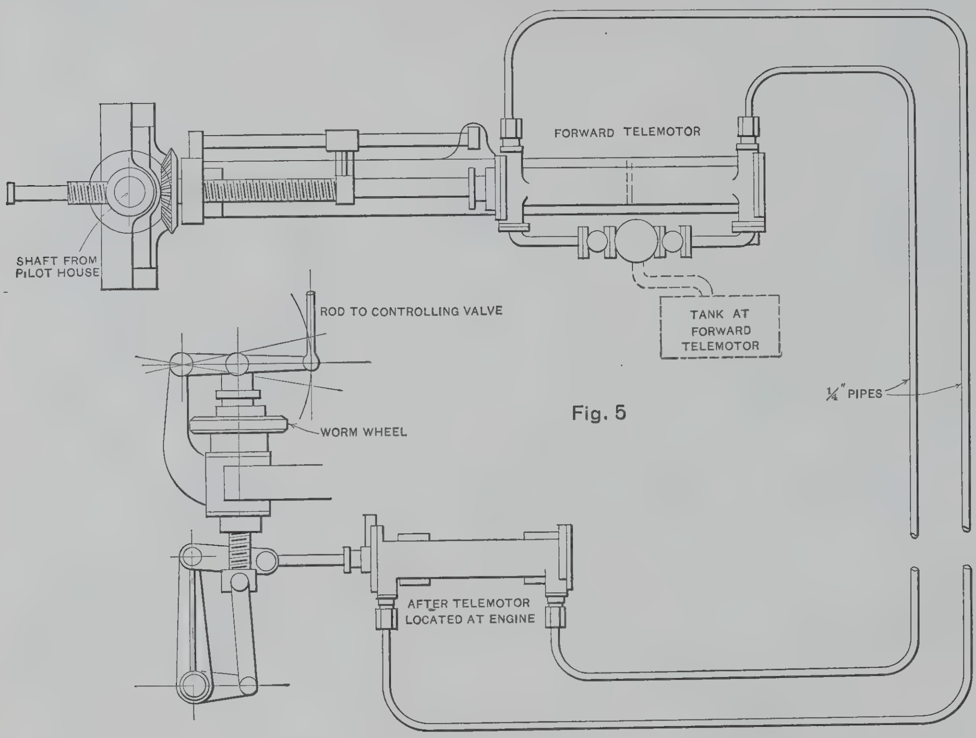

Fig. 5. Hydraulic Telemotor Type of Transmission.

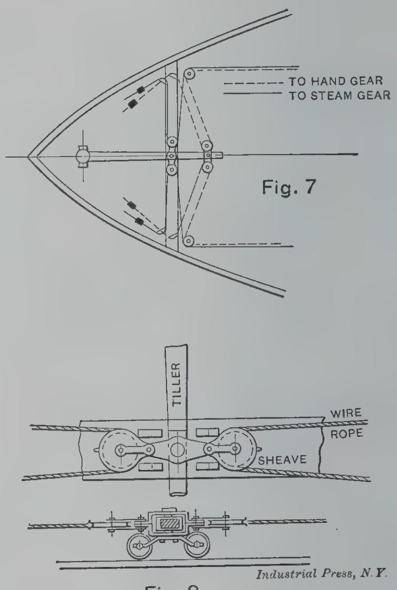

Industrial Press, N.Y.

Figs. 7 and 8. Rapson's Slide for giving Uniform Turning Moment to the Rudder.

There are, therefore, two forces acting on the valve: The one from the steering wheel, worked by hand, which moves the valve and starts the engine in a direction to put the rudder to starboard or port; and the other from the engine itself, which always tends to replace the valve in its central position and stop the engine. Consequently, the engine only keeps in motion while the steering wheel is being worked, and as soon as the steersman ceases turning the wheel the steering engine stops, the rudder remaining in the position to which it has been put. There are many other arrangements for producing this result, but the essential principle in all types of steering engines is the same as above described.

The valve being actuated by the hand wheel opens the same gradually as the rudder goes over, thus increasing the power as the load becomes greater. The controlling valve also effects economy in the working, and produces the same effect as increasing the number of revolutions per degree as the rudder goes over.

Of the three systems of "controlling gear" above mentioned, the most ingenious adaptation is that of the hydraulic telemotor, Fig. 5. Instead of transmitting the motion of the steering wheel to the engine by means of shafting and bevel wheels, or wire rope, the hydraulic telemotor is sometimes used. In this the motion is transmitted by water pressure in small pipes, a certain motion of the piston of a water cylinder at the steering position on deck, producing a similar motion in the piston of a water cylinder near the steering engine, by means of which the reversing valve is moved.

Where it is desired to lead a long distance from pilot house to steering engine, as in the case of government cruisers and battleships, wire rope in connection with Hanscom's patent transmission drums, Fig. 1, is preferable to shafting with bevel gears, or universal joints. It can be more easily led over sheaves whose roller bearings reduce the friction to a minimum, while that of the shafting must necessarily be considerable, especially when the lead aft may be very irregular. Again, a great saving in weight is obtained by employing wire rope transmission.

Various methods are adopted for making the connection between the steering engine and rudder. The first instance, I think, of the employment of right and left-handed screw steering gear was in the steamship "Lancefield," built and engined by Robt. Napier & Sons, Glasgow, in 1861. Fig. 6 is a copy of the sketch taken from the actual gear. Besides those shown in Figs. 2, 3 and 6, Figs. 7 and 8 show another arrangement, known as "Rapson's slide," also designed to promote uniformity in the turning moment for all angles of the rudder, and which has been generally found very efficient. The end of the tiller is rectangular in section, perfectly true and parallel. A carriage, fitted with a brass swiveling block, runs on guides carried from side to side of the ship, square to fore and aft center line. This swiveling block fits over the rectangular end of the tiller, and is arranged to allow a certain amount of rotary motion in a horizontal plane. The carriage is worked to port or starboard by chain or wire rope from the steering gear. As the rudder is turned, the end of the tiller slides in the block, and thus increases its effective length, whereby the turning moment is uniform for all angles of the tiller.

The "work" to be done in putting a rudder over to any angle includes that required to overcome the moment of the pressure about the axis, and that needed to overcome the frictional and other resistances of pintles, bearings and steering gear proper. The "useful work" is that done in overcoming the moment of the effective pressure on the rudder at each instant as it moves from amidships to the extreme angle.

Normal pressure on rudder $= 1.12$ pounds $\times$ area $\times$ $(V)^2$
Useful work $W =$ normal pressure $\times$ ½ mean breadth $\times$ versin, a $T =$ time in seconds in putting rudder hard over.

$$\text{Net horse power} = \frac{W}{550 \times T}$$

The force required at the end of the tiller to hold the rudder at any angle will, of course, depend upon the length of the tiller, and the mode of applying the force. In Fig. 9 an ordinary rudder is shown. The resultant pressure upon it is P, acting through the center of effort C, of the immersed rudder area. $A\,T$ represents the tiller. Q equals force required at its end.

$$P \times A\,C = Q \times A\,T.$$

Neglecting friction, the force Q at the tiller end will vary with distance $A\,C$ of the center of effort from the axis of rudder. On the same assumption the force Q may be determined approximately for any helm angle, if the distance $A\,C$ is known, since the normal pressure P can be roughly estimated.

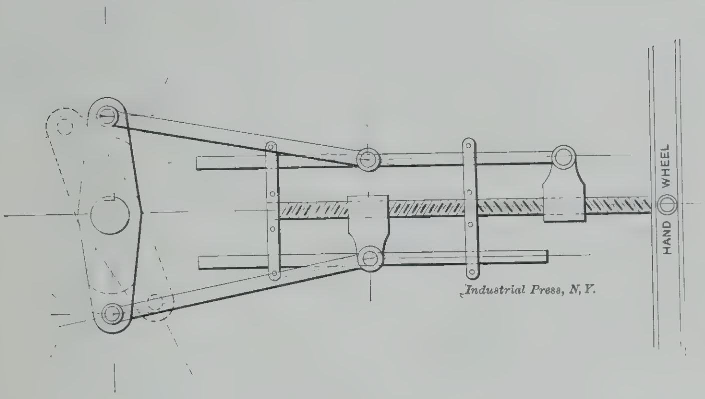

Fig. 6. Screw Steering Gear, S. S. Lancefield.

M. Joessel, of the French navy, was led from his experiments to a very simple law that confirms previous practice, which is, that "for a rectangular plate hinged at its fore edge, and inclined at an angle a to the line of motion, the moment of the normal pressure about the axis divided by sin a is a constant." Using the notation of Fig. 9, this law is as follows:

$$P \times A\,C = \text{constant} \times \sin a$$

The constant in this expression is simply the moment of the normal pressure when the rudder advances at right angles to itself, which moment can be found by rules already given. If this law be accepted, an estimate for the force required at the tiller end at an angle a can be readily made. Again, according to M. Joessel the center of pressure of a rectangular plate is at a distance from its forward edge. $d = .195\,b + .305 \sin a$; at an angle of 35 degrees this becomes $d = .37\,b$. As the center of gravity of a rectangle is at a distance of ½ b from the forward edge this distance would be .74 of the distance of the center of gravity from the forward edge. According to other authorities the pressure at any angle is approximately proportional to the direct pressure multiplied by the sine of the angle. This would make the moment on the rudder head at an angle a:

$M = 1.12 \times 12 \times A \times V^2 \times \sin a \times \frac{1}{2}\,b\,(.39 + .61 \sin a)$; or since $A \times \frac{1}{2}\,b = m =$ the geometrical moment of the rudder about its axis: $m = 13.44\,(.39 + .61 \sin a) \sin a\; m\,V^2$. Where

$M =$ the moment in pound inches.

$a =$ the angle of rudder to keel.

$m =$ the geometrical moment of the rudder about its axis in feet cubed.

$V =$ velocity of water in feet per second.

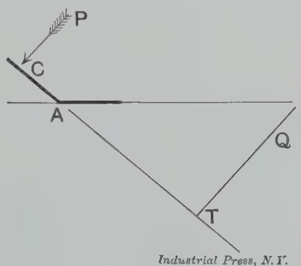

Fig. 9.

For an angle of 35 degrees this would be:

$$M = 13.44 \times .74 \sin a\; m\,V^2.$$

On the other hand, as above stated, the moment M is approximately equal to the moment of the direct pressure multiplied by the sine of angle a, hence $M = 13.44, \sin a\;\; m\;\; V^2$. The preceding value is therefore only about ¾ of that just given.

In the analysis of the trial of the U. S. S. "Minneapolis" steering gear the latter formula was used in determining the moments on the rudder head for every five degrees from 0 to 35.

Area of rudder = 166 square feet.

Moment = 975 feet cubed.

Hence $C\,G = 5.87$ feet from axis.

The following are the results in pound inches: 0 degree = 0000000; 5 degrees = 1841300; 10 degrees = 3668500; 15 degrees = 5467900; 20 degrees = 7225500; 25 degrees = 8928300; 30 degrees = 10563000; 35 degrees = 12118000.

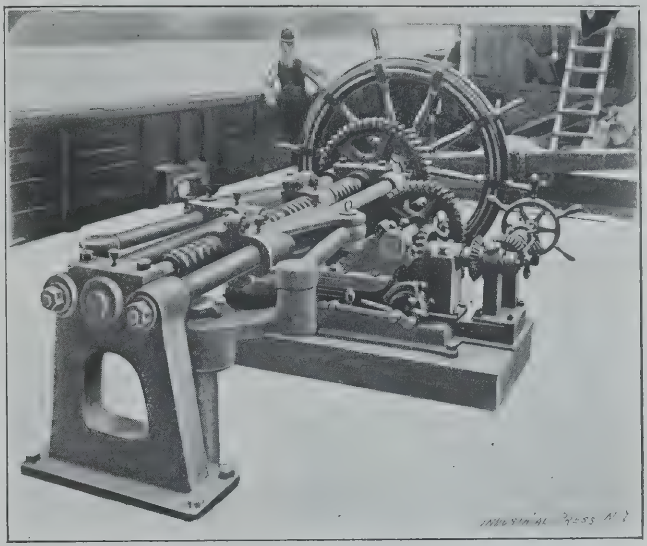

Fig. 10 Steering Gear of Steam Yacht "Aztec," Rear View.

Let us now consider the transmission of this moment to the screw shaft, "Minneapolis," receiving the power of the steering engine. The engine in this ship is similar to the one of the Williamson type, described above. Speed 23.77 knots. or $V = 40.15$ feet per second. The steering engine of this vessel has two cylinders, 13 inches × 10 inches, geared from the engine to the screw shaft with gears of ratio of 17 to 70. The reducing valve on this trial was set at 75 pounds per gage per square inch in the steam pipe. Adding 7 pounds for the vacuum in the exhaust pipe we have a total of 82 pounds. To this apply the coefficient K of the maximum turning moment for a cylinder of .35 or .70 for the two cylinders, then we have: Area of each piston $A = 132.73$; radius = 5 inches; steam pressure 82 pounds. The moment on screw shaft is:

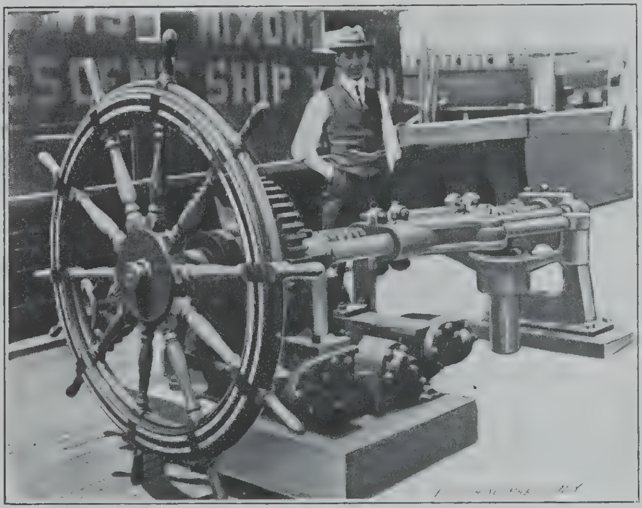

Fig. 11. Steering Gear of Steam Yacht "Aztec," Front View.

$M_2 = 132.73 \times 5 \times 82 \times .70 \times {}^{70}/_{17} = 156860$ pound inches.

That is to say, the maximum turning moment which the engine could put on the screw shaft while running at a fair speed is about 156860 pound inches.

In the steam trials of the U. S. S. "Brooklyn" the following conditions of the steering gear were noted: Area of rudder, 184 square feet; moment 1194.4 feet cubed; hence $CG = 6.5$ feet from axis. Speed 20 knots, maximum rudder angle 35 degrees. The screw shaft was geared to the engine shaft by gears 17 to 70; therefore $M = 13.44 \times 1198.4 \times \sin 35$ degrees $\times V^2$. Now the speed of the "Minneapolis" was about 20 knots, and that of the screw race 23.77 knots, equivalent to about 16 per cent. slip. The contract speed of the "Brooklyn" was 20 knots. We will take the same slip and speed V as on the "Minneapolis," where $V = 40.15$ feet per second. We thus obtain:

M_2 at 35 degrees $= 169360$ pound inches, without friction. If we allow an efficiency of the screw gear of 50 per cent. the moment which will be required to be produced on the screw shaft by the engine will be 338720 pound inches. This geared to the engine crank in the ratio of 70 to 17 gives a moment on the engine shaft of 82262 pound inches. Allowing 100 pounds steam per gage, 7 pounds vacuum and coefficient K of 70, we have: Since $KRAP =$ moment, $RA = 1098.6$ inches cubed, hence the cylinder volume should be about 2196.6 cubic inches.

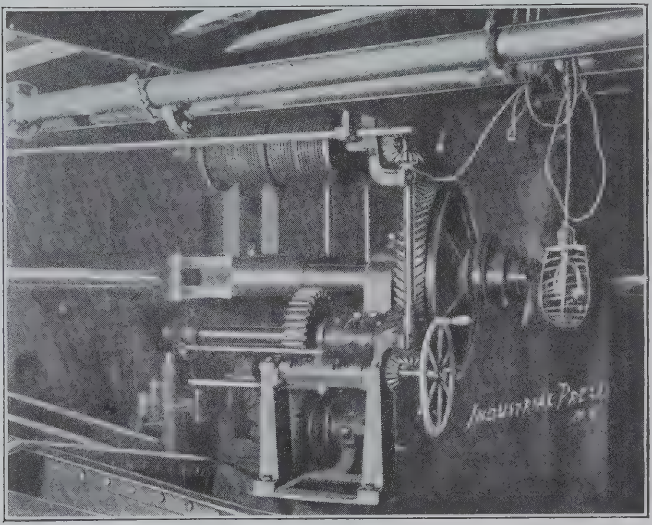

Fig. 12. Steam Steering Engine, U. S. S. "Florida."

I have considered here somewhat at length the steam steering gear, and while incidental mention has been made of the hydraulic steering gear, yet another and very successful form of steering gear has been found in the substitution of electric motors for the steam engine. That this form of steering gear is a success is demonstrated by the fact that after being carefully investigated and tested, it has been fitted and specified for several vessels of foreign governments, notably in the cases of the Russian cruiser "Variag," and the Russian battleship "Retvizan." The remarkable results obtained on trial of the former vessel, July 26th, 1900, may well be remembered, and the most successful operation of her steering gear during the voyage from the Delaware breakwater to Vladivostok resulted in the electric steering gear being added to the specifications of one or two large vessels now building for the U. S. merchant marine.

* * *

A number of portable machines of an interesting type are in use at the Fore River shipyard. They are for countersinking the rivet holes in ship plates. The practice commonly followed in shipyards is to have swing drills attached to the walls or supporting columns of the plate shed, which are in effect simple radial drills of great length of arm. The machines alluded to are mounted on two wheels and are provided with a long handle for the operator. An electric motor is mounted on the truck to drive the vertical spindle carrying the countersinking tool. The spindle is located between the end of the lever and the wheels near the latter so that the operator has in effect a long lever feed handle by which he controls the machine. The lever is also used to move the machine around from one hole to another in the plate as it lies flat on the floor. Altogether the application of electricity making a portable tool for this work makes a very neat and apparently effective tool for this class of work.

THE MACHINE TOOL METROPOLIS.

THE MACHINE TOOL SHOPS OF CINCINNATI—THEIR CONCENTRATION IN THE MILL CREEK DISTRICT.

Ten years ago Cincinnati was one of a half dozen cities in this country well known in connection with the manufacture of machine tools. Five years later it was one of three or four. To-day it leads the world; and a noteworthy feature of this remarkable development is that with few exceptions it has been confined to a strip of territory known as Mill Creek Valley, running north and south, and so narrow as to be readily shown in a single column of MACHINERY. Since 1894, when the movement to this machine tool section was begun by the Cincinnati Milling Machine Co., a score of manufacturers have built or are building plants in that territory—many of them new concerns that have leaped into prosperity during the last few years, and others who found the old quarters too small for their increasing business.

We have been unable to show on the map the location of several of the largest Cincinnati tool manufacturers—notably the Bickford Drill and Tool Co., the American Tool Works Co., R. K. LeBlond Machine Tool Co., and the Sebastian Lathe Co., as these works are some distance from the section covered by the map; nor have we made any effort to include other large manufacturers who are not makers of machine tools, such as the Fay & Egan Co., the Bullock Electric Co., Laidlaw, Dunn, Gordon Co., Lane & Bodley Co., the object of the article being primarily to show the new machine tool section of the city.

1—The Fosdick Machine Tool Co. was started in 1887 near the plant of the American Tool Works, and moved into their present plant in 1898. Their product is radial drills exclusively, and they employ about 100 men. Philip Fosdick is president, Thomas H. Richardson vice-president, and William Herman general manager.

2—The Roach & Von Wyck Machine Tool Co. began in February, 1902, to manufacture lathes, and are just starting up in their new building on Elmore St. and C. H. & D. R. R.

3—The Lodge & Shipley Machine Tool Co. was established in March, 1892, as the Ohio Machine Tool Works, Wm. Lodge, proprietor, and was incorporated in August of the same year as the Lodge & Shipley Machine Tool Co. Their present plant on Colerain Ave. was established in January, 1899, and gives employment to from 400 to 450 men, building lathes and their attachments exclusively.

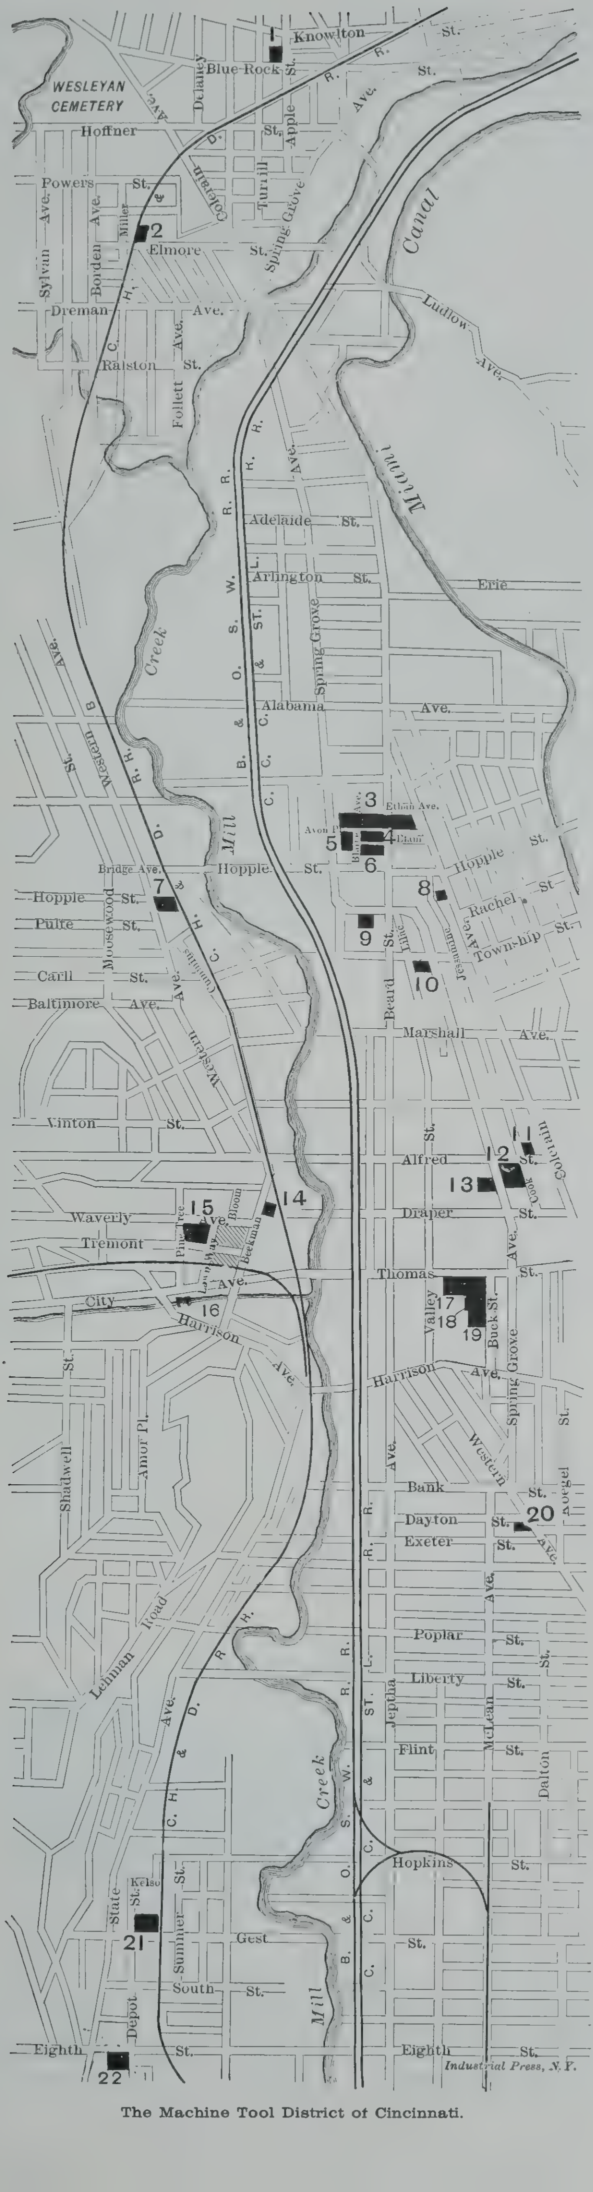
4—The Dietz Machine Tool Co. started in their new plant on Beard St., near Elam, in 1901 building engine lathes.

5—The Oesterlein Machine Co. was started by William Oesterlein in 1886 to manufacture friction clutches. In 1897 the manufacture of milling machines was added, and in 1899 they moved to their present plant at Beard and Elam Sts., where they occupy about 11,000 feet of floor space, manufacturing plain and universal milling machines, cutter and tool grinders, and friction clutch pulleys.

6—The Cincinnati Shaper Co. was established in 1898. They build pillar and traverse shapers exclusively, employing about 90 mechanics. They are at present located on Sycamore St., but are building a new shop at Colerain Ave. and Elam St., which they expect to have ready to occupy about the middle of October. Their new works will be 90 feet wide by 290 feet long, with a boiler and engine house 40 by 75 feet.

7—The Belmer Machine Tool Co. built their present shop on Western Avenue near Hopple Street in 1900 and produce planers exclusively.

8—John Steptoe & Co. was established in 1845, and on his death in 1888 the business was purchased by Mr. G. W. Otting and Mr. Adam Lauther, who ceased the manufacture of the general line of machine tools formerly made by Mr. Steptoe and devoted their entire attention to shapers. They now produce these machines of both the crank and geared type, making from 14-inch to 32-inch stroke. They employ 75 hands. For many years they have been located at 75 to 79 Elm St., but are now building a new plant on Colerain Ave., which they expect to occupy about October 1. The building will front on that avenue and extend to Jessamine St. in the rear. The main building will be 65 by 140 feet, two stories high, with two wings 50 by 100 feet each, one story high.



The Machine Tool District of Cincinnati.

9—The Rahn-Mayer-Carpenter Co. was established in 1895 and located in their present plant on Spring Grove Ave. in 1899. They build lathes exclusively from 16-inch to 32-inch swing, engine, turret, gap and pan lathes, employing about one hundred men.

10—Smith & Mills located at their present plant, corner Spring Grove and Township Streets, in 1896, and make a specialty of crank and geared shapers.

11—Greaves, Klusman & Co. was established in 1889 for the manufacture of woodworking machinery on West Second St. The personnel of the firm changed in 1898, W. A. Greaves, H. H. Klusman and Henry Korb succeeding the old firm of Greaves & Klusman; and in that year they began the manufacture of engine lathes, 17, 19, 22 and 24-inch swing. The firm moved to their present shops, Cook and Alfred Sts., in 1899, and employ 100 hands on engine lathes and on a large line of woodworking machinery.

12—The Cincinnati Milling Machine Co. had its origin in a partnership formed by Mr. Fred Holz and Mr. George A. Mueller in 1874. The business at that time was machine jobbing. Later the manufacture of screws, taps and dies was taken up and the company incorporated under the title of the Cincinnati Screw and Tap Co. Quite early in the existence of this company the need of a milling machine became apparent, and for lack of money a machine was built in their own shop, and from time to time others were built for some of their friends. In 1887 Mr. Fred A. Geier became associated with the firm, taking the office of secretary and treasurer. In 1889 the screw, tap and die business was sold out, and the manufacture of milling machines was taken up as a specialty. In 1891 they removed to their present location, Spring Grove Ave., Alfred and Cook Sts., erecting a two-story shop 50 by 120 feet, and inaugurating the movement to what is now the machine tool section of Cincinnati. Since that year a number of additions have been made to their land and buildings, and they occupy at present a plot of ground 170 by 240 feet, having a frontage on three streets, and practically all covered with buildings. Since 1889 the company has confined itself exclusively to the manufacture of upright knee and pillar type milling machines with power feeds, restricting its product to a limited number of sizes of these machines, which range in weight from 1,525 pounds to 5,000 pounds. The manufacture of a universal cutter and tool grinder was taken up in 1888, in which year the company received its first order from the European field, the trade from which subsequently grew to very large proportions. During its history the Cincinnati Milling Machine Co. has turned out about 4,000 milling machines and 2,000 cutter and tool grinders.

13—William Powell & Co., 2525 to 2531 Spring Grove Avenue, manufacturers of brass goods and specialties, were formerly located in the old manufacturing section and were one of the first to move into the district shown on the map. Their location in this section preceded by several years the movement of the machine tool builders.

14—The Knecht Bros. Co. occupy part of the Cincinnati Screw and Tap Co.'s building on Beekman Street for the manufacture of light drills.

15—The Lunkenheimer Co., while not manufacturers of machine tools, are building one of the largest plants in the Mill Creek section and on that account are entitled to mention in this article. This firm was established in 1862 and incorporated in 1889. They manufacture valves of every description, injectors, whistles, water gages, steam cocks, lubricators, oil pumps and oiling devices, employing over six hundred skilled mechanics, and are probably the largest manufacturers in their line in the world. The ruled sections show portions of their works in process of erection.

16—The William E. Gang Co. started in business in a small way in April, 1893. The following month the panic set in, but the young firm successfully struggled through it, and at the end of five years made arrangements to build a new plant on Queen City Ave., where they are at present located. They produce radial drills exclusively.

17—Schumacher & Boye occupy a large plant on the corner of Queen City Avenue and Buck Street devoted to the manufacture of lathes exclusively, from 18-inch to 42-inch swing.

18—The Dreses Machine Tool Co. was established in 1896 on Buck St. near Queen City Ave. They make a specialty of radials, screw and turret machinery, and average about 110 employees.

19—The Cincinnati Planer Co. started in business in 1899, erecting the plant they now occupy. The original buildings covered a floor space of 10,000 square feet, but have since been added to so that they now have a floor area of 26,000 square feet. This company employs about 100 men, and builds metal planers exclusively, from 24 inches to 72 inches.

20—The Cincinnati Machine Tool Co. was established in 1899 at the corner of Western Ave. and Dayton St. They make a specialty of upright drills and build a complete line, ranging from 21 inches to 42 inches, inclusive. This firm employs between 50 and 60 men.

21—The G. A. Gray Co., the largest manufacturers of planers in the country, were for many years located on Sycamore Street and moved in 1898 to their present plant, Gest Street and C. H. & D. R.R., which comprises three buildings aggregating some thirty thousand feet of floor space.

22—The Bradford Machine Tool Co. was established in 1840 by James Bradford under the firm name of James Bradford & Co. for the manufacture of mill machinery. In 1876, shortly after Mr. Bradford's death, it was incorporated as the Bradford Mill Co. with Jacob R. Stewart as president, who had been with the company since 1866. They began the manufacture of machine tools in 1889, and this branch of their business grew until it was found expedient to discontinue the manufacture of mill machinery, so as to make room for the increased demand for the company's machine tool product. They have been in their present location, Eighth and Evans Sts. since 1881, and their entire works for a number of years have been devoted exclusively to the manufacture of engine lathes, for which they employ about 60,000 square feet of floor space and 200 men. The company's name was changed in 1900 from the Bradford Mill Co. to the Bradford Machine Tool Co., and the officers are George F. Stewart, president, and W. T. S. Johnson, superintendent.

The following plants are located in parts of the city not shown on the map:

William Barker & Co. were established in 1880 and moved to their present plant, corner of Culvert and Pioneer Streets, in 1899. They manufacture lathes and shapers and employ about thirty hands.

The A. Streit Machine Co. was established in 1892 and located in their present plant in 1894. They manufacture boring machines, turning lathes and pulley tapping machines, and employ about twenty-five men.

The Wais-King Tool Co., 39 East Third St., was incorporated in 1901 and employs about 30 men, producing seven sizes of punches and shears and four sizes of vertical boring and turning mills.

The R. K. LeBlond Machine Tool Co. were established in 1887 and moved in 1888 to their present plant, 4621 Eastern Ave., which is at the other end of the city from the Mill Creek section. They employ 200 machinists and manufacture lathes and milling machines.

The Mueller Machine Tool Co. started last April building radial drills, having a well-equipped shop at 216 West Pearl St., occupying about 5,000 square feet of floor space and employing 30 hands. Mr. Mueller of this firm was formerly of the firm of Dreses, Mueller & Co.

The Sebastian Lathe Co. started in 1884 and have been building engine lathes continuously since that year, which makes them one of the oldest manufacturers in that line in Cincinnati. They confine their product to the smaller sizes of engine lathes and to foot lathes, and are employing about 45 men.

The Bickford Drill and Tool Co. was established in 1874 and employs 175 men, building radial and multiple drills exclusively. They have been in business in the present location, corner of Front and Pike Sts., ever since the company was started; but their plant has been entirely rebuilt during recent years. The officers of this firm are H. C. Hoefinghoff, president and general manager; Lewis G. Keck, secretary and treasurer, and H. M. Norris, works manager.

McCrosky & Huber, located at 208 Lawrence St., started in business about two years ago with very little capital, but through hard work have built up a prosperous business employing about twelve men in the manufacture of universal adjustable reamers. Both members of the firm are practical machinists.

The Hisey-Wolf Machine Co. are located at 77-79 Elm St. in the old manufacturing section of the city. This is practically a new concern, which started in business January 1, 1902, and manufactures portable electrically-driven center grinders, electrical bench grinders and electrically-driven sensitive drill presses. Their business has been remarkably successful in the short time they have been running.

The American Tool Works Co. operate a large plant at Sixth St., Eggleston Ave. and Culvert St. in the older manufacturing section. The original plant was established twenty years ago and was among the pioneers in machine tool manufacture in Cincinnati. The increased demand for their tools has necessitated a steady expansion of factory facilities until the plant as it now stands comprises a total of about 100,000 square feet of available floor space and gives regular employment to between six and seven hundred men. The American Tool Works Co. build engine lathes, planers, upright drills, radial drills, shapers and boring mills. Under the present system of shop management the works are divided into distinct departments—Department A, entirely devoted to the construction of small lathes; Department B, to large lathes; Department C, entirely to planers, and so on throughout the different work.

A detailed estimate by competent authorities places the total annual value of the product turned out by the thirty machine tool manufacturers mentioned above, at $5,046,000.

* * *

The Cramp shipyard in Philadelphia, says a history of the enterprise just issued by the William Cramp & Sons Ship and Engine Building Co., was founded in 1830 by William Cramp, who remained at the head of the company for 49 years. From a very small affair the main shipyard now covers 46 acres, with docks covering about 6½ acres, or 52.4 acres in all. The principal building is 1,200 feet long, 72 feet wide, with a ground and floor space of 460,000 square feet. It employs a maximum of 8,000 men. Counting vessels under construction, the Cramp shipyard has built 321 vessels and 220 engines. Of these vessels 25 have been United States steam warships, constructed at various dates since 1861, and including the New Ironsides, of the Civil War, and the new battleships Iowa, Alabama, Maine, Colorado and Pennsylvania, the three last not yet completed. One Japanese and six Russian warships have also been built at the same yards. —*Engineering News.*

HYDRAULIC TESTING MACHINE.

The accompanying half-tone illustrations are from photographs of a large, horizontal hydraulic testing machine, recently built by the Riehle Bros. Testing Machine Co., Philadelphia, Pa., for John A. Roebling's Sons Co., Trenton, N. J. As the machine was ordered primarily for testing the cables used in the construction of the new Brooklyn Bridge, now in process of erection, it has a timely interest apart from its mechanical features.

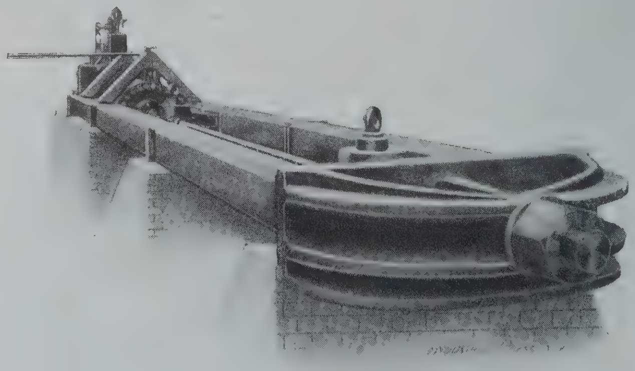

Fig. 1. Testing Machine from Anchor End.

The machine has a capacity for testing specimens in tension 18 feet long between the center of pins or shackles. The tensile stress is produced by means of a large hydraulic cylinder, in which the plunger has a travel of four feet to take up the slack and stretch in the cable. In Fig. 3 are shown details of the testing machine. The hydraulic cylinder, *E*, is suspended from the arched girders, *H H*, by links, and is free to swing slightly in an endwise direction. The cable is held by the pins *P P* and when pressure is applied in the cylinder the plunger moves to the left and the cylinder tends to move to the right, but is checked in its movement by the yokes, which hook over the knife edges 2 2, of the weighing apparatus at the left end of the machine. There are five levers in the weighing apparatus, marked *A*, *A*, *B*, *C* and *D*. Those at *A*, *A* are just alike and have fulcrums at 3, 3, while the stress due to the load on the machine is applied at points 2, 2, as mentioned above. The scale beam is at *D* and the connections between this and the primary levers, *A A* are clearly indicated. Two springs, *S S*, serve to retain the cylinder in its normal position to absorb any shock upon breaking a specimen.

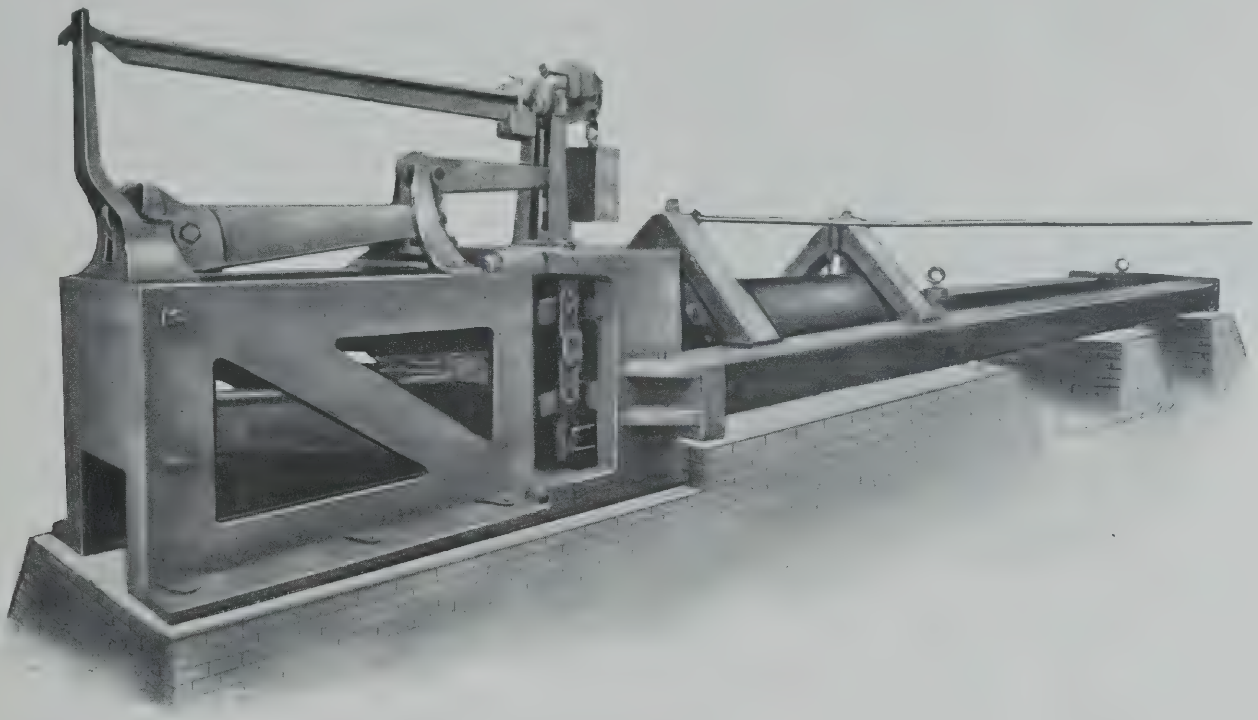

Fig. 2. General View of Machine for Testing Strands of Brooklyn Bridge Cables.

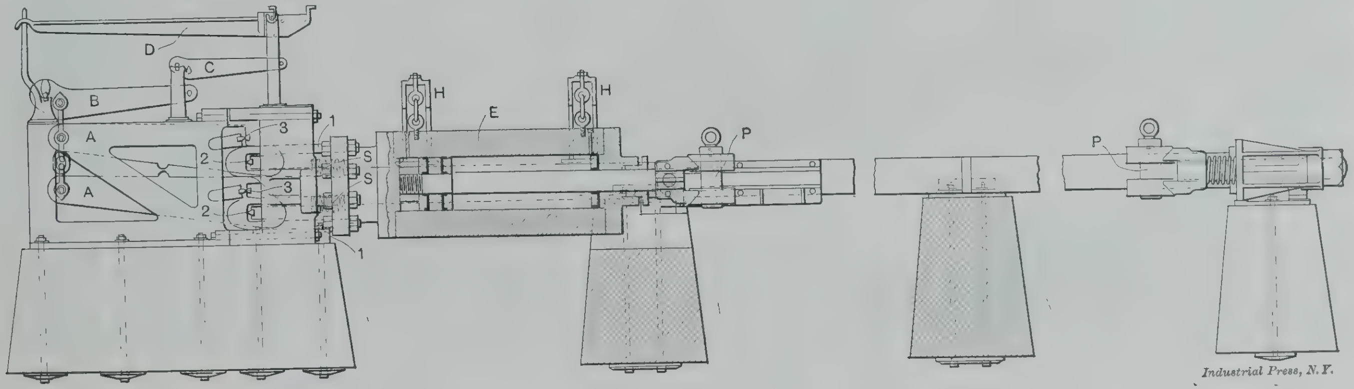

Fig. 3. Detail and Sectional View of Testing Machine.

While this particular machine is intended for specimens only 18 feet long, it may be adapted for cables of lengths as great as 100 feet, for example, in which case the plunger would be given a travel of six and one-half feet to allow for the stretch and slack in the cable. For these increased lengths the weighing and pulling end and the anchor end remain the same, with the exception of the length of the cylinder, and separating columns having a total greater length are placed between the two ends. The machine has a capacity of 800,000 pounds. The beam is arranged so that the poise is propelled by means of a screw, either by hand or automatically, as desired. The readings are by 5,000 or 10,000 pounds on the beam and 50 or 100 pound marks, as desired, are noted on a dial. The piston rod is seven inches in diameter, and the walls of the cylinder are 10 inches thick. A three-plunger hydraulic pump is furnished which operates under a pressure of 3,500 pounds per square inch. The pump is belt-driven, feeds into a reservoir to maintain a constant pressure, and is provided with a safety valve so attached that it cannot become deranged. The pump is not shown in the illustrations, but is connected directly to the pipe appearing in both half-tone cuts.

* * *

A newspaper account says the largest locomotive in the world, recently built for the Santa Fe to haul freight over the Step Raton Mountain Road, was piled in the bottom of a cañon at Seymour, N. M., July 29, under twenty-eight freight cars, which it was unable to control on the steep grade. An unusually long train was being taken over the mountain with three engines, two in the lead and the giant pushing. The train broke in two three times near Wooton, the part last time occurring two car lengths behind the second engine. The jolt started the long train back down the steep grade, the big pusher being unable to hold it. Engineer Leason whistled for brakes, and the two brakemen hurried about the task. They had tightened about twenty of the brakes, but the train was gaining headway every second, and they jumped for their lives. The train continued on its mad course for about three miles, and left the rails on a bridge 100 feet long and 50 feet high, near Seymour. The engine and all the cars piled over the structure and went plunging down the cañon.

STEAM MOTOR TRUCKS.

DESCRIPTION OF THE STEAM TRUCKS MADE BY THE MORGAN MOTOR CO.. WORCESTER, MASS.

During the past few years good progress has been made in England, France and Germany in the development of power trucks, but in America nothing worthy of note has been accomplished up to within the last two years. A number of automobiles designed to carry one or two tons had previously been built, but so far as we know none had given satisfaction. More recently, however, increased attention has been paid to the practical economy of motor-driven trucks, and it is quite certain that the number which will be manufactured and used by different firms will rapidly increase.

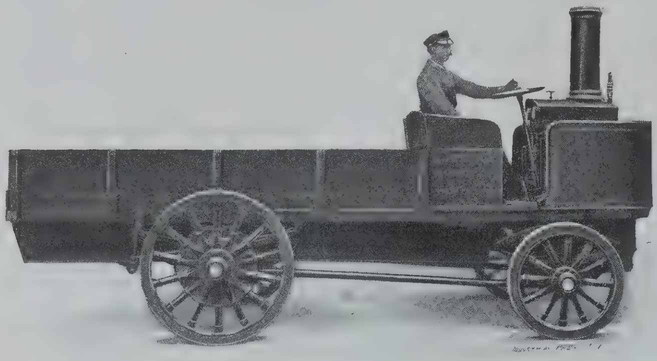

Fig. 1. Steam Truck built by the Morgan Motor Co.

One of the most interesting developments in this line in this country is the steam truck now manufactured by the Morgan Motor Co., Worcester, Mass. In the fall of 1900 Mr. R. L. Morgan, a mechanical engineer who had given much attention to automobiles in general, and commercial automobiles in particular, went to Europe on a tour of inspection. He investigated thoroughly all the trucks made upon that side of the water, and as a result, purchased, just before his return, a complete set of drawings and the rights to manufacture the steam truck then built by the Liquid Fuel Engineering Co. of England. He picked this out as the most promising machine to be found, and the one best adapted to the more exacting requirements of our roads and climate. He procured at the same time a truck which had been in use for some three years, and which had traveled some twenty odd thousand miles. This was to be a working model, and a machine upon which all experiments could be tried, with the idea that when new trucks were completed it would be known that all changes made were for the better.

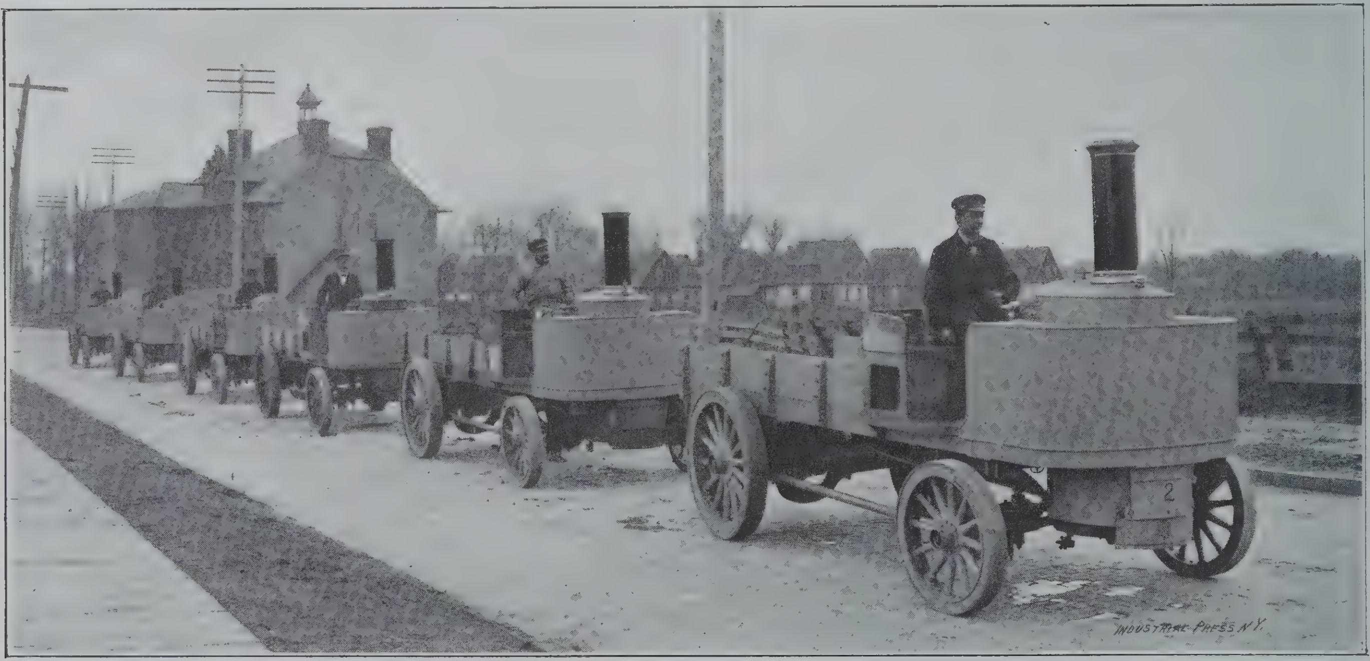

Fig. 2. Six American-built Trucks, after the Design of the Liquid Fuel Engineering Co., England.

Being at that time in the employ of the American Bicycle Co. as manager of their Toledo plant, Mr. Morgan had built there under his patents six trucks. These were started and nearly completed, when, at the beginning of the present year, he retired from the American Bicycle Co. and formed the Morgan Motor Co. The trucks were finished in Toledo, all six of them run up planks under their own steam onto cars and shipped to Worcester, Mass., where a small but up-to-date plant had been installed. All six of these trucks have been in successful operation, and through them Mr. Morgan believes he has demonstrated that hauling, which up to now has been done by horses, can be satisfactorily accomplished by steam trucks, and, not only satisfactorily, but at a cost much less than by the old methods.

In substantiation of his conviction in the matter he has sent us a brief history of the truck which was brought from England. He says: "At the time of its shipment to America it had already run some 20,000 miles. Part of that time it was working for a wholesale merchant in London, and part of the time for one of the large newspapers. While working for them the truck was run twenty-two hours a day, and its boiler was never cool from 12 o'clock Sunday night until 12 o'clock the following Saturday night. It ran this way for nearly six months. This was particularly exacting work, in that there were trains to catch, which meant the loss of considerable money if one were missed.

"On reaching America the truck was shipped to Toledo, O., where it was put into the regular service of the American Bicycle Co. It was found that the machine could easily do the work of a two-horse and a one-horse team, starting out about eight or half-past in the morning, taking an hour and a half off at noon, and being laid off by half-past four every afternoon. The machine, during that time, was frequently overloaded, and it was taken over some of the poorest roads which any American city can show. Hills are a minus quantity in Toledo, but the truck carried 6,500 pounds up a 16 per cent grade, which was the steepest that could be found.

"In the fall of 1901 the truck was taken to New York and started in the Endurance Contest between New York and Buffalo. Although it did not qualify, even at the end of the first day's run its showing was very satisfactory. The start from the club house of the Automobile Club of America was made at 7 o'clock Monday morning, and the town of Croton, which was 35 miles distant, was reached at quarter before twelve. The road contained some hills of 15 per cent grade and also some sandy stretches. At Croton, in turning out for a team near an embankment, the road gave way and let the truck down to the axles. In extricating the machine one of the boxes on the intermediate shaft was broken. The truck, however, proceeded as far as Peekskill, where the necessary repairs were made. Where the roads were hard the truck traveled as fast as 15 miles an hour, and showed itself equal to climbing a 20 per cent grade. That, however, was its limit. The machine was greatly delayed by soft roads, and many times sank to the hubs in mud. The reversing of the engine with high pressure steam on both cylinders and the rear wheels hub deep in mud was an ordinary occurrence. That, of course, meant that the truck was undergoing about as heavy a strain as could be put on it. Nothing, however, gave way. Albany was reached Saturday night with the truck in good condition. As the contest was declared off, the machine was shipped by train from Albany to Toledo. From then until the time it was shipped to Worcester, Mass., with the other trucks, it ran steadily at the Toledo factory, and it is to-day in operation in Worcester. After nearly five years of service, and after having traveled over 25,000 miles the truck is practically in as good shape as when it was turned out from the factory."

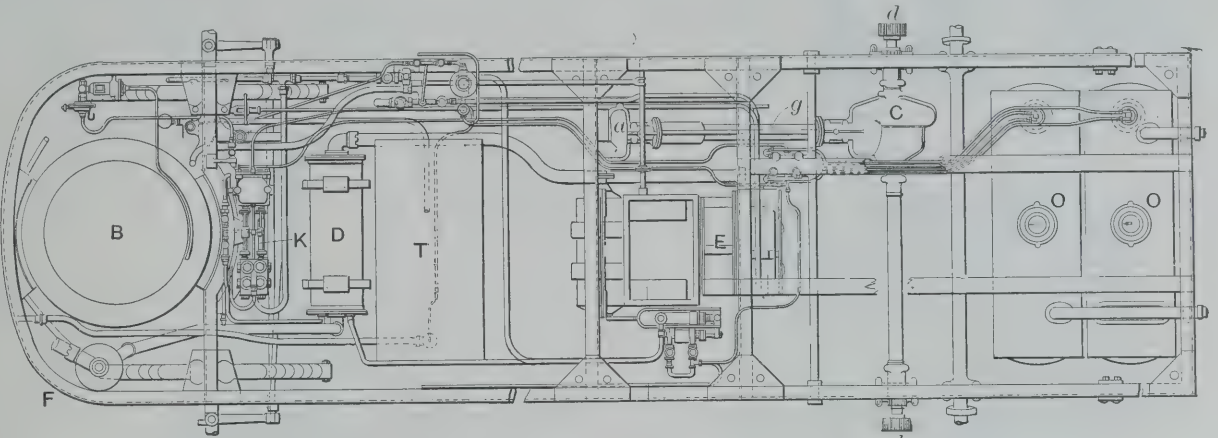

Fig. 3. Plan of Frame Showing Location of Machinery and Connections.

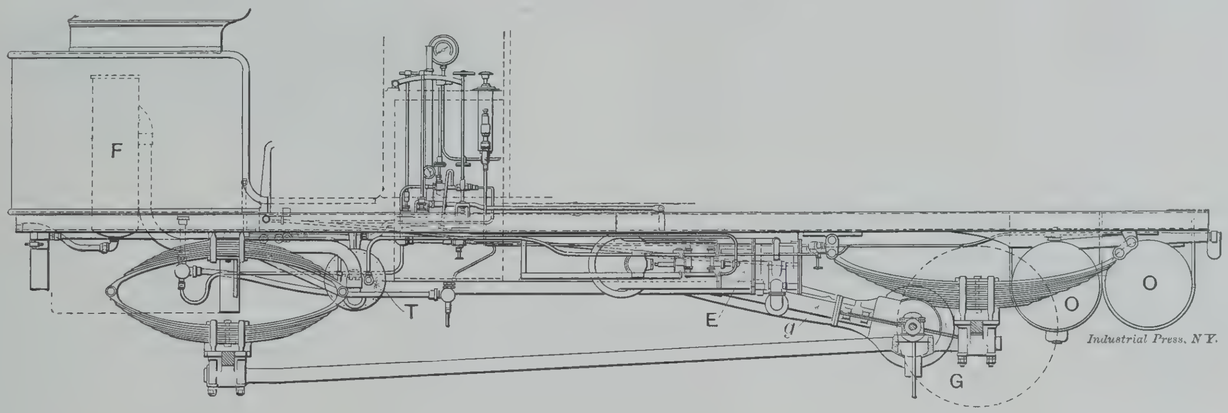

Fig 4. Side View of Frame.

The six four-ton trucks are, with the exception of a very few points, copies of the original. They are, however, a little stiffer all the way through.

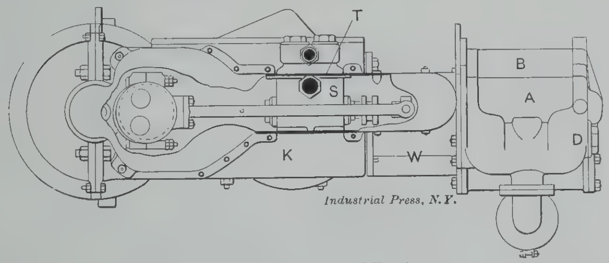

Fig. 5. Side View of Engine.

The frame is supported by elliptical springs in front and semi-elliptical in the rear, and is of 4-inch channel iron. The front axle is of 2-inch forged steel, and the rear axle of 2¾-inch. The wheels are of a special type. They have metal hubs and wooden spokes, which are set in metal spoke sockets, riveted onto a ½-inch inside steel tire. Wooden felloes and 6-inch tire for the rear wheels and 4½-inch for the front wheels, complete perhaps the strongest wheel that is at present in use for automobile work.

Fig. 3 gives a plan of the machine. The boiler *B*, which is of the water-tube type, is hung just ahead of the front axle, and also of the operator. The engine *E* is centrally located, and is tied rigidly to the main frame. Power is transmitted through beveled gears *a* and a telescopic shaft *g* to an intermediate shaft *C* on which is the compensating gear. On the new trucks there is a clutch for locking the compensating gear which is not shown in the cut. Pinions on the ends of the intermediate shaft mesh with internal gears on the rear wheels. The exhaust steam from the engine passes to the feed-water heater *D*, which contains 55 feet of copper tubing. From *D* the steam goes to *F*, which is a centrifugal separator. What steam escapes from *F* is carried to a perforated coiled pipe at the top of the boiler, where it escapes into the stack with the products of combustion. The condensed water which collects in the separator is returned to the tank *T*. This tank holds 100 gallons. The two tanks *O*, at the rear, contain fuel oil, and together hold 56 gallons. *K* is a Worthington duplex pump, which may be used for filling the boiler when the truck is standing.

The driver sits at the right hand side of the vehicle, and the auxiliary air pump, the link lever, the main throttle, and that for admitting live steam to the low-pressure cylinder, the duplex pump throttle, and also the valve for regulating the water supply, are at his right hand. The machine is steered with a lever, since it has been found that such action is much quicker than that of a wheel, and that the machine

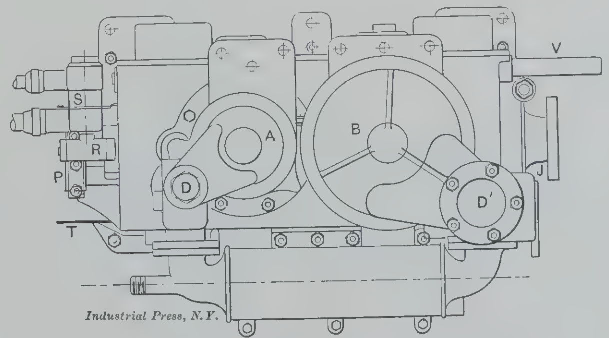

Fig. 6. End View of Engine.

is small enough to handle in that manner. Fig. 4 gives a side view of the machine.

The engine is of the horizontal, cross compound type, the cylinders being 3 inches and 6 by 5 inches. The cylinders are separated from the main case, which encloses all the working parts, by a spreader or intermediate frame which admits of the packing of the glands, both on the main case and the cylinders, without disturbing any of the other parts. It also prevents the formation of water in the engine case from leakage in the piston rod packings. The main case is made of very stiff bronze. The crossheads are of phosphor bronze and run in steel slides, and the connecting rods are of forged nickel steel. The main engine crankshaft is also forged from a single piece of nickel steel, and is made amply strong to withstand any strain which may be put upon it.

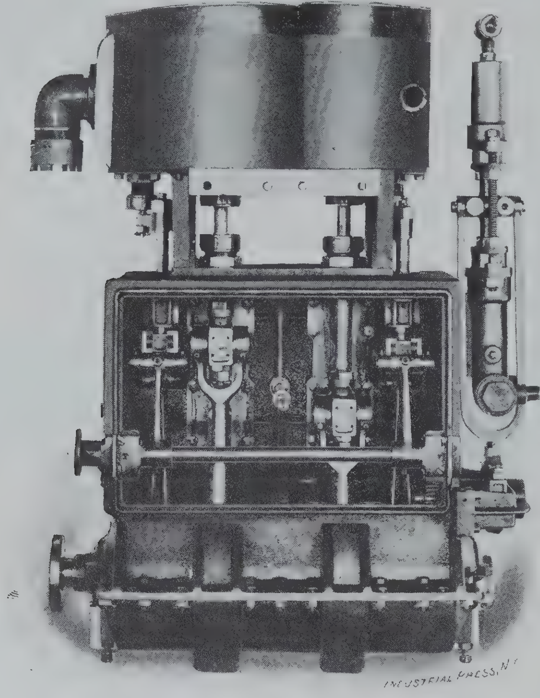

Fig. 7. Compound Engine, with Casing Removed. Cylinders, 3 and 6x5 inches.

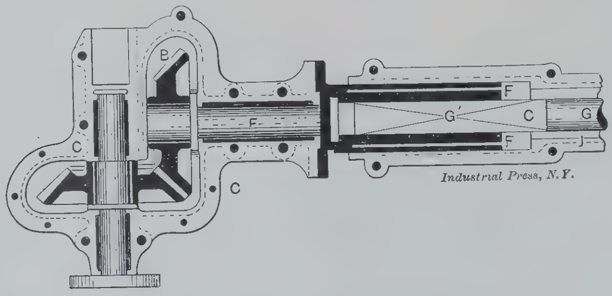

Fig. 8. Encased Bevel Transmission Gears.

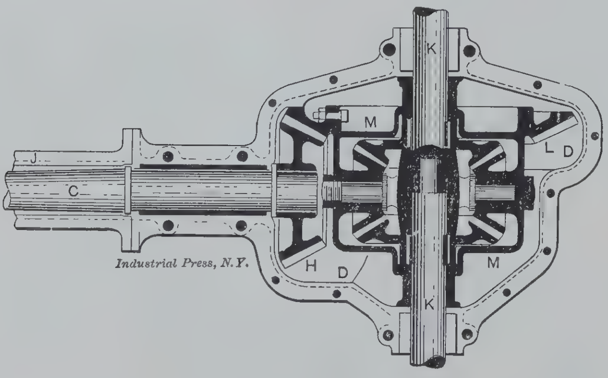

Fig. 9. Compensating Gear.

The working parts of the engine run in oil. They are easy of access, in that practically the whole top of the case may be removed by the loosening of one nut. The air and the water pumps are driven by a pinion on the main engine shaft. They are both single acting and of ample capacity for the work required of them.

Fig. 5 is a side view of the engine on the pump side. Fig. 6 is an end view from the rear. From these two cuts it will be seen that the engine is very compact.

Figs. 8 and 9 show the transmission gears, Fig. 8 being the bevel gears at the engine end, which are enclosed in a metal case and run in oil. *C* is the telescopic shaft, it being through this that the motion of the springs is taken up. Fig. 9 shows the compensating gear and also the main driving gears which are upon the intermediate shaft. The clutch for locking the compensating gear, which has been mentioned, is not shown in the cut.

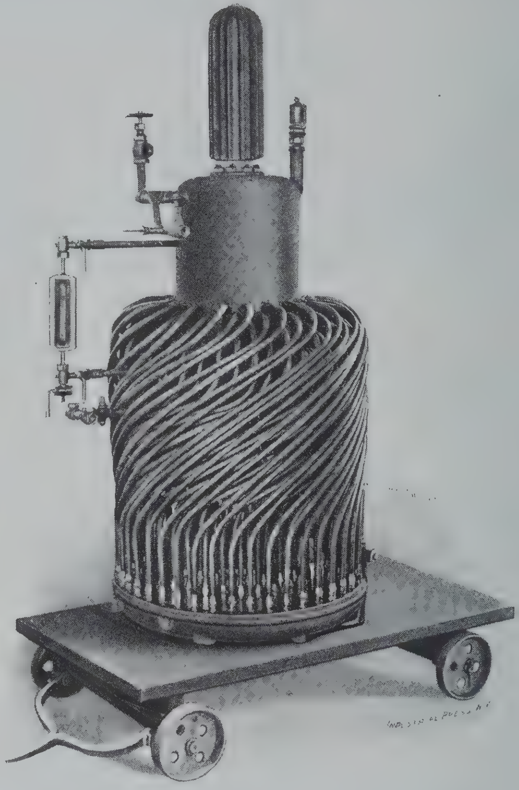

Fig. 10. Boiler with Shell Removed, showing Tubes.

Either kerosene or fuel oil may be used for generating the steam, and one mile with full load can be made on three-quarters of a gallon. The supply of oil is adjusted by an automatic regulator, very much after the pattern of those used in the ordinary steam carriage. The water tank is good for about 25 miles of steady running. The ordinary stops of the vehicle, however, in a day's work will considerably reduce the mileage per tank.

The average speed of the truck is from six to ten miles per hour, and it can be handled at these speeds even in crowded streets. Given a good level road and no traffic twelve miles an hour can be made. This is an important point when figuring the economy of the machine, in that it means that the truck hauling as much as would make a load for one two-horse team can do the work of three or even four. Furthermore, it is possible to run the machine 20 to 22 hours a day, whereas a horse-drawn vehicle can be operated at the outside but 10 hours.

* * *

In the discussion at a meeting of the Engineers' Society of Western Pennsylvania, the fact was brought out by Peter B. Wight, consulting architect, that corrosion in steel structures is not as serious as supposed. He said' "In an extreme case I have seen I-beams taken out of a building which were put in in 1858, and were exposed to leaking water from 1858 to 1870. That is 12 years. During those years I do not think there was a particle of corrosion in the parts of the beams not exposed to leaking water. In the parts exposed to leakage which I measured there was not more than 1-16 of an inch of loss on both sides. They were beams used to support a water-tank in Chicago. A water-tank is always sweating and is always damp. In the center I could not see any deterioration at all, and the beams were just as good as when they were put in.

ENGINEERING REVIEW.

A SYNOPSIS OF CURRENT TECHNICAL LITERATURE.

Mr. W. C. Leland, a machinist of Brooklyn, referring to our inquiry some time ago for a spring made of a substance which would not be affected by heat, says the *American Machinist*, has sent us some pieces of mica arranged to act as a flat spring, and he says that a mica spring continues to act as a spring when exposed to very high temperatures. The specimen sent us acted as a spring when held in a gas flame and continued to so act as long as the test was made. Of course, as many layers of mica may be superposed as is necessary to get the desired thickness, and for experimental purposes at least we would imagine that such a spring may be quite useful.

The boiler of a B. & O. locomotive exploded at Ravenna, Ohio, July 23, killing the engineer. The boiler was lifted vertically off the frames and truck, leaving all the running gear and cylinders on the track. It was carried forward directly over the track a distance of 70 feet where the front end struck the ties and buried itself five feet in the ground, breaking a 90-pound rail squarely in two. The fireman asserts that the water glass showed three gages of water and that the injector was working at the time of the explosion. The illustrations of the wreck published in the *Railway Age* show that the crown sheet gave way. The crown sheet showed that it had been burned; the crew claimed that this was due to a fire being started in the boiler at some time previous when there was no water in the boiler! An engine of the same class belonging to the same road exploded three days later at Connellsville, Pa. The boiler first mentioned bore general evidence of structural weakness and neglect.

EVOLUTION OF THE COAL CAR.

Mr. F. F. Gaines, M. E., of the Lehigh Valley R.R. exhibits photographs in the *Railway Master Mechanic*, which show graphically the growth of the coal car on that railroad during the past 36 years. The first cars of 6-ton capacity were built in the summer of 1863. Their weight was 3½ tons, and capacity 12,000 pounds. The next step was in 1877, when 20-ton cars were built, with a capacity of 40,000 pounds, and an average weight of 20,530 pounds. In 1884 came the 25-ton cars, with a capacity of 50,000 pounds, and weighing about 23,590 pounds. The first 30-ton car was built in May, 1887, with a capacity of 60,000 pounds, and about 27,490 pounds' weight. By the early fall of 1899 the size of cars had increased to 40 tons, the load 80,000 pounds, and weight about 36,650 pounds, and in November of 1899 were built the 50-ton all-steel cars, with a total capacity of 100,000 pounds, and weighing 37,420 pounds.

PROPERTIES OF SELENIUM.

In reply to a correspondent's inquiries regarding the properties of selenium, the *Scientific American* says that it is not a metal but an elementary substance which in its ordinary condition is a brittle solid of a glassy lustre and fracture and a brown color. It melts at about 430 degrees F., vaporizes at about 1,300 degrees, and burns with a blue flame, giving out an odor resembling that of putrid horseradish. Ordinary selenium is a very poor conductor, having an electrical resistance 37,500,000,000 times that of copper. When annealed for several hours at a temperature just below its melting point, with subsequent slow cooling, it forms a crystalline substance with a lower resistance. It is now sensitive to light. Its resistance is reduced, not increased, in proportion to the square root of the illumination; and also the effect is greater with a high electromotive force than with a low one. Narrow strips of annealed selenium are formed between the edges of broad plates of metal, so that the cross section is considerable, and thus the resistance is reduced while the area exposed to light is considerable. This is a "selenium cell." When the light strikes it, its resistance may be reduced as much as one-half. A cell whose resistance in the dark was 300 ohms dropped to 150 ohms in the light. Such a cell is not a generator of electricity, but a measuring instrument for determining the intensity of light.

FRENCH LOCOMOTIVE PRACTICE.

In the July issue there appeared a brief note on the prevailing American practice of machining parts of machines which do not of themselves require to be machined, but which is done to save time in erection or subsequent operations. In the description of the building of a first-class locomotive at the famous Belfort locomotive works in France published in the *Engineer*, statements are made that indicate such practice is not followed there. The sides of the locomotive frames are not ground or planed, but are left rough. Consequently when the frames and motion work is erected it has to be done entirely by reference to stretched lines and gages. Lines and special squares are also used to test the parallelism and squareness of the frames. In these shops milling machines are generally employed for surfacing operations, in preference to shapers, planers and slotters. Tapping staybolt holes and reaming rivet holes is done by power, the power being conveyed by means of rigid splined shafts driven by bevel gears. Flexible shafts or pneumatic motors do not appear to be used. The staybolts are made of either manganese bronze or copper, preferably of the former metal.

VANDERBILT FIREBOXES COLLAPSE BECAUSE OF DEFECTIVE CIRCULATION (?)

Charles F. Prescott, a locomotive engineer on the Santa Fe Pacific R. R., has communicated to the *Railway Age* a suggestion which he believes would, if adopted, greatly improve the Vanderbilt boiler, especially when used with fuel oil. Several of the Vanderbilt fireboxes have collapsed in service, but not because of structural weakness so much in his opinion as because of defective circulation. He has noticed that with two full gages of water the water level will fall to a scant gage when the throttle is opened and the water will not return to the normal level until the throttle is closed. The contention is that the fireboxes of these boilers repel the water in all directions, bottom as well as top, when burning liquid fuel, and that as a consequence the top portion of the firebox is often left bare. A circulation pipe is advocated having sufficient capacity to carry the water from the front end of the firebox by an exterior route, the circulating pipe being connected to a mud drum in front and the lowest part of the firebox at the rear with, possibly, intermediate connections with the barrel of the boiler between these points. These boilers are said to be poor steamers, although they have large heating surfaces; so the suggestion that defective circulation may be one cause of the trouble is worthy of consideration even if the means suggested for its improvement is not.

BOATS BUILT SO AS TO BE TRANSPORTED IN SECTIONS.

It is always a cause for considerable wonder to the average person as to how the large steel steamships which ply the inland lakes have been constructed, since they obviously must be carried to the waters on which they are to ply, in sections small enough to be placed on a railroad car. Lately there was a description in *Marine Engineering* of the process of erecting a boat that had been shipped in sections to Lake George, N. Y. This was reprinted, in part, in the Philadelphia *Record*, and called out a communication to that paper by J. A. Robinson, of Marshallton, Del., with regard to early work of this description. His father, Thomas M. Robinson, was engaged in the years 1850-57 in building side-wheel steamboats at Newcastle, Del., which were afterward shipped to California. He writes:

> The hulls were wood, and two of the boats, after having been launched and given their trial trips, were taken apart and loaded on sailing vessels and sent around Cape Horn to California, where they were rebuilt. Had they been built in the regular way, with heavy rib timbers and planking spiked or treenailed to them, this would probably not have been possible. These hulls were built somewhat on the principle

of a hooped barrel. They were not "whale backs," but were flat-decked, as other boats. Iron or copper hoops were used outside of the planking in a manner that not only did away with a great deal of timber in their construction, but avoided the necessity of calking the seams. This style of building originated with my grandfather, who built several small sailing vessels before my father entered into the building of larger sailing vessels and steamboats, and on account of the accuracy required in building such, the art virtually died with my father, no one else having made a success of it.

These boats sent to California fifty years ago may even at this time be in service, as two others built in the early 60's are in comparatively good condition and still in service on the Chesapeake Bay.

Mr. Robinson contends that this was a greater feat than building iron or steel boats for service in inland waters, inasmuch as the latter are merely set up in the builders' yards and not launched as were the builders' boats.

HOW TO MAKE SMALL CASTINGS WITHOUT A CUPOLA.

The English Mechanic, 1902.

The *English Mechanic* says that many mechanics have no doubt heard of a somewhat mysterious substance known generally by the name of "thermit." This is nothing more than a mixture of aluminium and an oxide of iron mixed in proper proportions. If a portion of this mixture is raised to a higher temperature, the aluminium extracts the oxygen from the oxide of iron, reducing the iron to the metallic state, and becoming itself oxidized to alumina. The heat resulting from this oxidation of the aluminium, even though the iron is deoxidized, is so great that not only is the reaction propagated through the whole mass of thermit present in a very few seconds, but the resulting pure iron and alumina slag are quite fluid, and have a temperature of about 3,000 deg. Cent. (5,400 deg. Fahr.). Iron at this temperature is so unnecessarily hot that 20 to 25 per cent. of clean wrought-iron punchings or scrap may be added to the thermit, and it, too, will be melted, and so about double the yield of iron, since thermit produces about half its weight of iron.

In order to make use of thermit for our special purpose, the required quantity is put into a crucible, which is made simply of sheet-iron with a refractory lining. There is a small tapping-hole at the bottom of the crucible, which is covered with a wrought-iron punching about as big as a silver quarter dollar and perhaps ⅛-inch thick, this again being covered with ½-inch or so of dry sand. The thermit, mixed with the wrought-iron scrap—which, however, must be perfectly free from oil—is then placed in the crucible, and about half a teaspoonful of a special igniting powder is placed in a little heap on the top. The crucible is supported in some convenient way, with the tapping-pole directly over the mould. A small iron rod is supported by the aid of a lever, so that it can be jerked up through the hole and displace the iron blank when the iron is ready to run. When all is ready, a fusee is pushed into the igniting mixture. The reaction may be watched through a dark glass (some protection to the eyes being necessary), and as soon as a quiet glowing mass is seen, free from bubbles, the time has arrived for tapping the crucible. The rod is jerked up, and the iron immediately runs into the mould. The lever should be quickly jerked to one side; otherwise the end will be melted off by the hob iron.

A few words may be added as to the mould. The ordinary sand mould answers well with small castings. It is best to dry it thoroughly, and it is well to paint the surface with a mixture of blacklead and water while hot. It is well, where possible, to lead the runner into the mould at the bottom, and to provide a riser for the escape of a small amount of metal. Further, as the slag formed occupies about three times the volume of the thermit iron or about one and a half times that of the total iron, it is well to provide a channel outside the mould in loose sand, by which the slag and any superfluous iron may escape.

Where it is required to fill a defect in a casting, or to melt a piece of iron for any purpose onto a casting or a forging, a mould must be extemporized and placed in position, and the iron run in so as to pass over the metal, which it will immediately melt on the surface, and with which it will unite. There is one precaution here, however, which should not be overlooked: if the mould is warm and is not absolutely dry, it would be sure to deposit moisture on the cold iron, which might lead to a serious accident. It is a precaution, therefore, whenever running thermit iron on cast iron, steel, or wrought iron, to warm the metal first to a temperature which is at least hot to the hand, to prevent such condensation of moisture. The thermit iron produced as described above works in the lathe and under the file like the mildest steel.

NEW EDISON CEMENT PLANT.

Scientific American, 1902.

The extensive and growing use of concrete construction in almost all branches of engineering work makes the announcement of the starting of the large Edison cement plant at New Village, near Stewartsville, Pa., of general interest, especially as the new process is promised to greatly cheapen the price of Portland cement, rumor having it that the first cost will be so little as fifty cents a barrel. A force of over 300 men will be employed from the start, which is expected to be materially increased when the business is under way. Regarding the new process and the plant the *Scientific American* says:

"After conceiving the idea of improving upon the old process and discovering an inexhaustible deposit of cement rock at Stewartsville, Mr. Edison formed a company. This was more than two years ago, and since that time about sixty-six men have been at work constructing the twenty-seven buildings and installing the machinery. The plant, which is one of the largest of its kind in the United States, covers a space half a mile long, and one-quarter of a mile wide. It has thus far cost over a million and a half dollars. The machinery is built for a capacity of 10,000 barrels per day; but the buildings were made to accommodate half that amount at the start, and if the business proves successful the plant will be increased to its fullest capacity in a few years. There are twenty-seven buildings and the roasting-house is separate from the others. All the others are connected by a deep tunnel half a mile long, fifteen feet wide and twenty-five feet deep. The stock-house contains two 600-foot corridors, one above the other, and connected by big flues. There the cement rock will be roasted and prepared for the refining process. From that building starts the tunnel mentioned. The raw material will be conveyed by means of an electric railroad through the tunnel from the stock-house to the crusher, and thence to the dryer. The tunnel is made of solid rock walls and paved with concrete. The dryer is a simple stone shaft twenty feet square and forty feet high. Inside is a series of drying pans.

"The crusher is located in a building four stories high, the two sides being of solid masonry, ten feet thick at the bottom and five at the top. The floors are of steel construction. The machinery is capable of crushing 25,000 barrels of cement rock every twenty-four hours. The rollers have a pressure of 100,000 pounds to the square inch. In order to get results Mr. Edison made use of a discovery by means of which, with the aid of pulleys worked in connection with air compressors, he could get the great pressure directly upon the steel rollers with less than 1,000 pounds pressure on the bearings. All the cement rock will be transported through the tunnel as it is moved from one building to another. The raw material is received at the roasting-house and there the cement rock will be roasted and prepared for the secret refining process invented by Edison, and which is expected to revolutionize the cement industry. Before the product is again handled by hand it will automatically travel several miles through the many buildings. One hundred and twenty-five electric motors are used in the plant. When the last stage of the process is reached the cement will flow into barrels, in a building through which several railroad tracks pass, thus permitting the barrels to be loaded as fast as filled. All the buildings are of steel, covered with corrugated iron and painted black."

HYDRAULIC ELEVATORS FOR OFFICE BUILDINGS.

Engineering News, July 31, 1902, p. 74.

In an article in the *Engineering News* on the selection and installation of hydraulic elevators, Henry D. James says that elevators for office buildings are generally made 5 or 6 feet square and that a load of 75 pounds per square foot of floor area must be allowed for in all passenger elevators. Also that one elevator, approximately, is required for each 25,000 square feet of floor area. This ratio, however, varies greatly according to the location of the building, the demands on the service being much heavier in the vicinity of stock exchanges than in some other localities. The speed depends on the height of the building; 300 feet per minute being fast enough for a ten or twelve-story building, and double that, or 500 to 600 feet for twenty-story buildings. As a matter of fact, however, it has in many cases been found advantageous to reduce this to 400 feet per minute for local elevators, as the lower speed was more agreeable to the passengers and the service nearly equally as efficient since more time is consumed in stops than is taken by the vertical travel. Of course higher speed is desirable for express service. Hydraulic elevators are made with both vertical and horizontal cylinders. Each type has its advantages and disadvantages. The vertical type has a lower gear, therefore less friction, and takes up less floor space. The cylinder can be placed in the elevator shaft back of the car so that only the pumping plant need be placed in the basement. The cylinders rarely exceed 40 feet in length, and generally their length is not more than 30 feet. Where the horizontal cylinder machine is used, it is placed in the basement, but a number can be stacked one on top of the other so that the floor space required under these conditions is not great. All horizontal machines require a separate counterweight to partially balance the weight of the car and the same is true of all vertical machines where the ratio of the gear is greater than 4 to 1. The unbalanced weight of the car must be sufficient to overcome all friction of the gear and cause the car, with the weight of the operator, to descend at about the same speed at which it is required to rise. The modern office building elevator car often weighs from 3,000 to 4,000 pounds, which requires 500 pounds or more unbalanced weight. Both types should have a chain attached to the bottom of the car to compensate for the weight of the rope lifting the car. The object of the chain is to compensate for the weight of the rope as it shifts from the car to the machine. Thus when the car is at the bottom of the shaft, all the weight of the rope is added to that of the car and *vice versa*, when it is at the top none is included. The chain exactly compensates for the varying load of the rope. In some cases the chain is omitted and a column of water exhausting against an increasing back pressure is used to compensate for the weight of rope; but this is not recommended. There should never be less than four lifting ropes for a passenger elevator attached to a hydraulic machine, and these should have a factor of safety of ten to one. Wrought iron rope with a center of hemp is preferred to steel, strangely enough. The reason given for this preference is that wrought iron rope is more pliable than steel, and that there is no guarantee if steel rope is used in the start that it will not be replaced with iron by the repair men, so it is considered safer to calculate on iron in the beginning. In addition to the regular safety stop placed in the bottom of the car, stops should be provided at each limit of the travel so that cars will be automatically stopped even if the attendant neglects to do so. Elevator cars are often provided with an emergency lever which enables the operator to grip the vertical guides attached to the sides of the elevator well in case an accident occurs and the ordinary device fails to work. Speed controllers are also employed which automatically check the speed of a car if it exceeds a certain limit. The "air cushion" is another device employed for cases of extreme emergency. It is not effective unless the velocity is high. Tests have shown that it will save life in case of a free fall, but it must not be considered as a substitute for the other safeties commonly employed.

POWER FOR ELECTRIC CRANES.

Journal Society of Western Engineers.

The following data on the power required for electric traveling was given by Mr. S. S. Wales at a meeting of the Engineers' Society of Western Pennsylvania.

An electric crane is divided into three general parts—bridge, trolley and hoist, each of which has its own motor and controlling system, and each subjected to different conditions of work.

For the bridge, where the ratio of axle bearings to diameter of wheel is between one to five and one to six, the following table will answer our purpose for weights and traction for different spans:

Let L = working load of crane in tons.
W = weight of bridge alone in tons.
w = weight of trolley alone in tons.
S = speed in feet per minute.
P = pounds per ton required.

Span	W.	P.
25 ft.	.3L	30 lbs.
50 ft.	.6L	35 lbs.
75 ft.	1. L	40 lbs.
100 ft.	1.5L	45 lbs.

For the trolley we would assume the weight and traction as shown in the following table:

L.	W.	P.
1 to 25 tons.	.3L	30 lbs.
25 to 75 tons.	.4L	35 lbs.
75 to 150 tons.	.5L	40 lbs.

Now the power required for bridge will be:

$$\frac{(L + W + w) \times P \times S}{33{,}000} = \text{H. P.}$$

which result will be used in connection with the motor characteristic to determine the gear reduction from motor to track wheel. As the nominal H. P. rating of a series motor is based on an hour's run with a rise of 75° C. above the surrounding air and as conditions of bad track, bad bearings or poor alignment of track wheels may be met with, 1½ times the above result should be taken as the proper size motor for the bridge.

For the trolley the power required would be:

$$\frac{(L + w) \times P \times S}{33{,}000} = \text{H. P.}$$

which will be used for speed and gear reductions, but 1¼ times this should be used for size of motor.

For hoist work we cannot have so large margin of power, as the variation from full load to no load may imply a possible dangerous increase of speed, and unless the crane is to be subjected to its maximum load continuously or is to be worked where the temperature of the surrounding air will be high, it is safe to use the size found by assuming 1 H. P. per 10 ft. ton per minute of hoisting. This is nearly equal to assuming the useful work done as 60 per cent of the power consumed.

As an illustration, let us take a crane of 50-ton capacity, lifting speed of hoist 15 feet per minute. Bridge to be 70 feet span and to run 200 feet per minute with load. Trolley to travel 100 feet per minute with full load. On the foregoing assumption the bridge would weigh 50 tons and require 40 pounds per ton for traction, and the trolley would weigh 20 tons, and require 35 pounds per ton for traction.

The power for the bridge would be:

$$\frac{120 \times 40 \times 200}{33{,}000} = 29 \text{ H. P.}$$

and the size motor 1½ times this would give 43½ H. P. or 50 H. P., this being the nearest standard size, and the specification should read not less than 50 H. P. motor to be used for bridge travel.

Assuming Westinghouse motors to be used, as they are more commonly known in this district (Pittsburg), this would call for a No. 38—50 H. P. railway motor. By referring to characteristic sheet for this type furnished by the Westinghouse Company we find that at 29 H. P. this armature will run 612 revolutions per minute, which, when the diameter of the track wheel is known, will give the gear reduction needed.

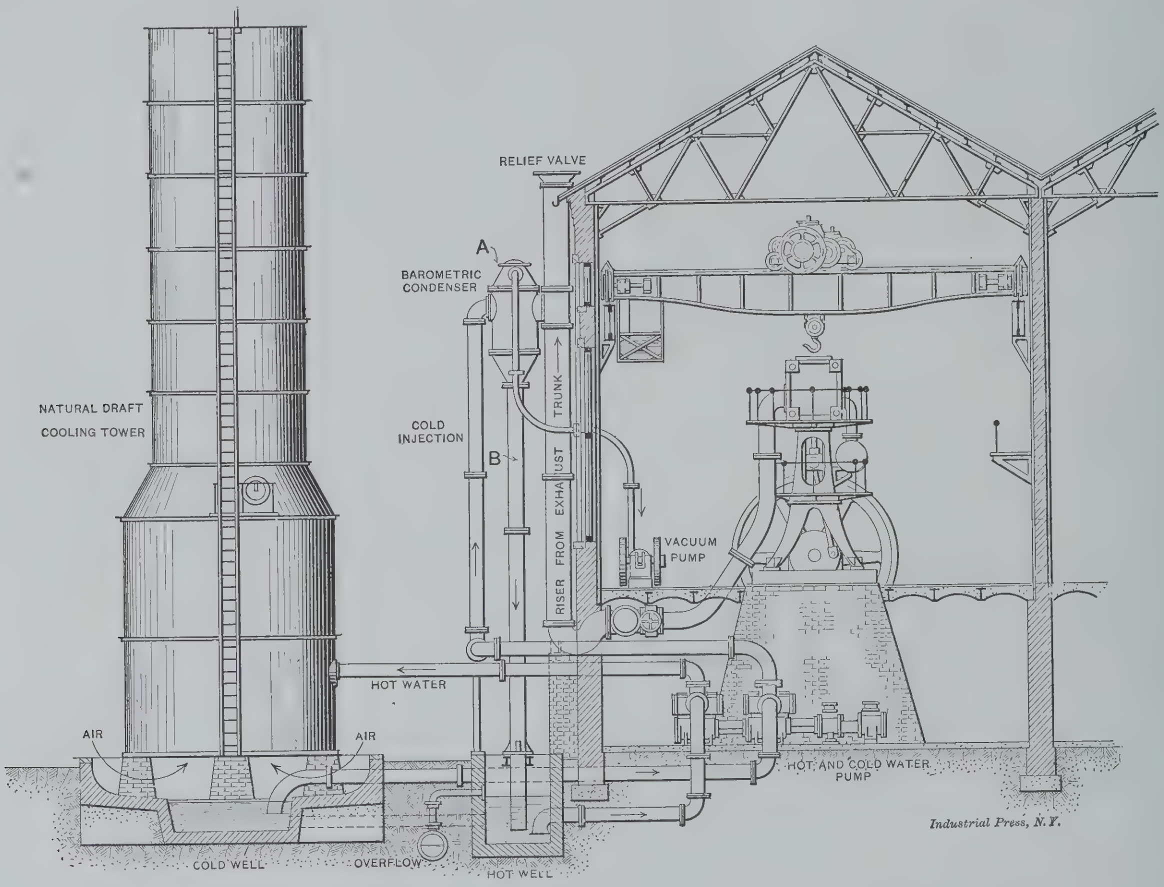
Similarly the trolley will require $\frac{70 \times 35 \times 100}{33{,}000} = 7.43$ H. P. and the size motor required will be 1¼ times this, or 8.28 H. P. The next larger standard size motor is 10 H. P., and the specification would read not less than a 10 H. P. motor to be used. The characteristic of a Westinghouse 10 H. P. motor shows that the armature will run 820 revolutions per minute at 7.43 H. P.

The hoist would require $\frac{50 \times 15}{10} = 75$ H. P. and would be specified not less than 75 H. P. motor to be used on the hoist. The next standard size Westinghouse motor suitable for crane service is rated at 80 H. P. at 220 volts and the armature speed at 75 H. P. is shown on the characteristic sheet to be 460 revolutions per minute. The required power will of course be modified by the requirements of special cases, the use of rope or chain, whether the reduction is made mostly in the chain or in the gearing, etc., but still they will give reliable results to the user.

CONDENSERS AND COOLING TOWERS FOR THE POWER HOUSE OF THE NEW YORK SUBWAY.

Street Railway Journal, August 15, 1902.

New York City will soon add to her list of very large power plants another one which is being built to operate the Rapid Transit Subway now in process of construction. The engines of all these large power plants, are, of course, condensing, but a large percentage of the gain effected by the use of condensing engines is offset by the great cost of condensing water. The 50,000 horse power plant of the Metropolitan Street Railway and the 65,000 horse power plant of the Manhattan Elevated Railway, use surface condensers and salt water from the East River. Theoretically the use of a surface condenser should enable the condensation to be used over and over again in the boilers, it being only necessary to replace the small losses occasioned by leakage in the system. This would make such a plant as either of those named practically independent of the water system of the city, as the daily amount of fresh water required to replace the leakage would be comparatively small. As a matter of fact, however, it has not been found feasible to use the condensation for feed water to the boilers, so it has to be thrown away and fresh water drawn from the mains for boiler feeding. This is on account of the practical impossibility of eliminating the lubricating oil from the condensation when such large quantities have to be handled. To use feed water contaminated with lubricating oil is both unsafe and uneconomical, the latter on account of the greatly increased boiler repairs made necessary. It follows, therefore, that if the condensation cannot be used for feed water there is no need for using surface condensers which are bulky and expensive to keep in repair. Consequently in the new power station for the Subway the type of condenser variously known as the injector, siphon or barometric condenser will be used in conjunction with a cooling tower, both condensers and towers being of Alberger type.



Industrial Press, N.Y.

Section of New York Rapid Transit Subway Power House, showing Atmospheric Condenser and Cooling Tower.

The illustration taken from the *Street Railway Journal* shows the arrangement of the barometric condenser and the cooling tower, which in this case will be made for natural draft. The condenser *A* in this type of apparatus must be located at least 34 feet above the level of the water in the hot well in order to get the greatest possible vacuum, since the atmosphere will support a column of water of this height at the level of the sea. The cold injection water mixes with the exhaust steam as it comes from the engines and of course condenses it, leaving a vacuum in the apparatus. No pump is required to remove the condensing water from the condenser, since it will flow down the pipe *B* against the atmospheric pressure. An air pump is required, however, to remove the entrained air carried into the system which, if not removed, would impair the efficiency of the system and finally destroy the vacuum entirely. The water from the hot well is pumped to the top of the cooling tower (usually built about 80 feet high) where it is allowed to trickle downward over boards of cypress arranged in a regular manner so as to provide uniform flow of the sheets of water and their exposure to the air. During the passage of the water downward it comes in contact with the cool draft of air ascending the interior of the tower, which cools it to approximately the same temperature by the time it reaches the cold well at the bottom. In this way the cooling water is used over and over again, the loss being that which evaporates and is carried away by the air during the cooling process.

The power house for the Subway lines will be built to contain twelve engines of a rated capacity of 7,500 horse power each, at best efficiency, with a maximum capacity of 11,000 horse power each. Eight of these engines will be built by the Allis-Chalmers Company. They will be of the same general type as those being put in the Manhattan Elevated Railway power plant. Each engine consists of two component engines, operating on one shaft, with a 5,000-kilowatt alternator between the engines. Each of these component engines will have a vertical low-pressure and horizontal high-pressure cylinder acting on the same crank. The cranks at opposite ends of the shaft are located 135 degrees apart. The high-pressure cylinders are to be 42 inches in diameter and 60 inches stroke, and the low-pressure cylinders, 86 inches in diameter by 60 inches stroke. The engines will operate with 175 to 200 pounds initial pressure, and at 75 revolutions per minute. The high-pressure cylinders will have poppet valves, and the low-pressure cylinders, Corliss valves. The object of the poppet valves in the high-pressure cylinders is to insure the successful operation of the valves without excessive use of oil at high steam temperatures. It is expected that they will operate successfully with steam superheated to 500 to 550 degrees F.

ROLLING MILL DRIVEN BY A GAS ENGINE.

Iron Age, August 7, 1902, p. 19.

There are magnificent installations of gas engines in Germany, but thus far it has been understood that the gas engine, in large units, has been employed exclusively in two directions, that of driving blast furnace blowing engines and in operating the dynamos for the electric service at furnaces, steel works and rolling mill machinery. Of course the furnaces have had the incentive of very high fuel prices to urge them to a thorough utilization of the coke charged into their blast furnaces. Yet with all that credit must be freely accorded to them for the energy and skill which they have brought to bear upon many perplexing if minor problems involved.

It is interesting to note that they have gone a step further, and with apparent success, by employing the gas engine, using waste blast furnace gas, for driving roll trains. An account of such an engine, which has been in regular operation at a German mill since April, 1901, is given in a recent issue of *Stahl und Eisen*. Of course no attempt has been made to apply a gas engine to those requirements in rolling mill work in which sudden and heavy fluctuations in power are frequent. But the claim is made that it may be very advantageously used to supplant flywheel steam engines for driving sheet, rod and bar mills. The particular gas engine described is a horizontal tandem flywheel four-cycle engine coupled direct to the train. It was built by the Augsburg & Nuernberg Company, and at a speed of 120 revolutions develops 600 to 700 horse power. The two cylinders are 35.4-inch bore and have a 39.4-inch stroke, the diameter of the flywheel being 21 feet. The regulation is effected by a mixing valve. This latest development of the gas engine into rolling mill works is a further step in putting those localities that suffer from high fuel cost upon a closer parity with the sections blessed with cheap coal.

REMARKABLE DRILLING FEEDS.

American Machinist, July 24, 1902.

The Bickford Drill & Tool Co. have found feasible unprecedented rates of feed for ordinary commercial twist drills when used in their radial drills. The remarkable results attained are largely attributed by Mr. Norris to the design of the radial arm of these drills, which is made in the form of a complete tube instead of having one side open as in the ordinary form of construction. A complete tube is, of course, much stiffer as regards torsional stress than a tube having one side cut away when both have the same amount of metal. The torsional stress on a radial arm is very severe when driving large drills since the drill spindle is offset by the center of the radial arm. Lack of stiffness causes spring and chatter which breaks drills at far lower rates of feed than would otherwise be the case if the arm was rigid. It is pointed out, however, that the quality of twist drills now made may be considerably superior to those of a few years ago when the Morse Twist Drill & Machine Co. made out its well-known table of drill feeds. The rate of feed for a ¼-inch drill established by the Morse people is .005 inch per rotation of the drill and for a ½-inch drill .007. The Bickford people find it feasible to increase the feed of these drills to .025 and .035 inch respectively, or five times as great. A test of a ⅜-inch drill is given in which the drill was run 267 turns per minute with .064 inch feed. This rate of feed is equivalent to 17 inches per minute, yet the drill stood the test for a depth of 3 inches without breaking. A 1¼-inch drill stood a feed of .072 inch in steel but broke when the feed was increased to .10 inch; a 1 9-16-inch drill with hand feed cut chips 9-32 thick, of which a photograph is shown; a 4-inch drill was driven into solid .45 carbon steel, at the rate of 1¼ inches per minute or 6 feet 4 inches per hour, the feed being .072 inch and speed 17.68 turns per minute; and so on. The following table gives the turns per minute which the Bickford Co. regularly use when drilling cast iron:

Size of Drill	Revolutions per Minute.	Peripheral Cutting Speed Feet per Minute
½	267	35
⅝	222	36
¾	184	36
⅞	153	35
1	128	33
1⅛	106	31
1¼	88	29
1½	73	28
1¾	61	28
2	51	26
2¼	42	25
2½	35	23
2¾	29	21
3	24	19
3¼	20	17
3½	17	15

GERMAN LOCOMOTIVE PERFORMANCE AS TESTED BY VON BORRIES.

Railroad Gazette, August 8, 1902, p. 628.

The following table gives the results of some experiments made by Herr von Borries for the purpose of comparing the performances of three classes of engines: (A) A four-coupled, eight-wheeled, four-cylinder compound; (B) an engine of similar build to that of (A), but having two cylinders and using steam superheated to about 300 degrees C. (592 F.); (C) an older type of four-wheeled, eight-coupled, two-cylinder compound.

The run in each case was for a distance of 77½ miles and back, at an average speed of 55 miles per hour. The load ranged from seven to nine coaches, according to the rated capacity of the engines.

	Engine.		
	A.	B.	C.
Weight of locomotive, tons.	53.0	52.3	47.6
Grate area, sq. ft.	24.7	24.7	24.7
Heating surface, sq. ft.	1,270	1,140	1,345
Superheating sur., sq. ft.	..	.301	..
Boiler pres., lbs. per sq. in.	200	170	170
Horse power developed	879	809	755
Coal per H. P. per hour	2.31	2.53	2.55

The four-cylinder compound (A) proved the most powerful as well as the most economical engine. The two-cylinder engines of both types were practically equal in efficiency. It is stated that the four-cylinder engine ran remarkably smooth.

CONCRETE PILE CONSTRUCTION.

Railroad Gazette, August 15, 1902, p. 645.

A system of concrete pile construction has lately been perfected by Mr. A. A. Raymond, of Chicago. The method involves driving into the ground a sheet-iron shell of the size and shape of pile desired. A tapered steel core is used to accomplish this, the shell being fitted over this core and the whole driven as the ordinary wooden pile. The construction of this core is such that it may be contracted after the proper depth is reached, and withdrawn from the shell. The core is in three parts, an outer shell in halves, and a central tapered part having a head, the whole being held rigid by keys. When it is desired to withdraw the core the keys are removed, permitting the central tapered part to be raised a sufficient distance to allow the shell to collapse slightly, when the whole may be easily lifted out. The shell is then filled with concrete, which is carefully and continuously tamped as it is fed in, to prevent the formation of voids.

In a trial of this system made in Chicago the tapered steel core was 20 feet long, 18 inches in diameter at the butt and 6 inches at the point. The hammer weighed 2,200 pounds and the penetration for the last few blows was but an inch to the blow, with a fall of 25 feet. An oak pile 12½ inches at the butt and 10 inches at the point had a penetration of 5½ inches for the last blows, using the same hammer and drop, and driven only a few feet away. It was computed from these tests that the wooden pile had a carrying capacity of 17,000 pounds, while the concrete pile would carry 65,000 pounds. The greater carrying capacity of the concrete pile is, of course, due to its increased taper. This taper may be varied according to the nature of the material to be penetrated. The relative appearance of the two kinds of piles is shown in Fig. 1. A comparison of wooden and concrete piles for wall foundation work is shown in Fig. 2, the number of concrete piles being one-half that of the wood, while the bearing surface is nearly 39 per cent. greater. The Bryson building, Chicago, costing $250,000, has concrete piles under its foundation after the manner shown in this illustration. The system used at the works of the J. I. Case Plow Works, Racine, Wis., is shown in Fig. 3. The ground on which this plant stands is of such a character that some system of piling was necessary. The water level is so far below the level of the ground that the driving of timber piling below the water line would have required an expensive filling of concrete from the piles to the surface.

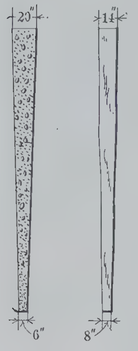


Fig. 1.

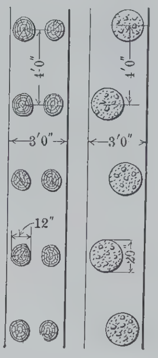

Fig. 2.

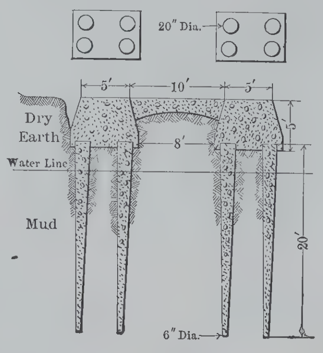

Fig 3.

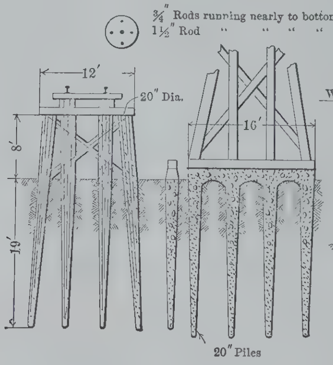

Fig. 4.

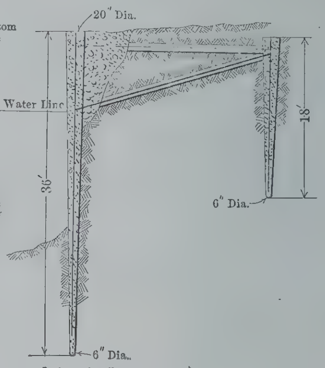

Industrial Press, N.Y.

Fig. 5.

It is possible to use the concrete piles for trestle work, two methods being illustrated by Fig. 4. Where the pile comes above the surface it is stiffened and strengthened by steel rods imbedded within its length from top to bottom, as shown. They may also be sway-braced by steel rods and concrete. For docks it would seem that the concrete system should be especially desirable because of the permanency it insures. They are naturally more expensive than those of timber, but the latter can only be regarded as temporary. The illustration, Fig. 5, shows the construction, with concrete backing and anchorage. The advantages of the concrete pile may be summarized as follows:

It is practically everlasting, the surrounding conditions of soil or water not affecting it. The water line in the soil may be entirely disregarded, unlike timber piles, which must be cut off below this line to prevent decay. On the wooden piling solid foundations of considerable depth must be built in order to reach the surface, involving a large amount of excavation. Use of concrete piles avoids this. The concrete pile may be made with practically any desired taper, an increase of which is held to give increased supporting power. Timber exposed to sea water must be renewed periodically as a result of the ravages of the teredo. Relief may be obtained from this difficulty through the use of the concrete pile.

THE PRODUCTION OF STEEL IN THE UNITED STATES.

Cassier's Magazine, July, 1902, p. 376.

Theodore W. Robinson, first vice-president of the Illinois Steel Company, says that in 1870 the great Menominee, Gogebic, Vermilion and Mesaba iron ore ranges in the United States, were unknown wilderness. The annual production of all grades of steel was under 70,000 tons, an amount less than the monthly output of a modern Bessemer plant. Thirty years have sufficed to increase the annual production to 10,500,000 tons. In 1870 the principal product of the rolling mills was iron rails; now iron rails are a thing of the past and the price of steel rails has dropped from $166 to $28 a ton. Machinery has made startling changes in the iron and steel industries. Where formerly 1,200 tons per month was a large product for a blast furnace, it is now possible to produce 19,000 tons of pig-iron per month from a single stack. This means that 1,800 tons of raw material must be handled every twenty-four hours. In the steel mill machinery has replaced manual labor. Where formerly a small army of employees was necessary, a few skilled mechanics and engineers suffice. The mill was a teeming hive of sweating humanity pulling and hauling, raising and shoving masses of white-hot metal from roll to roll, from pass to pass, with clumsy hooks and tongs by force of brawn and muscle. The tendency was in the direction of the development of brute strength rather than higher intelligence; now the conditions are reversed. The introduction of automatic machinery brought about a new order of things. The rolling mill machinery that has replaced the former crude appliances, is a monument to mechanical ingenuity and engineering skill. Twenty-seven hundred tons of steel rails—enough to lay twenty-one miles of track—have been produced in a single mill. This performance was all the more remarkable as the specifications allowed a sectional variation of not more than one sixty-fourth inch. Regarding wages: In 1876 the average production of a rod mill was twenty tons per twenty-four hours and the average daily wages was $3.66; it is now no uncommon occurrence for a rod mill to roll 400 tons a day. The present average wage is $4.71 per day.

ELECTRIC THIRD RAIL SYSTEM OF THE B. & O. R. R.

Book of the Royal Blue, July, 1902.

August 4, 1902, was the seventh anniversary of the first operation of electrical railway trains on the Baltimore & Ohio R.R. in the Baltimore tunnel and on the Belt Line. This application of electricity to the hauling of heavy railway trains was the pioneer installation of its kind, so its operation has always been regarded with general interest. The first electric locomotives used were built by the General Electric Company. They weighed about 96 tons and had a hauling capacity of 1,000 tons up a 60-foot grade at a speed of ten miles an hour. Current was conducted to them by means of overhead conductors. These were made up of two Z-bars held together by a cover plate, making a sort of box-like construction. The conducting shoe of the locomotive was made to slide in the overhead slot thus formed. The conductors were supported by iron columns standing on each side of the tracks, and by cables. The columns were connected across the tracks by metal framework and lengthways

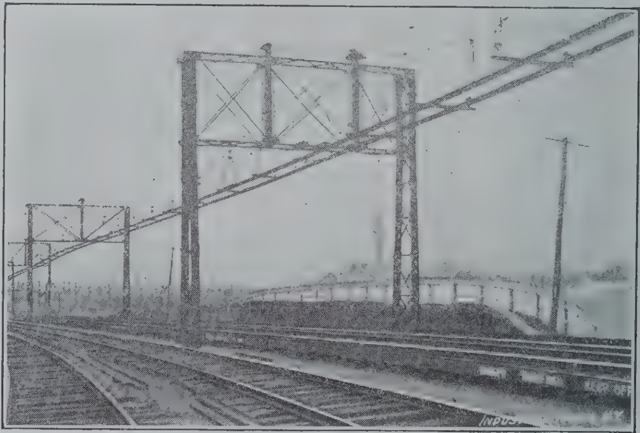

Fig. 1. The Old and New Way, showing the Overhead Framework and the Third Rail. The Overhead Framework has since been Removed.

of the tracks by the cables hung in catenaries. The sections of conductor between the columns were suspended from the cables in about the same manner as a suspension bridge. This system was used until last March, when it was abandoned for the third-rail system, in which the third-rail is placed outside the tracks.

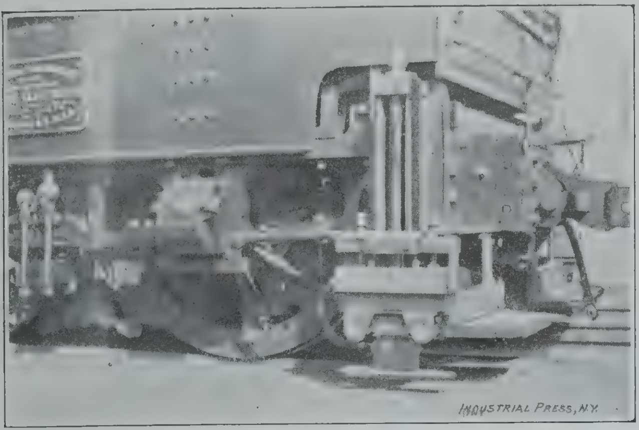

Fig. 2. Conducting Shoe of Electric Locomotive; one is attached to each of the Four Corners.

The third rail is placed along the outside of the east and west bound tracks. It is supported by means of guard and insulator stands, which are attached to ties at centers of approximately twelve feet. These guard and insulator stands form a support for planks placed on either side of the rail, acting as a guard to prevent employes coming in contact with it. Through the two passenger stations, Camden and Mount Royal, which are about a mile and one-half apart and at the ends of the tunnel passing under the city, it was necessary to modify this construction in such a way as to prevent all possibility of the traveling public coming in contact with the charged conductor. To accomplish this, there were several precautions taken. The third rail was laid through the station at the standard height and on the insulators in the regular way, but it was completely covered over, the conducting shoe being allowed to make a contact through a wooden covered slot supported by iron members from the under side. In addition to this, the rail was cut into sections, each of which was insulated from the one next adjoining, and controlled by the Murphy safety switch in such a way that the current would be on a section only when the locomotive was passing over that particular section. In the same way, the third rail adjacent to crossings of foreign roads, special work and in the yard was cut up in sections and protected by safety switches.

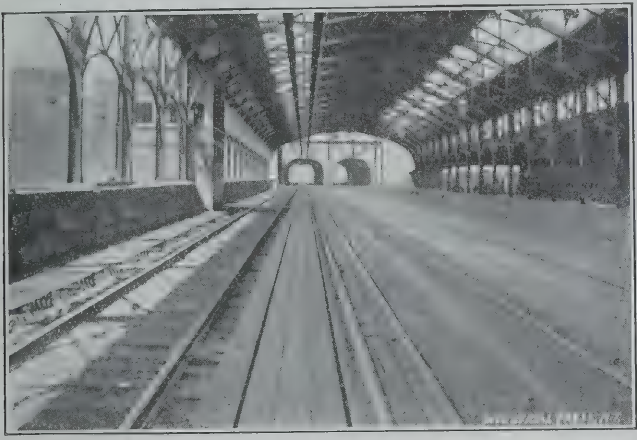

Fig. 3. View of Tracks in Mount Royal Station, showing Conductor Slots, which are the Black Lines in the Center.

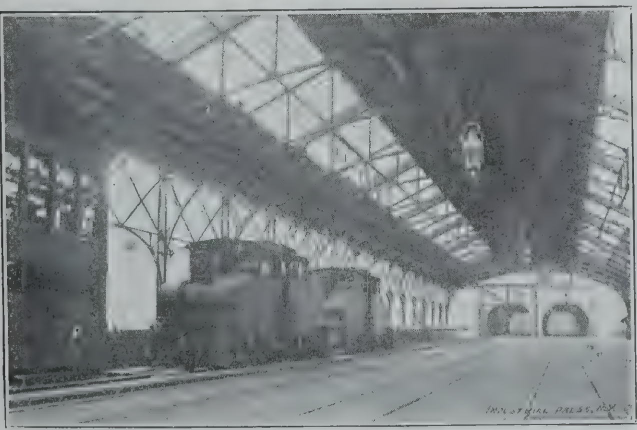

Fig. 4. Electric Locomotives in Mount Royal Station, Baltimore. Switch Towers at Left Foreground.

The advantages of the third-rail system are that it is cheaper than the overhead construction, costing only about one-fourth as much; it is more easily adapted to changes of the tracks that may have to be made from time to time, and is more easily repaired. The element of danger to employes is the one drawback, but this is not considered serious. It is held that the public have no business to be on the right of way except at stations and crossings, and at these points ample protection is provided. Each locomotive has four conducting shoes to take current from the rail, one at each corner. The matter of designing a shoe that will pick up at least 2,500 amperes without excessive sparking was a difficult one in itself. Each shoe is flexibly connected to the locomotive so that it can at all times conform to all inequalities and irregularities of the tracks and third rail. It has eight distinct movements within limits: Up and down, out and in, rocking laterally, and tilting in either direction to take inclines.

The number of freight trains hauled by electricity on this line has practically doubled in seven years, taking the figures for the months of September, 1895 and May, 1902. In the first month mentioned, 333 freight trains were hauled, and in the month of May, 1902, 641 freight trains. Two new locomotives of heavier design (150 tons) will be put on next spring having 50 per cent more hauling power than those now in use.

FRICTION OF WATER IN PIPES.

The Engineer, July 1, 1902, p. 470.

In hot water heating of buildings the circulation of water through the pipes and radiators depends (usually) on the difference in weight of the water before it enters the radiators and after, when it has lost some of its heat and consequently has a somewhat higher specific gravity. Since this is the motive force of circulation, and as circulation is vitally necessary for the success of the heating system, the calculation of pipe sizes for a hot-water heating system should be carefully done. For economical reasons the pipe sizes for the risers and re-

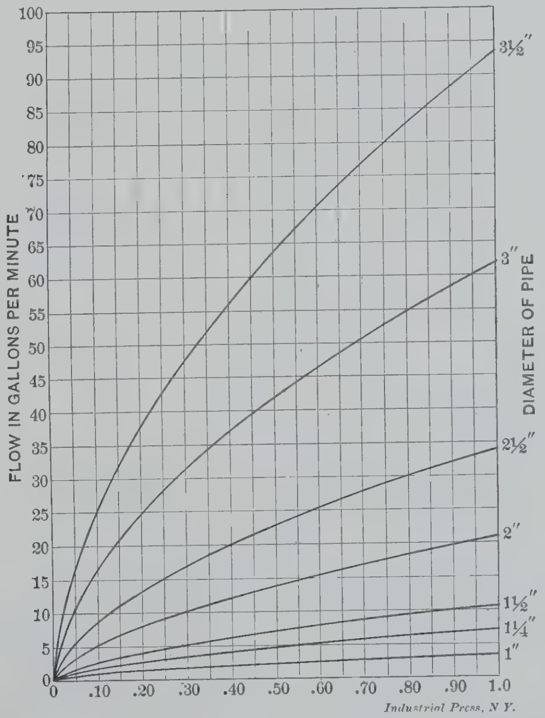

Fig. 1. Friction Loss in "Feet Head" per 100 feet in Length of Pipe.

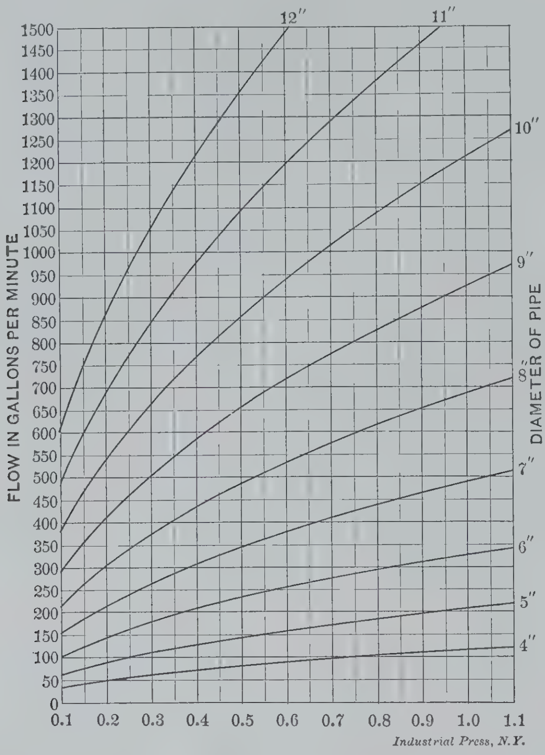
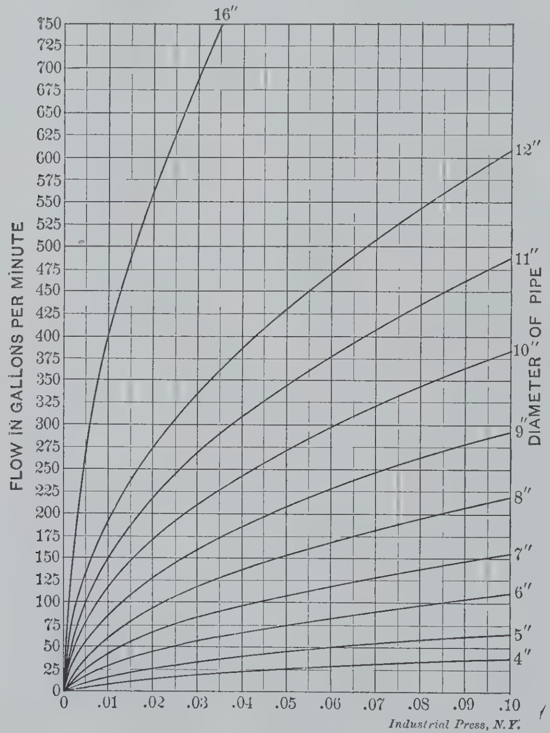
turns must be kept as small as possible and still have the circulation equal to the demands of the system.

A column of water 1 inch square and 12 inches high gains .000154 pound in density for each degree it is cooled between the limits of temperature of ordinary hot-water heating, or, say, 212 and 150 degrees F. In pipe size calculations this is usually expressed in "feet head" instead of pounds. The weight of a column of water 1 inch square and 12 inches high at a temperature of 170 degrees is .422 pound. One foot divided by .422 equals 2.37 feet head necessary to produce a pressure of 1 pound. So a pressure of .000154 pound multiplied by 2.37, which equals .000365, transforms it into "feet head." The elevation of a radiator is usually measured from the center of the water space in the boiler to the top of the radiator. If the elevation of a radiator above the boiler is 40 feet the temperature in the flow pipe is 180 degrees and that in the return pipe is 160 degrees, what is the head for producing circulation? 180 — 160 = 20 degrees difference in temperature; therefore 20 × 40 × .000365 = .292 feet.



Industrial Press, N.Y.

Fig. 2. Friction Loss in "Feet Head" per 100 feet in Length of Pipe.



Industrial Press, N.Y.

Fig. 3. Friction Loss in "Feet Head" per 100 feet in Length of Pipe.

In the case of long pipes and low heads only the friction of the pipe need be considered in calculating the flow. With constant velocity and diameter of pipe the friction head varies directly with the length of the pipe, so that having been calculated the friction head for one length of pipe the others may be found directly by proportion. The friction head, in pipes having a smooth interior similar to lead and brass, and from ½ inch to 3½ inches in diameter, may be computed by the following formula:

$$H = \left(.0126 + \frac{.0315 - d\,.06}{\sqrt{2}}\right)\frac{l}{d}\,\frac{v^2}{2g}$$

in which

H=the loss of head due to friction, in feet.

d = internal diameter of pipe in feet.

v = the velocity of flow in feet per second.

l = the length of pipe in feet.

$2g = 64.32$.

For pipes 4 inches in diameter and over, and having interior surfaces similar to new cast iron, the formula should be changed to

$$H = \left(.019892 + \frac{.00166573}{d}\right)\frac{l}{d}\,\frac{v^2}{2\,g}$$

Diagrams have been made from which the friction head can be determined without calculation. The curves in the three diagrams were laid out by means of Weston's formula, and give the flow in gallons per minute for different size pipes with low friction heads as met in hot-water systems. Suppose that the radiator mentioned having 40 feet elevation above the boiler required 40 gallons a minute in order to supply the necessary radiation. What pipe size will be required for the riser and return? Since the elevation of the radiator is 40 feet, assume 80 feet of pipe through which the water must pass. Since the diagram is laid out for lengths of 100 feet we may conveniently take the flow to be such a proportion as our pipe length is of 100 feet or 80-100 equals 4-5. 4-5 of 40 gallons equals 32. Since the available head for flow is .292 pound we follow up the ordinate marked .30 in the diagram, Fig. 1 (that one being near enough for the purpose of illustration), until the horizontal line corresponding to 32 gallons is reached. At about this point the curve for 3-inch pipe intersects, showing that this size pipe would be necessary for the required flow when no allowance is made for elbows and valves. An elbow is considered to oppose as much resistance as a length of pipe equal to 60 diameters and a return bend, 120 diameters. A globe valve is regarded to have about the same resistance as an elbow.

* * *

A REVEREND INVENTOR.

A Western bishop, who has invented an improved cutting box and a folding saw-buck, has now turned his attention to railroad matters and devised a spark arrester that is simplicity itself. The smoke stack of the locomotive is curved backward and discharges into a sheet iron pipe attached to the tops of the cars. The section of pipe on each car is made funnel-shaped at the front end, which enables the rear end of the section of the car ahead to enter and give the necessary room for flexibility at curves. The funnels also cause cold air to mix with the smoke and sparks from the locomotive and insure that all sparks will be cold and lifeless by the time they are discharged from the rear end of the train. This beautiful arrangement also insures that the passengers will not hereafter be troubled by dust and cinders from the engine, so that it will make no difference what kind of coal is burned so far as it affects their comfort. Now a little study of the different devices that have been invented and patented for this purpose, and which can be seen in the *Official Gazette* of the United States Patent Office, kept on file in almost every public library, would have saved the reverend gentleman considerable trouble and expense, and probably some distress of mind. If Andrew Carnegie's free public libraries, being so liberally distributed throughout the land, can be made of sufficient educational force to discourage such freak inventions that result alone would be worth a good deal to a certain class of misguided people, but it is doubtful if anything could discourage some of them.

LETTERS UPON PRACTICAL SUBJECTS.

AXLES FOR INDUSTRIAL CARS.

Editor MACHINERY:

At the machine company where I am located at present we have occasion to turn quite a large number of axles for industrial cars. These are made from 2-inch square steel about 65 inches long and have their ends turned to 1 15-16 inches diameter for a distance of eight inches. The bodies of the axles are left square. When wanted we usually had to get them out in a hurry and the work required nearly all of our medium size lathes, each lathe averaging about eight axles per day. Fig. 1 shows an old timer of a lathe rebuilt, on which we are turning out forty axles per day. While we do not think the machine is a beauty in design, it is not far behind in its output.

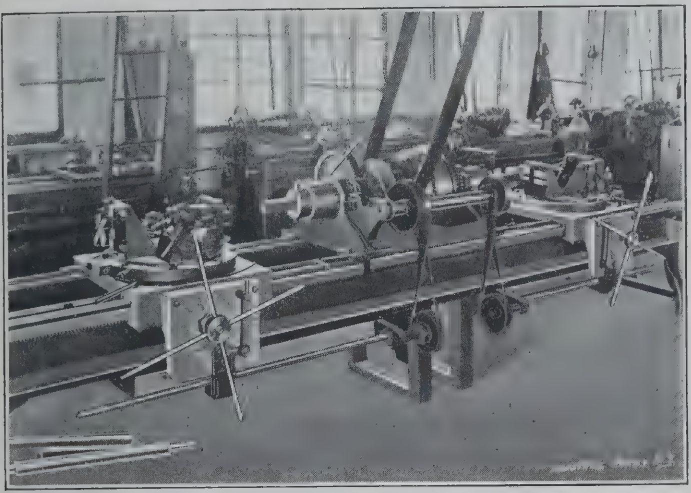


Fig. 1. Old Lathe Rebuilt for Turning Axles.

It consists of a strongly made headstock carrying a hollow spindle large enough for the material to pass through freely. On each end of the spindle is a cast-iron chuck with square hole and four setscrews for a slight adjustment of the work. The plate on which the turret tools are fastened has equally spaced holes in which the locking pin locates each tool in its correct position. Around the plate is a clamping ring *B*, Fig. 2, which is tightened by the cam lever *C*, and holds the plate-carrying tools in a rigid manner.

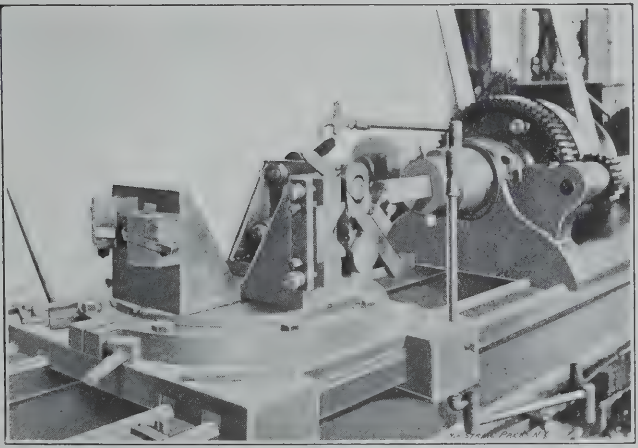

Fig. 2. Turret and Tools Equipment.

For turning axles we have only three operations. The tool *D* is for pointing the end; the other two tools are similar to those on a Jones & Lamson turret lathe—one being used to rough out, the other to finish. The cut shows the construction quite plainly, and also indicates that plenty of cast iron and steel has been used to make it stand the abuse that it gets in coarse feeds, and the shock from turning off corners of square stock.

While not in use as an axle lathe, we use one end of the lathe to do larger work than our Jones & Lamson turret can handle, having a tool holder in which the automatic die for threading from the other turret lathes interchange. We have also fitted a regular four-jawed chuck to one end of the spindle, so that the possibilities of the machine have been multiplied for quite a number of jobs. A. A. AVERY.

Warren, Pa.

THEORY AND PRACTICE.

Editor MACHINERY:

In W.'s article on page 361 he asks for an explanation of the paradox concerning scientific laws and actual practice in the matter of frictional resistance. First permit me to quote the stock phrase, "Theory and practice are never at variance," and then I will attempt to show that it is true in this case.

All surfaces, however smooth or polished they may be, have minute elevations and depressions in them, owing to the porosity, to a greater or less degree, of all matter. Consequently, when two surfaces are in contact the elevations of one drop into the hollow of the other and a resistance called friction is offered to an attempt to move one body over the other in the plane of their contact. This friction consists in the resistance offered by the elevations in the material to breaking off or bending over and in the weight or perpendicularly applied pressure that must be overcome in order that the body may rise sufficiently to allow the elevations to slip up out of one hollow and down into the next, etc. From this it is evident that friction is dependent upon the kind of material, upon the condition of the surfaces as to smoothness, and upon the weight or pressure perpendicularly applied. That is, the harder the substance the more difficult it will be to break off the elevations and fill up the hollows; the rougher the surface the higher will be the elevations and the deeper will be the depressions; the greater the weight or perpendicularly applied pressure the greater must be the force exerted in order to raise the body so that the elevations may pass from depression to depression.

Friction is independent of the area of the surfaces in contact. Provided the weight was the same there would be no more friction or resistance to the motion of a large planer bed upon its ways than there would be to the motion of a small planer bed upon its correspondingly small ways. I hear you say that the larger the ways the greater would be the number of elevations and hollows in the surfaces of the rubbing parts. All of which is true, but the weight is distributed over a larger area and is proportionately less upon each particular roughness of the surface; consequently the friction of each particular particle is less with a surface of large area than with a surface of small area where the pressure upon each particle is greater. The aggregate friction is the same whether you have a large number of small frictions or a small number of large frictions.

When, however, the pressure becomes so great that the material is unable to withstand it and crushes down, a cutting action is produced when an attempt is made to slide the surface of one body over the other in the plane of their contact. Take a flat plate of lead and place upon it a weight, with a flat side in contact with the plate, so heavy that it sinks slightly into the lead plate. Now attempt to slide the weight along on it and a shaving of lead curls up in front of the weight. That is not mere sliding friction resisting the motion of the weight—that is a shearing or cutting action, *i. e.*, an intense friction increasing more rapidly than the pressure. When the surfaces are large enough to stand up under the load without crushing and cutting then the friction is the same, regardless of the area of the surfaces.

It was originally supposed that friction was also independent of velocity, but the later experiments of Bochet show that after a speed of approximately one foot per second is exceeded it decreases gradually as the velocity increases.

It will take more force to overcome the friction of quiescence than it will to keep a body in motion. This is especially noticeable where one body is sufficiently heavy to slightly indent the other when at rest, but this excess of friction may be instantly overcome by a slight jar.

Thus far I have only followed in the footsteps of X and stated the general laws of friction. Much more might be said on this interesting subject but it does not come within the scope of this article. For the benefit of any who may desire to go farther into this subject or obtain values of the coefficient of friction for different substances, I will refer them to: "Machinery and Millwork, by W. J. M. Rankine," pages 348-354 inclusive; "Theoretical Mechanics, by Julius Weisbach," pages 309-370 inclusive; "Nouv. Recherches expérimentales sur le frottement de glissement, par M. Bochet," in the Annales des Mines, Cinq. Serie, Tome XIX, Paris, 1861.

I will now endeavor to explain why a larger disk would have had more effect than the small one in checking the speed of rotation of the drum, and why the small shaft revolved when the live center was in the deeper hole in the end of the shaft, and remained stationary when the shaft was turned end for end.

The question in dispute between X and Y is, in reality, not one of friction at all; but, instead, one of moments. Place the one-inch disk against the end of the four-inch drum with their centers coincident and the frictional resistance is not applied at the center or axis of the drum, but at a distance from it equal to two-thirds of the radius of the disk. Perhaps if I work a few examples my meaning will be more clear. First, let us assume that the condition of surface, velocity of rubbing and pressure exerted remain constant. We will consider in all four cases: The one-inch disk with its center coincident with the axis of the drum; a four-inch disk having its center coincident with the axis of the drum; the one-inch disk with its center at a given distance from the center of the drum, and a ring with its inner and outer diameters three and four inches respectively and its center coincident with the axis of the drum.

Let P = the pressure applied perpendicularly to the disk—say ten pounds.

Let f = the coefficient of friction, *i. e.*, the ratio of the friction for a given material and condition of surface to a perpendicularly applied pressure of one pound = .5 for dry leather on a metal surface.

Let l = the leverage, or distance from the center of application of the frictional resistance to the center of the rotation.

The mechanical effort = P l f.

Let r = the radius of the disk.

In the first two cases the mechanical effort equals

$$Plf = \frac{2Prf}{3} = \frac{2 \times 10 \times r \times .5}{3} = \frac{10 \times r}{3}$$

As r in the second case is four times the length of r in the first case, the mechanical effort must necessarily be four times as great as in the first case; or, in order to obtain the same effort the pressure exerted would only need to be one-fourth as great. Thus Y was correct in thinking that the use of the larger disk would show a better design, and also in saying that "The disk would last longer." The larger disk would retard the rotation of the drum more than the small one—not because of more friction, but because of the greater effort or moment obtained on account of the greater radius of the larger disk. Moreover, it would last longer because the unit pressure and consequently wear of the larger disk would be less than that of the smaller one.

Now let us see what the result would be if we should move the smaller disk toward the circumference until its center is at a distance from the center of the drum equal to two-thirds of the radius of the larger disk. As the moment arm is the same we would have the same effort exerted and the same pressure required to produce the result obtained by using the large disk with its center coincident with the center of the drum; but, as before, the wear on the small disk would be greater on account of the greater unit pressure.

We will now consider the fourth case, of the ring and the effort exerted by it to retard the motion of the drum. Take the large disk previously spoken of and cut out the center of its face, leaving a ring bearing surface at the outside one-half inch in width.

Let r_1 = the larger radius of the ring.

Let r_2 = the smaller radius of the ring.

Then the center of application or leverage of the frictional resistance will be at

$$\frac{2}{3} \times \frac{r_1^3 - r_2^3}{r_1^2 - r_2^2} = \frac{2}{3} \times \frac{8 - 3.375}{4 - 2.25} = 1.762$$

inches from the center of the drum. As the center of application of the resistance is at a distance from the center of the drum of only .33 inches in the case of the small disk and 1.33 inches in the case of the large one, we find that we only require .187 as much pressure in the one case and .755 as much in the other by the use of the ring as we do if we use the disks and bring the center of application nearer to the center of rotation of the drum. This shows that the greater the leverage the greater will be the effort retarding the rotation. If we continue this idea the leverage of the resistance may be made so great as to entirely overcome the turning effort and we have an effectual brake holding the drum stationary after the clutch that holds it has been thrown out.

It was the same principle of moments involved in the turning or non-turning of the piece of shafting between the centers. Thus theory—when it is known—agrees with practice.

Sc. Pr.

SPACING THE TEETH FOR A RACK PATTERN.

Editor Machinery:

We have had, at various times, to make patterns of a double rack, Fig. 1, on which a gear runs alternately first on one side and then on the other, and which is used for driving the beds of printing presses. In measuring the patterns I have been surprised at their exceeding accuracy, and also at the rapidity with which they were made, and it has occurred to me that the method used in making them might be of interest to your readers.

a
Industrial Press, N.Y.
TOOTH FACE FOR DRIVING GEAR WHEN ON UNDER SIDE OF RACK

Fig. 1.

The teeth b, Fig. 1, are made separately with a tenon which fits a corresponding mortise in a. All of this is simple enough until we get to making the mortises and spacing them accurately. The back part a is made in two parts divided on the line m, Fig. 2. The mortises are cut on a circular saw and the spacing is done as follows: First a hardwood stick q, Figs. 3 and 4, about ⅛ inch x ¾ inch, and of sufficient length for the rack, is carefully spaced to the correct pitch, the center of each tooth being cut square across with a knife and to a considerable depth. This is temporarily fastened to the top of the back a, being left square as indicated at k, Fig. 2.

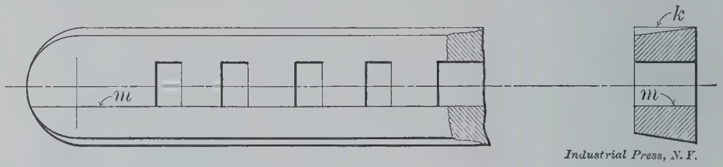

Fig. 2.

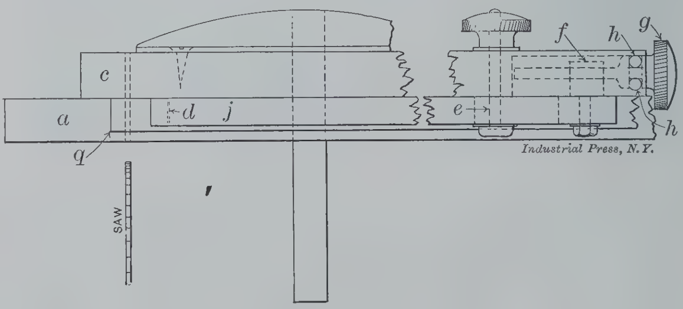

Fig. 3.

The cross-cut gage of the saw table is screwed firmly to a piece *c*, Figs. 3 and 4. A piece *j*, shaved down thin enough on the end to spring easily, is held to *c* by means of a bolt *e* in a slot in *j*, and is adjusted crossways of the saw table by means of a nut and thumb screw *f* and *g*, the end motion of the screw being checked by the pin *h*. At the left end of *c* is a thin knife edge, *d*.

To use this device the back *a* is placed against the gage *c*, and the knife edge dropped into the first notch in the spacing stick, when a saw cut is made. Then take hold of the piece *j* and spring it up while the back is moved along until the knife edge will drop into the next notch, when another saw cut is made. Proceed thus until one side of all the mortises has been sawn. Then go back to the first cut and saw the other side of the mortises in a similar way, first adjusting for the width of mortise by means of the bolt *e* and thumbscrew *g*.

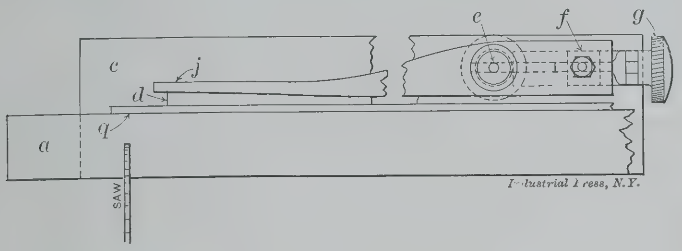

Fig. 4.

The tenons on the teeth must be a good fit in the mortises and all be alike. In driving them care must be taken to get them straight, which is not a difficult matter if the glue is properly used. The glue should be thin and used sparingly, a little good glue being much better than more, for any kind of work.

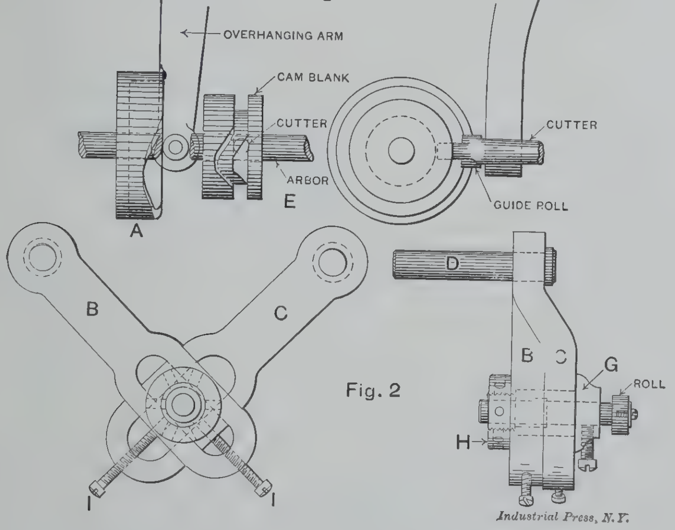
MILLING CAMS.

Editor Machinery:

The accompanying sketch and photograph show a very convenient method of milling the grooves in positive motion cams of the type shown at *E* in Fig. 1.

The guide *A* is a cup-shaped casting, the walls of which are about ¼ inch thick. Castings of these guides can be kept on hand and the grinding edge easily finished by hand for any cam required. In preparing the guide it is well to face the outer edge at the back so as to have a true surface from which to work when laying out the throws of the cam. If the circumference of the guide is divided into any desired number of divisions and the different distances measured endwise from the true edge, the cam can be easily laid out.

Fig. 1



Details of Cam Milling Fixture.

Having shaped the edge of the guide to the desired form, the guide and cam blank are put on an arbor and mounted on the index centers of a universal milling machine. The overhanging arm of the milling machine is fitted with a pin and guide roll and is set slightly to one side of the center of the spindle so as to bring the guide roll in contact with the edge of the guide. This guide roll is made long enough to allow the cutter to be fed into the cam the full depth of the grooves.

In operation the arbor with the form and blank is revolved by turning the index crank. At the same time the guide is held against the guide roll by moving the table of the machine. The cutter is fed, a little at a time, endwise into the cam blank.

I have found that a very convenient machine for doing this work is a vertical mill, or die sinking machine, provided with some means for holding the guide roll. The photograph shows a cam being cut by this method. As will be seen, the cam blank and guide are mounted on the same arbor, which is held on the index centers.

Fig. 2 shows the device which is used to hold the guide roll. It consists of two cast-iron arms, *B* and *C*, one of which, *C*, is offset to allow the end to pass under the end of *B*.

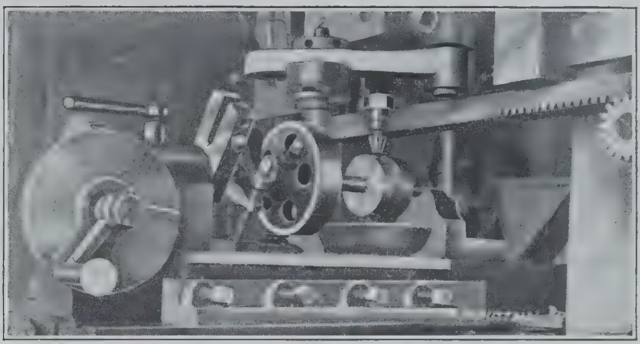


Fig. 3. Fixture Attached to a Milling Machine.

In the end of each arm is driven a pin, the projecting ends of which are fitted to the guide pin holes on each side of the spindle. Setscrews secure these pins when they are put in place. The outer ends of the arms are clamped together by the nut *H* and the bushing *G*, through which runs a pin carrying the guide roll. The setscrews *II* provide for locating and adjusting the guide roll.

I have found a two-lip mill to be the best for roughing out either steel or cast-iron cams, and it is sometimes the best for the finishing cut also.

MORE ABOUT FRICTION.

Editor Machinery:

In the August issue "Practice" discusses the reason for the deep center and shallow center and apparently proves his case. When it comes to the theory and practice of friction, however, there are some cases which keep a fellow guessing. Take modern locomotive practice and we find some peculiar features. The driving boxes carry from 18,000 to 25,000 pounds each, or in the neighborhood of 300 pounds per square inch of projected area. These boxes must have a good bearing nearly halfway round or there is trouble from heating.

The truck boxes of the same locomotive seem to be governed by a different law, but of course they are not. These carry perhaps 10,000 pounds each, but instead of having a full bearing on top of the axle there are two babbitt strips running lengthwise. These strips are usually one inch wide and spaced quite a distance apart. Take the projected area of these strips and we find it a pretty small amount, making the pressure per square inch run up pretty high. Yet these bearings run cool until the strips wear down so there is a bearing at the top of axle and box; then they heat. Why?

The tender truck boxes, on the other hand, have the regular full bearing the same as the car truck, and they run without much trouble, carrying heavy loads.

The driving box has to stand the thrust of the cylinder and requires the side bearing, while the top of the box carries the load. The truck or leading wheels have bearings almost all front and back, which takes the rolling thrust, but what carries the hood in the absence (practically) of projected area is something of a mystery.

I certainly do not believe that contact surface means friction in every case or a roller bearing would always have more friction than a ball bearing. As showing the tendency in this direction I may mention that the leading automobile builders are abandoning ball bearings in the wheels and other parts for long plain bearings.

Who has the right theory?

I. B. Rich.

MECHANICS IN THE COUNTRY.

Editor Machinery:

The firm for which I used to work once sold a second-hand threshing engine, and three or four days after, word came that the feed pump of the engine would not work, and "to send a man out at once to make it work." At this the Old Man said: "That is strange; it worked all right here when we tested the engine. We are very busy and I don't see how we can spare a man, but I will just go out myself and see what is eating those fellows anyhow."

He rode out on the train about 15 miles to a small town where a man and team were to meet him. At the station he found a man but no team. The man told him there would be a team and driver in pretty soon with a load of grain, and that they could ride out with him. After waiting some time the Old Man got nervous. He wanted to get home on the noon train. Finally he asked the man how far it was out to where they were threshing, and was told that it was just two and a half miles from the edge of the town. "Well," said the Old Man, "I can walk it if you can." So they started out. It was pretty warm weather and after walking about an hour the Old Man inquired if they were not almost there. "Do you see that little red schoolhouse on ahead there? Well, that is just half way." The schoolhouse appeared to be a mile or more ahead of them. They got to the place at noon and found most of the men at dinner.

Steam was down. The engineer and another man were putting water in the boiler. They had removed the safety valve, and were pouring the water in out of a bucket, whereupon the Old Man remarked that was a sure way to get the water into a boiler. They gave the Old Man a good "roasting" for letting a rig leave the shop when the feed pump could not be made to work, and wanted to know why he didn't send out a man who knew something about engines and pumps; Tom, the foreman, for instance.

The Old Man got a monkey wrench and started to examine the pump. The first thing he did was to open the suction valve, and under it he found a lump of coal large enough to keep the valve open all the time. He called the attention of the engineer (?) to it, but the engineer knew that was not the trouble. So the Old Man said: "Well, I will get my dinner while you get up steam, and we will see if that lump of coal was not the cause of the trouble."

On the farm were three or four crops of corn, plenty of stock and every indication of a prosperous farmer. That dinner, however, "cooked" the Old Man. They had "side meat" (Breakfast bacon) and fried eggs—fried to a crisp: biscuits as hard as hardtack and yellow with soda; dried apple pie sweetened with sorghum molasses; water-logged potatoes and coffee made from scorched wheat, with no sugar and skimmed milk. Even the women folks were mad about the engine not working and would hardly speak to the Old Man, who is generally a great favorite with the women.

But when the engineer got up steam he found that the feed pump worked all right. The crowd then got into better humor, and "guyed" the engineer a little; and the farmer hitched up his buggy and let his wife take the Old Man to town. He got home at 7.30 P. M. Had spent a whole day to take a piece of coal out of a check valve! What any schoolboy could have done in five minutes.

We once rebuilt an engine for a tile and brick factory. The front head was what is sometimes called a false head—held between the cylinder and frame, and quite a job to get at. Originally it had been ground in. The man who put the engine together in the shop had put in a paper gasket, and after the engine had run a short time complaint came to the shop that the front head was leaking. The Old Man, Josh and I went out to fix it. We went Saturday evening about 8 o'clock so as not to interfere with the work at the tile and brick factory. We had the tools necessary to do the work and some good packing to take the place of the paper, which had evidently blown out. We got the head out at about midnight; then the Old Man took a notion that he would like to have that head ground in again. We had not brought any emery, as we were not expecting to grind in the head. I asked the engineer if he had any emery or broken glass. He said: "No, but I have a piece of emery paper." "Well," said I, "bring it here, and also your fire shovel." "You can't grind in a head with emery paper," said the Old Man;; "let Josh go to the shop and get some emery." But it would have taken three or four hours to have gone to the shop and back, so I rolled up the paper and set fire to it. With the ashes we soon had a nice joint, and we got through in time for church next morning.

Decatur, Ill.

FORMULAS FOR BEVEL GEAR BLANKS.

Editor Machinery:

It is necessary when designing to know the outside diameter of gears; both, in order to be sure of a proper amount of clearance between them and a near-by shaft or wall, and also in order to detail the blanks.

For spur gears, every hand-book gives the following or similar formulas:

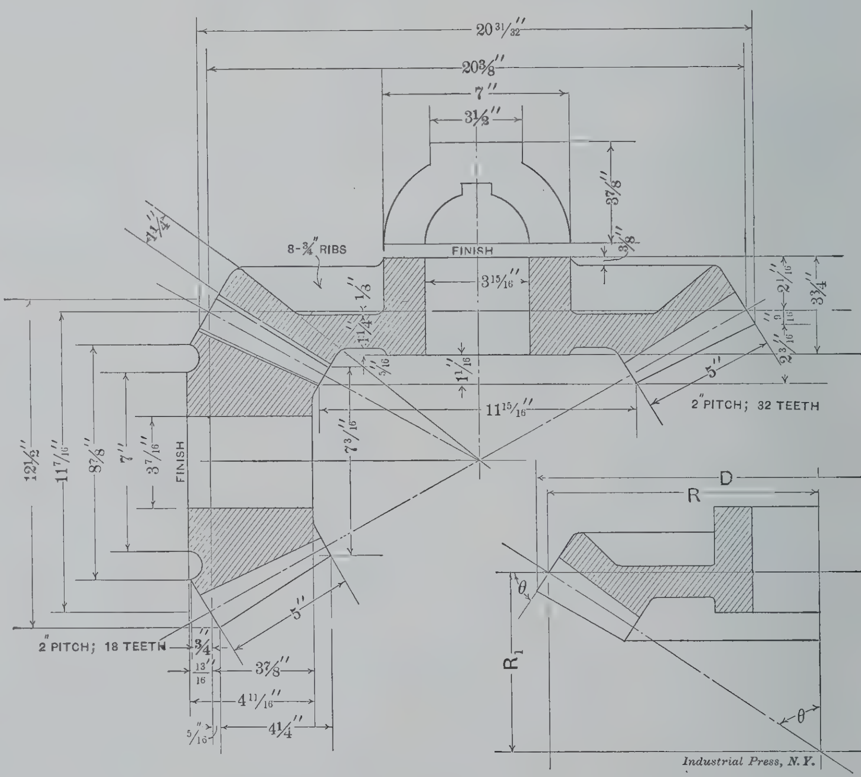

Diagram showing Method of Laying Out Bevel Gear Blanks.

Letting N = Number of teeth
P = Circular pitch
P' = Diametral pitch
d = Pitch diameter
D = Outside diameter.

We have:

$$D = d + .6\,P, \text{ and } D = d + \frac{2}{P'}$$

For a bevel gear, however, the designer, in order to know the outside diameter, must lay out the gear to full size and scale it up, as hand-books do not give any formulas for finding the desired diameter.

This is annoying as it requires the stretching of another sheet of paper and thus takes quite a little time. As a consequence the following formulas were deduced, to get rid of this difficulty and afford a quick method of arriving at the desired result:

R = One-half pitch diameter of required gear.
R_1 = One-half pitch diameter of meshing gear.
θ = Pitch angle.

Whence

$$D = d + .6\ P \text{ Cosine } \theta.$$

$$D = d + \frac{2 \text{ Cosine } \theta}{P'}$$

Or to avoid trigonometrical expressions:

$$D = d + \frac{.6\ P\ R_1}{\sqrt{R^2 + R_1^2}}$$

$$D = d + \frac{2\ R_1}{P' \sqrt{R^2 + R_1^2}}$$

The following (see the cut) is an actual case in which the above method was used, and may help to illustrate its use.

Bevel gear:

$d = 20.375$ inches.
$P = 2$ inches
$R = 10.1875$ inches
$R_1 = 5.719$ inches

$$D = 20.375 + \frac{.6 \times 2 \times 5.719}{\sqrt{103.8 + 32.7}} = 20.375 + .59 = 20\tfrac{31}{32} \text{ inches}$$

Bevel pinion:

$d = 11.4375$ inches
$P = 2$ inches
$R = 5.719$ inches
$R_1 = 10.1875$ inches

$$D = 11.4375 + \frac{.6 \times 2 \times 10\ 1875}{\sqrt{32.7 + 103.8}} = 11.4375 + 1.05 = 12\tfrac{1}{2} \text{ inches.}$$

A. E. H.

THE METRIC SYSTEM IN THE MACHINE SHOP.

Editor MACHINERY:

As the metric system of weights and measures seems to be making considerable progress in this country, it is a good plan for mechanics to become familiar with it so as to keep abreast of the times and so that if Congress should eventually pass a bill making the metric system compulsory after a given time they will be prepared for the change.

The chief objection to the metric system is really an objection to the present system of notation (the Arabic), which has 10 for a base. It is said that if the human race had been created with six fingers on each hand instead of five the base would have been twelve, and if they had neglected to count their thumbs the base would have been 8. Either of these numbers would have been better than 10, as they could easily be sub-divided a greater number of times. When France first used the metric system it was applied to divisions of the circle and time in astronomy and navigation, but this was found unpractical owing to the base being 10. The system was then confined to weights and measures, and has gradually been adopted by the various countries, and seems destined to become universal. The advocates of the metric system have probably been over-zealous in its cause, and, on the other hand, the opponents have said things against it that are not justified by fact.

But on the whole, the adoption of the metric system seems to be desirable, as our units of weight and capacity have no relation to those of measure, and other countries cannot use them in trade with us without considerable inconvenience; and we ourselves are put to a good deal of labor in reducing measures to a common denomination, which in the metric system would be very simple. For machine shop measurements, however, the English system is superior to the metric, because the foot and inch can be readily sub-divided into halves, quarters, etc.

There may be ways to obtain all of the advantages of the English system and still conform to metric units. Had the meter been made 40 inches long instead of about 39⅜ inches the metric system would probably have been adopted by English speaking people long ago, in order to have a universal standard. It is not likely, however, that the length of the meter can be changed by the countries using it. A meter contains 1,000 millimeters and 1000/40 gives 25 millimeters, which is nearly our present inch. Calling this one-fortieth meter, I would suggest a supplementary table of linear measurements for machine shop use as appended:

25 Millimeters = 1-40 Meter.
4 Fortieth Meters = 1 Decimeter.
10 Decimeters = 1 Meter.

This table would enable us to subdivide the one-fortieth meter the same as we do our inch at present. This would be of great convenience both in the drawing room and machine shop. The scales graduated into millimeters and centimeters are not so convenient for drawing purposes; one is rather too fine, corresponding to 1-32 of an inch; the next higher division, the centimeter, is 10 times as large, and in the machine shop to express fine measurements we use the fraction of the millimeter. For example: To make an allowance for a shrink fit for a shaft about 3 inches in diameter (which is about .006 inch) we would have about 8-50 of a millimeter. If the meter was divided into 40 parts our scales and micrometers could be graduated the same way as at present.

Ordinarily the decimeter need not be used, everything up to one meter being expressed in fortieth meters. This would be a better way of marking dimensions on drawings than feet and inches. Instead of using our two-foot rule the meter measure folded in four parts would make each part nearly 10 inches long, and if it was divided into 40 equal divisions and subdivisions, there would perhaps be fewer mistakes made and time would be saved in using it instead of the two-foot rule. The number 40 can be subdivided into halves, quarters and eighths, so that it is more convenient for subdivision than our dollar of 100 cents.

It is quite likely that the difficulty of changing to the metric system has been magnified. Of course there would be some extra labor in making the change. New measuring instruments would have to be procured, etc., but once the change was made we would get along in the shop the same as before. Much time would be saved in making calculations, estimates, etc., but the greatest benefit would be felt in our foreign trade, as our weights and measures would harmonize with those of the Old World, and England would be likely to soon follow us in adopting the system.

Now, supposing that in five years we were compelled to use the metric system as the only legal standard of weights and measures, what would be the result? This would give time enough so that we would be fully prepared for the change, and there ought to be very little trouble in making it. Probably before that time considerable new machinery would be designed and made to metric measurements. Machines already designed and on the market could be made from the same patterns and with the same tools as before. Standard screw threads and pipe threads would probably not be changed, as there seems to be no metric standard of screw threads used by the different countries, although one was recommended in 1898 by the International Congress for the Standardization of Screw Threads. This system was given in the supplement of MACHINERY for March, 1901. If it was required to cut metric screws the same lathes in use at present could use the same change gears by adding to the set translating gears. One inch = 127-50 of a centimeter; if we use two gears of 127 and 50 teeth for a compound it will enable the cutting of threads in terms of the centimeter instead of the inch. For example: Required to gear a lathe having a lead screw of 6 threads per inch to cut 4 threads per centimeter. 6-4 = 36-24. We could place the 36-T gear on the spindle or stud of lathe; 127-T gear as a follower or first gear on compound stud; the 50-T gear as the second driver, and the 24-T gear on the lead screw. It should be remembered that the 127-T gear should always be a follower, and the 50-T gear a driver. For some cases the compound need not be used, but a 127-T gear is always required to make an English pitch lead screw cut a metric thread, and it should be a follower or driven gear.

But if metric threads were to be the standard, metric pitch lead screws would be furnished with new lathes, and a lead screw of 4 millimeter pitch could replace the common lead screw of 6 threads per inch. Then the common change gears would answer as at present. For example: Required to cut a thread of 1¾ millimeter pitch, with a 4 millimeter pitch lead screw,

$$\frac{1\frac{3}{4}}{4} = \frac{7}{16} = \frac{28}{64},$$

and 28 on stud and 64 on screw would answer.

The changes to the metric system would, of course, first begin in the drawing room. Probably during the transition period both systems may be necessary for a while, as repairs on machines built on the English system may necessitate this. The change suggested with reference to dividing the meter into 40 parts would enable draftsmen's scales to be graduated the same way as at present. It would not be advisable to call this one-fortieth of a meter an inch, as it might lead to mistakes.

Of course the change to the metric system would necessitate new standard gages, tools, etc. Since the one-fortieth meter is slightly smaller than the inch the reamers, arbors, plug gages, etc., could be ground down to the new standard when it was not desirable to keep them for repairs on old machines.

East Providence, R. I. John T. Giddings.

A BEARING FOR OVEN-CARS AND DRAWERS.

Editor Machinery:

Sometimes it is necessary to have a bearing in a place where the varying temperature causes considerable trouble by expansion and contraction, if it is a closed bearing.

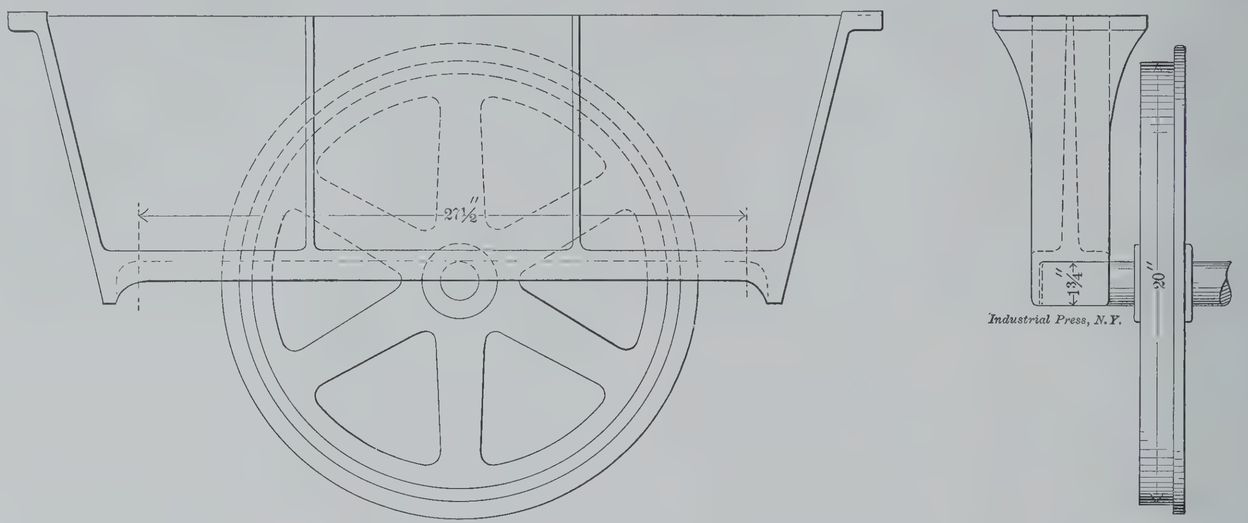

Fig. 1. Compound Wheel and Axle for Oven Cars.

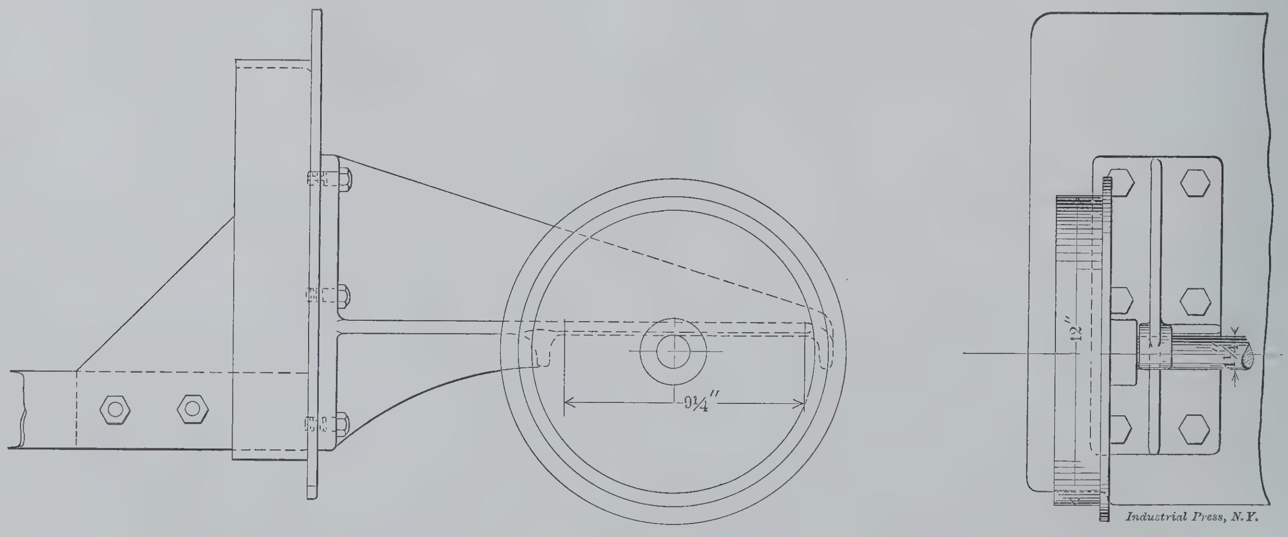

Fig. 2. Another Form of "Rolling Bearing" for use on Drawers.

We are planning a core-oven car and drawer (where the travel required is not great) to have a bearing like Fig. 1, which makes a combination for a car, and one like Fig. 2 for the back end of a drawer. The bearing surface is made long enough to allow for a little more than the distance covered by rolling the axle, which travels with the wheel, being fastened to it. A bearing 27½ inches long for a 1¾-inch axle rolling with a wheel 20 inches in diameter, will carry a car a distance of about 28 feet, and one 9¼ inches long for a 1¼-inch axle rolling with a 12-inch diameter wheel, will carry a drawer a distance of about 8 feet.

This bearing requires no oiling or cleaning. It shields the axle and if any dirt should get on the axle it falls off in revolving. The axle is kept in line by the face of the hub of the wheel for the drawer, and its (axle) end for the car, as can be seen by the sketches.

Taken altogether it makes a very practical bearing for this purpose. Both car and drawer move very easily, cost but little to fit up, do not need attention and are not affected by heat. Edwin C. Thurston.

Providence, R. I.

METHODS ADOPTED IN THE MANAGING OF A MACHINE SHOP.

Editor Machinery:

Having had charge of a shop where a great many duties were "up to me," I decided to relieve my mind as much as possible from unnecessary worry. With this point in view I took a large book about 8 inches by 14 inches with about 300 pages, and subdivided it as I saw fit. For instance, there were jobs continually coming up which were in no especial hurry, these I would jot down in the note book under the proper heading. If it was a job for machinists it would be put down under this heading; if for the office or blacksmith or patternmaker it would be noted in its proper place. Divisions were made in the book for every class of work throughout the shop. Whenever a man ran out of a job unexpectedly on my part I had but to refer to the book and start him off immediately. I made small cardboard pasters and marked them to correspond with the subdivisions in the book thus: "Machine Shop," "Office," etc., and pasted them where they belonged, with the name projecting about ¾ inch. This made it possible to turn right to the place desired without loss of time. The note book proved to be worth its "weight in gold." Each time a job was given to a man from the book a lead pencil line through the note showed it was "a dead one."

It was very necessary for me to refer to the material order books quite often. Finding this was very annoying and took a great deal of valuable time, owing to the fact the books used were ordinary duplicate order books, each order having its own number, I instructed the clerk to do as follows: Keep a record of each order on the front inside cover of the book as the orders were made out and when the book was finished transfer names and order numbers to inside back cover of book, but in a classified form, that is, alphabetically. This was a very easy matter when the book was completed. For instance, the order book ran from order No. 450 to No. 525, and the first order in the book was to Blank & Co., then it would be immediately jotted down in the front of the book. Say the next order was See & Bro., followed again by Blank & Co., etc. Then the columns would appear thus:

Blank & Co.,	450—452—456—
See & Bro.,	451—454—
Angel, A.,	453—
Doolittle & Co.,	455—

Then when, as previously stated, the list was classified and transferred to the back of the book, the above would appear in this manner:

Angel, A.,	453—
Blank & Co.,	450—452—456—
Doolittle & Co.,	455—
See & Bro.,	451—454—

From the foregoing it can be readily seen that with very little work it is possible to keep the order books in such shape that any order can be located at once at any "stage of the game." Pasters on the outside of books show the order numbers and dates thus:

Jan 1, '02. Feb. 4, '02.
450 — 525

Chicago, Ill. ROBT. A. LACHMANN.

LACING BELTS.

Editor MACHINERY:

Figs. 1 and 2 show a way of lacing or sewing a belt, which is not new but which has some good features that are often overlooked. I have found that a feed belt for a lathe or drill-press joined in this way lasts longer than any other style I have ever tried.

In making a splice of this kind care should be taken in laying out the holes to space them exactly the same distance apart and this distance should be the amount that will be generally cut off when the belt is taken up; or on a long belt the distance may be made half of this amount, and when the belt needs to be taken up, cut off one or two rows of holes as the case may be and punch new holes further back to match the other half. This kind of lacing is to be recommended for any place where a belt is kept very tight and gives trouble from tearing out the holes and breaking laces when laced in the ordinary way.

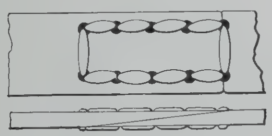

Fig. 1.

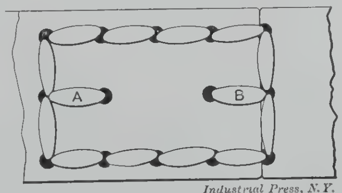


Industrial Press, N.Y.

Fig. 2.

The holes are made much smaller and a very small lace used, and is sewed together the same as a harnessmaker sews a piece of work, i. e., by drawing both ends of lace through the same hole at same time from opposite sides. The larger belt shown in Fig. 2 is done in the same way, except that the loops at *A* and *B* are used to keep the ends of belt down in place and are made with one end of the lace only. When this point is reached it is best, if there is any difference, to use the longest end of lace to make this loop.

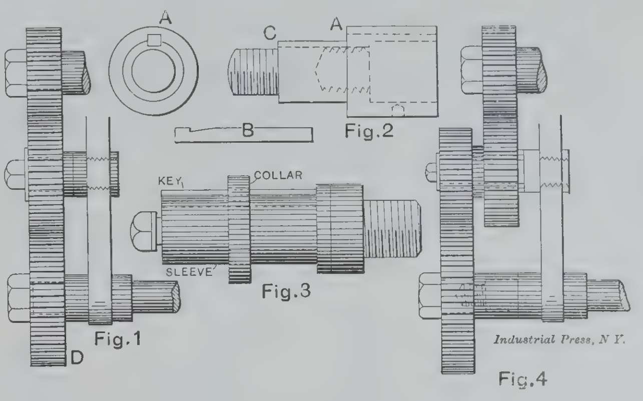
Watervliet, N. Y. M. H. BALL.

A COMPOUND GEARING ARRANGEMENT.

Editor MACHINERY:

Having a lathe which was single geared and desiring to increase its thread-cutting capacity, I arranged it for compound gearing, as shown in the accompanying sketches.

Fig. 1 shows the original gearing on the lathe, with which I could cut from three to 48 threads per inch. I removed the key from the end of the lead screw and in place of the gear *D*, shown in Fig. 1, I screwed on the extension shown in Fig. 2. A keyway was cut in this extension, so that the long key *B* extended from the end of the shoulder at *C* through *A* and into the keyway in the end of the lead screw. It thus locked the extension onto the lead screw and also provided a key for the gear *D*. The notch in the key is to facilitate its removal.



Industrial Press, N.Y.

Method for Compounding a Single-Geared Lathe.

In the place of the original intermediate stud I substituted the stud shown in Fig. 3. On this stud the gears were separated by the collar, while a key, running the entire length of the sleeve, made the gears run together.

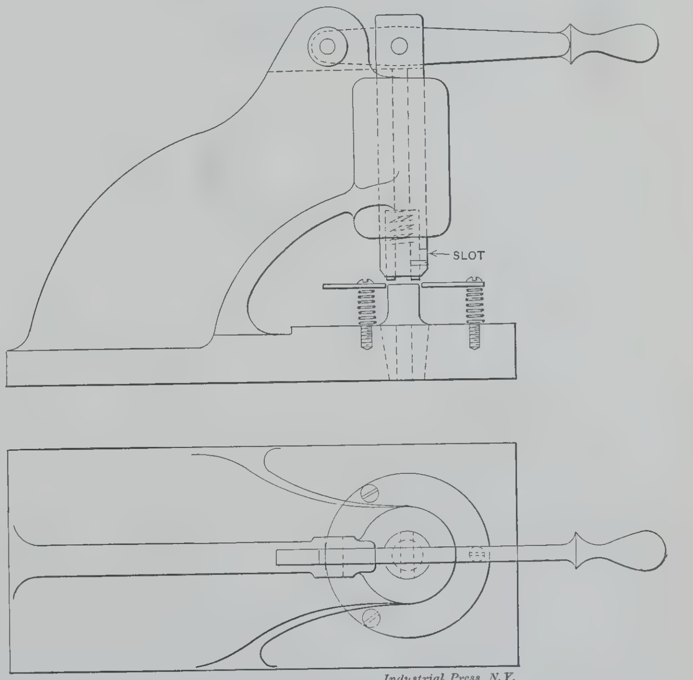
The complete arrangement is shown in Fig. 4. By making this alteration I am now able to cut from 1 to 144 threads per inch.

Meriden, Conn. JAMES P. HAYES.

PUNCH PRESS AND DIE.

Editor MACHINERY:

Accompanying this is a sketch of a small punch press and die for cutting washers from any kind of soft material. By the peculiar construction of the combination die a complete washer is cut at each stroke of the press. It also has the additional advantage of a quick and easy interchange of the various sizes of dies in the same press.



Industrial Press, N.Y.

Small Press for Punching Washers.

After the casting has been bored and reamed the taper hole in the base should be line-reamed with a reamer whose shank is a snug fit in the long ¾-inch hole. This will insure the absolute alignment of all punches and dies, without the necessity of clamping the die to the press. To obtain the best results both the punch and die should be ground all over; but some may think this an unnecessary refinement. On thick material, however, the hole in the die should be given a little draft to allow the punchings to drop through. It should not be excessive, though, as this will increase the size of the hole at each successive grinding.

I have obtained the best results on mica and fiber by leaving the die almost glass-hard. Because of the numerous small parts such as springs, screws, etc., it might be inferred that there is much repairing connected with the successful operation of the press; but I have found that this may be avoided by a little care in construction. The stock to be used need not be any particular size or shape and on small washers good results have been obtained by using scrap.

New York. H. J. Bachmann.

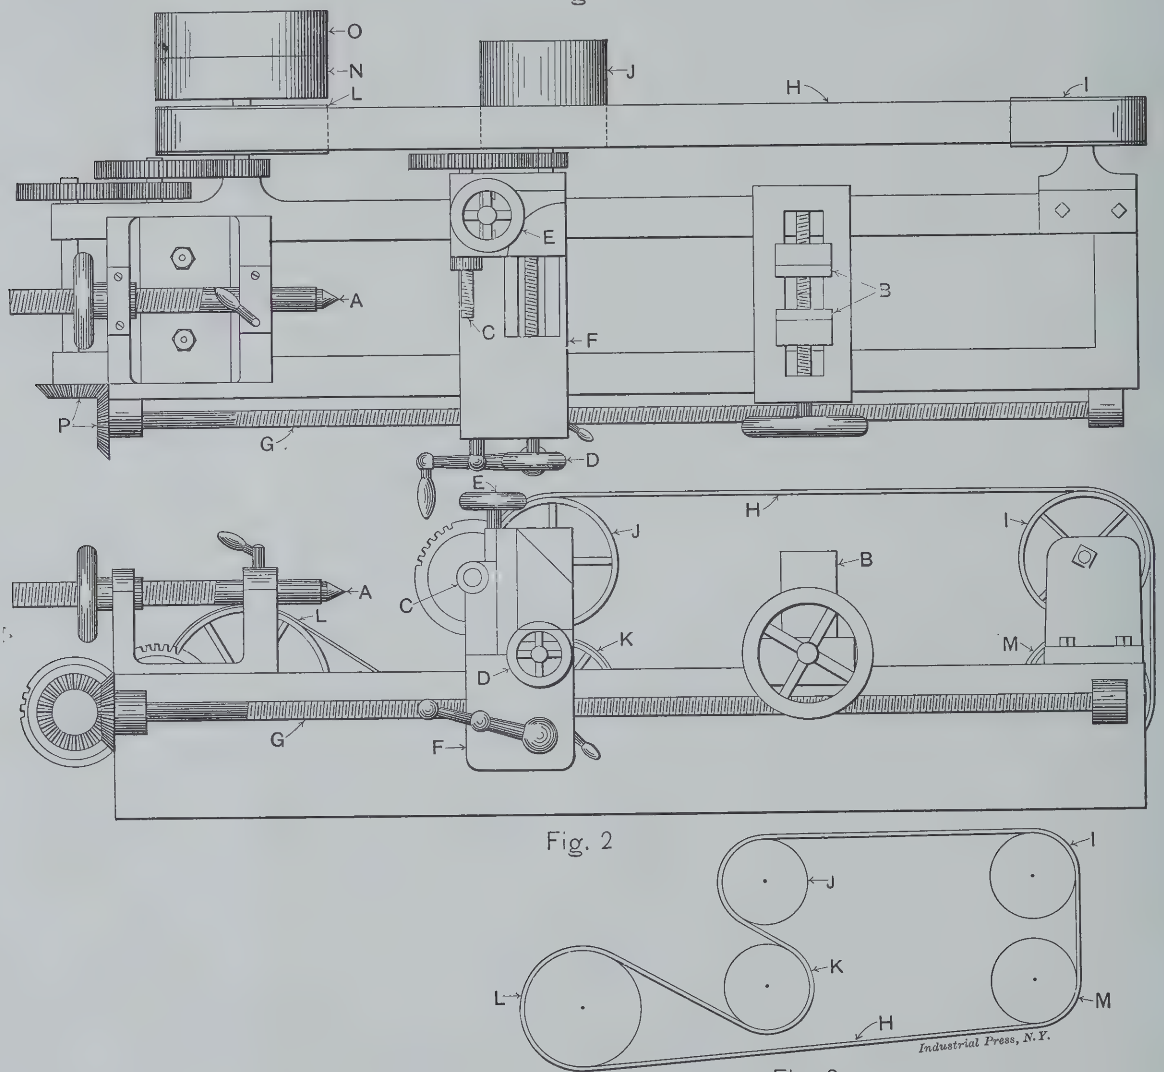

Fig. 3

Splining Machine made from an Old Lathe.

A HOME-MADE SPLINER.

Editor Machinery:

Fig. 1 shows the plan and Fig. 2 the elevation of a very serviceable splining machine which was made from an old lathe.

One end of the shaft to be splined is supported by the center *A*, while the other end is held in the chuck *B*. The keyway is cut by a milling cutter carried on the spindle *C*. Handles *D* and *E* with their feed screws provide for the adjustment of the cutter both centrally and vertically. The carriage *F* carrying the cutting mechanism is fed along the bed longitudinally, by the lead screw *G*, driven by the bevel gears *P*.

The machine is operated by a belt running on the tight and loose pulleys *N* and *O*, while the cutter is driven by the belt *H*. In order to maintain a constant tension in this belt, while the carriage travels from one end of the bed to the other, the pulleys are arranged as shown in the diagram, Fig. 3. As will be seen in the plan, the faces of the pulleys *J* and *K* are made of extra width so as to allow a liberal cross adjustment of the driving mechanism on the carriage.

Connersville, Ind. E. M. Burgess.

HOW A LONG JOB WAS DONE ON AN OLD PLANER.

Editor Machinery:

About ten years ago I had the pleasure (?) of occasionally using an old planer, one of the kind with but one belt and a return motion through gears. During the cutting stroke power was transmitted from the pulley to the table-rack through a train of eleven gears. The best of the bearings were worn not less than 1-16 inch loose and all the teeth (that were left) were worn to a knife edge, so there was quite a period of rest at the end of each stroke to take up the lost motion in the gears and bearings, and the motion of the table that followed was not unlike that of a tin can tied to a dog's tail.

The table was of the thin, flexible kind and had a piece three feet long spliced on at both ends, adding more to the length than to its stiffness, and often when I see a rainbow it reminds me of that planer table at the end of a long stroke.

One day an unusually long piece of work came in. It was so long indeed that I had to remove part of the scrap-heap to give the table room to travel. I got the work bolted on all right, but then my troubles commenced. The table, when near the end of its stroke, hung down badly and was so nearly overbalanced that the rack raised out of mesh with the bull-wheel. I hardly knew what to do; the job was not very particular, but with the table getting one end down and the other up in the air no job at all could be done. I wanted to get a pulley block over each end of the table and have ropes with weights to counterbalance the ends of the table when traveling in air, but nothing suitable for this arrangement could be found around the shop, so I had to resort to other means.

I found a piece of 1-inch x 3-inch iron and had the blacksmith give it a quarter twist. A stout pin was put through it near the bottom end and two turned cast-iron rollers were mounted on the pin, one on each side of the piece. The piece was bolted to the cross-rail, just alongside of the head. Then by screwing these rollers down tightly against the table by means of the cross-rail screws I succeeded in holding the table down on the ways and the rack in mesh with the bull-wheel until a fairly good job was done.

One good feature about this old planer, or at least one that helped some in this case, was its flexibility. The work was such that I could not keep the chips away from the rollers that held the table down, and when a handful would fall right in front of these I expected a smashup, but it was fun to see that cross-rail accommodate itself to the circumstances and allow the rollers to climb over the chips in fine shape.

There are still many of these old planers scattered through the country, and some of them still capable of producing good work when skillfully handled. But what *can* be done on a machine is not a measure of its usefulness in the shop; good work can also be done and has been done with chisel and file, but the time element is too important a factor to be ignored, and if these old-timers were placed in direct competition with modern heavy, stiff, quick-acting planers it would be an odd kind of a job indeed on which the modern tool would not prove a better investment than those made shortly after Noah's time.

The firm who owned the old planer mentioned above failed, as many firms with such equipments do.

In the August issue of MACHINERY Mr. J. T. Giddings advocates the use of formulas for finding speeds of pulleys and gears. I don't know how it may be with others, but I rarely resort to formulas for such simple calculations. I think Mr. Giddings would find that all these can be solved on the slide-rule in less time than it takes to solve by a formula.

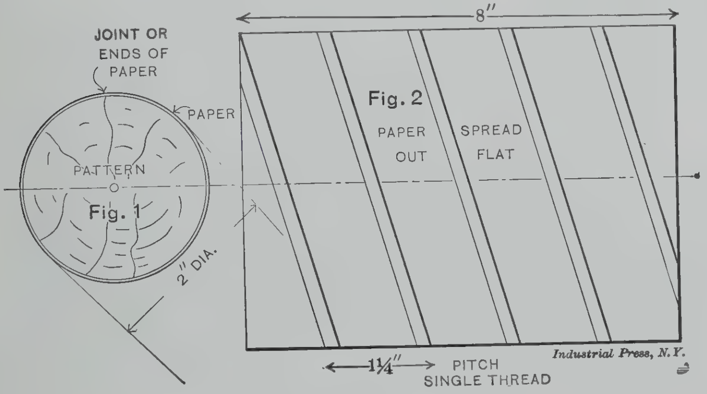
Grand Rapids, Mich. CORNEIL RIDDERHOF.

LAYING OUT A WORM GEAR PATTERN.

Editor MACHINERY:

A few days ago I was asked to make a small worm conveyor pattern, 2 inches in diameter, ¼ inch pitch and 8 inches long. I am sure that some of your readers will remark on reading this: "That's old; every patternmaker knows how to make a worm gear." Twenty years' experience and close observation have proved to me, however, that not one-half know how to *lay out* one, much less to make one. I will simply state my method of tracing the lines on the turned pattern. I have traced these lines with a flexible flat spring, also with paper cut to the pitch angle and by other methods in common use, but a better method in my estimation is the following: After turning the pattern to the required diameter, as indicated in Fig. 1, roll a piece of thin paper on the circumference. Now remove and pitch, and draw lines as in Fig. 2, then *glue to the pattern.* This gluing to the pattern is the "kink" that brings success.

"GLUE."



Laying Out Pattern for a Worm.

DEVICE FOR CUTTING OIL GROOVES.

Editor MACHINERY:

The accompanying sketches show a device, which I have used for cutting blind oil grooves in bearings, that may be of interest to MACHINERY readers.

Fig. 1 shows the bearing for which this device was designed, but it can easily be adapted to any style of bearing or used for grooving the hubs of loose pulleys.

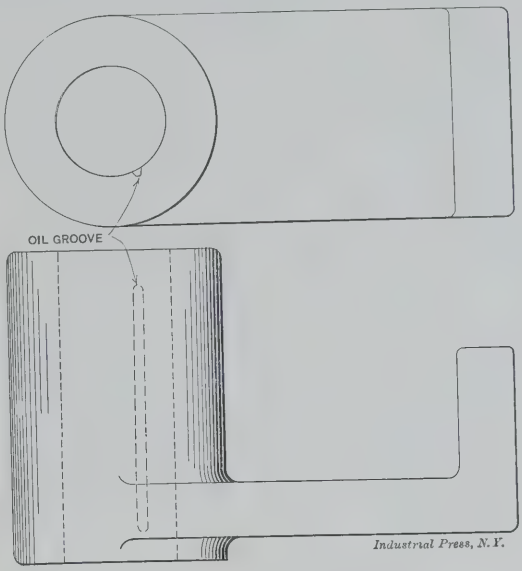


Fig. 1.

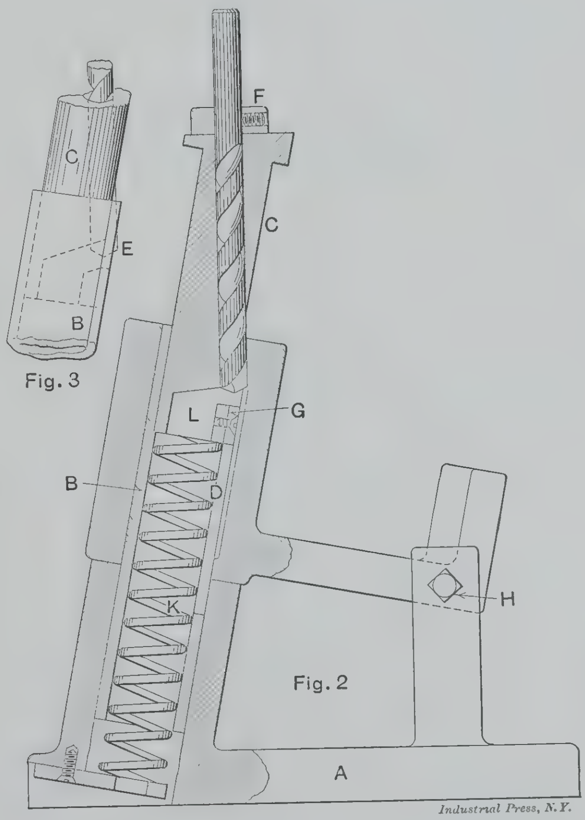
The base *A* has an inclined hub in which is forced the hollow bushing *B*, the outside diameter of which is the same as the hole in the bearing. Sliding in this bushing is the plunger *C* through which is drilled a hole perpendicular to the drill table. In one side of the bushing is a slot *D* through which the point of the drill projects a short distance, as shown at *E* in Fig. 3. This cuts the oil groove in the bearing. The amount that the point shall project, and consequently the depth of the oil groove, is regulated by the collar *F* which is held at the desired place on the drill shank by means of a headless setscrew.



Drill Jig for Cutting Oil Grooves.

The key *G* runs in the slot and prevents the bushing from revolving and also acts as a stop to prevent the plunger from coming out of the bushing. The shoulder at the top of the plunger serves as a gage for the depth of the oil groove.

To use the device, the bearing is slipped over the bushing as shown in Fig. 2. A lug and setscrew *H* serve as a gage to locate the groove at the proper place in the bearing. The drill is fed down through the plunger as far as the collar *F* will allow and then drill and plunger together are fed down through the bearing until stopped by the shoulder on the plunger. The base *A* is left free to slide along the drill table to provide for the change of position due to the inclination of the plunger.

When the drill is withdrawn a spring *K* returns the plunger to its original position. A hole *L*, drilled in the end and side of the plunger, allows for the escape of the chips. As the cut is very light the drill may be run at a high speed and rapid feed. Charles Thiel.

Lawrence, Mass.

TOOL FOR TURNING BALL BEARING RINGS.

Editor Machinery:

At a shop with which I was connected we were making pieces, as shown in Fig. 1, at the rate of 1,200 per day. They were ball race rings for use in the steering heads of cycles. It was necessary that the groove should finish perfectly smooth, which necessitated continual grinding of the tool. The first tool we tried consisted of a shank containing three loose cutters, with a ring and set pins to hold them in position. This worked very nicely as regards finish, and we used it for a considerable time. The loose cutters were cut at an angle as shown in Fig. 2. When made in this way they could be ground without losing their shape, which of course was absolutely necessary. To find anything to beat this for cheapness appeared somewhat difficult, but we have since made a tool that does beat it, not only in cheapness, but likewise in convenience of grinding and setting. When replacing the loose tools after grinding considerable time was wasted in resetting; it is obvious, that only a slight variation in the diameter of the groove would make a defective bearing, as the rings are used in pairs.

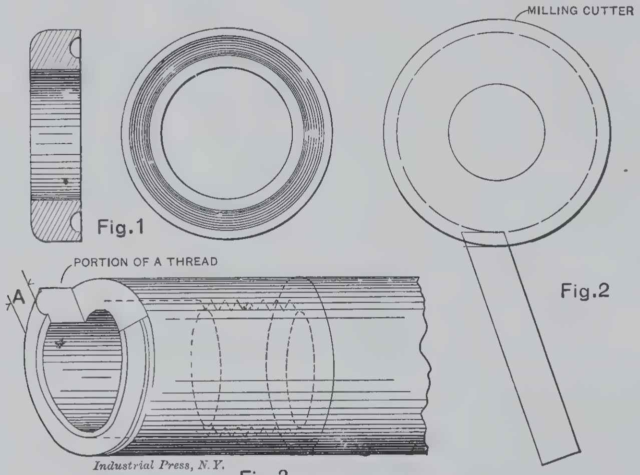


Fig.3

Formed Cutter for Annular Grooves.

The tool shown in Fig. 3 is so simple that it can be ground and reset by the operator, thus dispensing with the aid of a toolmaker. One of these tools has made as many as 6,000 pieces before it was worn out. After hardening, I find it necessary to grind about ⅛ inch off the cutting edge before using, owing to spring in turning tool, which causes the tool to run off at *A*, and so round the cutting edge, causing it to rub; in fact the first one I made would not cut at all through neglecting to do this.

Birmingham, Eng. J. C. Hafner.

SOME HINTS FOR DRAFTSMEN.

Editor Machinery:

Many draftsmen have a habit, and a very good one, of covering the drawing board at night. The majority use a sheet of paper for this purpose; the writer has found that a piece of table oilcloth forms the best covering, as it will not tear; it is heavy, therefore lies flat, and is cheap. In regard to the color to select, white is to be preferred, as dirt can be easily seen on it. To clean, just wipe the glazed side with a damp rag; the rough or unglazed side should be placed next to the drawing. For convenience and to prevent its cracking, tack a stick of wood at one end; it can then be rolled up when not in use.

Frequently a little drop of ink gets down to the edge of the tee-square; the draftsman sees it, and nine times out of ten he pulls his tee-square downward, with the result that he has a very beautiful ink spot ornamenting his drawing. To prevent this it is a good plan to take a slight shaving from the bottom edge of the blade of the tee-square. This can be readily done by scraping the edge with a piece of glass. Triangles may also be treated in this way.

In most cases where it is necessary to erase a small part of a finished drawing it cannot be done without erasing a number of other lines, which, of course, adds to the pleasure of the draftsman, that is, if he is a saint. If, however, the draftsman will take a piece of waste drawing paper and cut out an opening a trifle larger than the portion to be erased and place this over the drawing, then by holding it firmly in place with one hand, he may erase the portion without disturbing any of the other lines. When the part to be erased is circular the opening in the piece of drawing paper is best made by using the low dividers set to the proper radius and turning it around until the paper is cut through.

In regard to the stool used by draftsmen, the writer does not like those with a solid wood seat, as a lake is likely to be formed in the hollow by an innocent chap walking by with a wet sponge accidentally losing some of its water, much to the discomfiture of the owner of the stool when he sits down, and to the amusement of the other occupants of the room.

New York. Charles G. Peker.

AN IMPROVED SPANNER.

Editor Machinery:

The spanner shown in Fig. 1 may not be new to all your readers, but it is an improvement over the form shown in Fig. 2, which is the kind usually sent out with drill chucks, etc. The trouble with the old kind is its propensity to act as a lever with the fulcrum at *A*, in which case the hook *B* draws out of the notch so that the spanner slips off. In fact, it is not uncommon to see a workman using a bar or some near-by tool to hold the hook into its notch while the chuck is being turned. In the construction shown in Fig. 1 a hole is drilled into the handle into which a pin *C* is driven which will fit loosely into a hole in the chuck. In using this spanner it is necessary to push instead of pulling upon the handle.

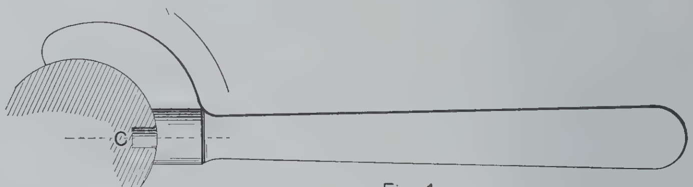

Fig. 1

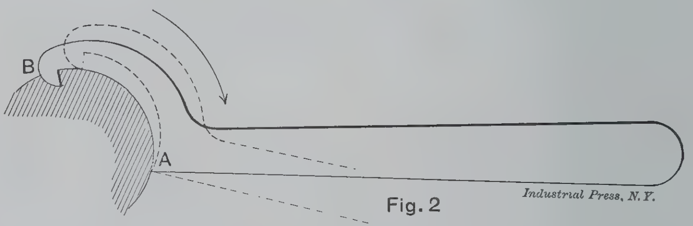

Fig. 2

* * *

Tests were conducted last May by the Automobile Club of America to determine the distance in which an automobile can be brought to a full stop by the application of the brake, when running at different speeds. Seventeen automobiles of different types were tested and their speeds were estimated by running them over a course of 1/10 mile. The average results as reported by the technical committee of the club, were as follows: Running at about eight miles an hour, the vehicles stopped at an average distance of nine feet; at a 15-mile speed the stop was accomplished in an average of 29 feet, and at 20 miles the average distance was 53 feet.

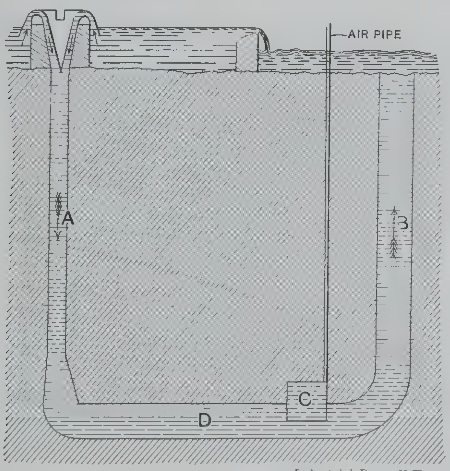
HYDRAULIC COMPRESSION OF AIR.*

METHODS OF COMPRESSING AIR BY FALLING WATER—THE EFFICIENCY OF THIS METHOD.

Probably one of the oldest applications of the use of water power to the wants of man was a form of hydraulic air compressor which operated as an entrainment apparatus. This was the well-known water bellows or trompe of the Catalan forges.

This apparatus, briefly described, consisted of a bamboo pole, disposed at a slight inclination from the perpendicular, into the upper end of which a stream of water was led, entraining air with it in its downward passage. The low end of this bamboo pole was introduced into a bag made of the skin of some animal, the air being allowed to escape from the water into the upper part of the bag, whence it was led by pipes or tuyeres to the forge, the water being allowed to escape from the lower edge of the bag. From this original device a great many improvements have been worked out, and besides this a number of other forms of hydraulic air compressors, or of compressors using other liquids for compressing air or other gases, have been designed.

One of the first inventions carrying out this idea was made by J. P. Frizell, Boston, Mass. His invention made use of an inverted syphon having a considerable horizontal run *D* between the two legs *A* and *B*. A stream of water was led into the upper end of the longer leg *A*, and at the top of the horizontal run *D* between the two legs of the syphon was provided an enlarged chamber *C* in which the air separated from the water. The water was then led off from the lower part of this air chamber and passed off through the short leg *B* of the syphon, the pressure of the air accumulated in the air chamber being therefore due to the height of water maintained in the shorter leg of the syphon. This application of carrying upward the water, after the air was separated from it, so as to produce a considerable pressure upon the air, seems to have been original with Mr. Frizell, and in this feature his device differs from the old trompe.



Industrial Press, N.Y.

Fig. 1. Frizell System.

Another device, Fig. 2, differing somewhat from that of Mr. Frizell, was invented by A. Baloche and A. Krahnass in 1885, and consisted of a syphon *B* carrying water from an upper to a lower reservoir, the lower end of the syphon being projected through an inverted vessel *R* placed nearly at the bottom of the second reservoir. Just beyond the bend of the syphon and in line with the axis of its longer leg, an air pipe *T* projected into the descending leg of the syphon. This entrained the air with the descending column and carried it down into the inverted chamber *R*, from which the air escaped at the top, while the water passed out from the bottom into the lower reservoir. This apparatus produced pressure on the air in the top of the inverted chamber, due to the height of the water column upon it.

Another device, Fig. 3, patented by Thomas Arthur in 1888, differs from the last in having a stream of water led directly into the top of the vertical pipe *A*. Inserted into the mouth of this pipe was a double cylindrical cone *C* forming an annular air passage between it and the walls of pipe *A*.

Owing to the increase in the velocity of the water in passing through the narrow throat of the double cone, air is inhaled through the pipe *D*, through the annular space mentioned and through perforations in the lower cone, and is entrained with the falling water.

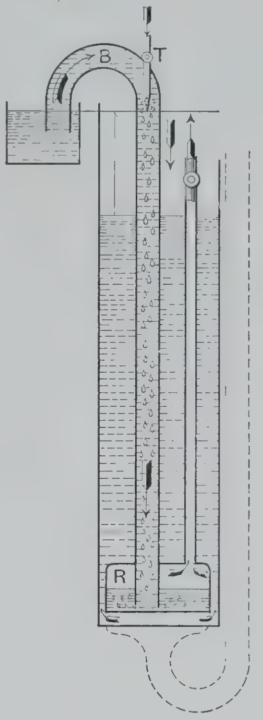


Fig. 2.

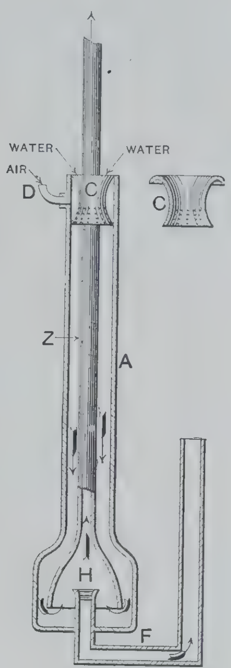
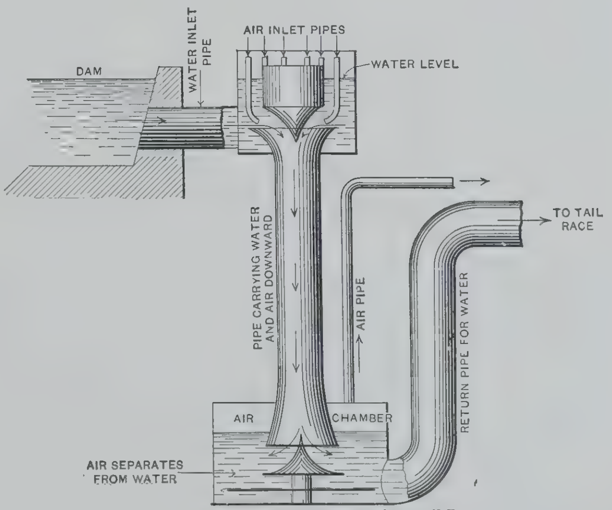


Industrial Press, N.Y.

Fig. 3.

Through the downflow pipe *A* rises a vertical delivery pipe *Z* for the compressed air, having its lower end *H* enlarged and open at the bottom. Projecting upward into this enlarged air-delivery pipe was a water escape pipe *F* through which the water passed after having parted with the air. The escape pipe was in the form of an inverted syphon and maintained on the air in the delivery pipe *Z* a pressure due to the elevation of the water at the discharge point above the air line in the large end of the delivery pipe.



Industrial Press, N.Y.

Fig. 4. Taylor System.

A number of other patents on apparatus of this type have been issued to Charles H. Taylor. His invention, Fig. 4, consisted principally of a downflow passage having an enlarged chamber at the bottom and an enlarged tank at the top. A series of small air pipes project into the mouth of the water inlet from the large chamber at the upper end of the vertically descending passage, so as to cause a number of small jets of air to be entrained by the water, Taylor seemingly having been the first to introduce the plan of dividing the air inlets into a multiplicity of smaller apertures evenly distributed over the area of the water inlet.

---

* From a paper by Wm. O. Webber read before the N. E. Cotton Manufacturers' Association.

The first of these compressors on the Taylor principle was installed at Magog, Quebec, to furnish power for the print works of the Dominion Cotton Mills Company. The head of water is 22 feet; the downflow pipe extends downward through a vertical shaft 10 feet square in cross section and 128 feet deep. At the bottom of the shaft the compressor pipe enters a large tank, which is known as the air chamber and separator.

A series of very careful tests demonstrated that with 19.5 feet head, using 4,292 cubic feet of water per minute, was recovered the equivalent of 1,148 cubic feet of free air per minute, which would represent 248 cubic feet of air per minute compressed to 53.3 pounds pressure, showing that out of a gross water horse power of 158.1, 111.7 horse power of effective work in compressing air was accomplished, giving therefore an efficiency of 71 per cent. In the tests at Magog 81 horse power was recovered, using as a motor an old Corliss engine without any changes in the valve gear; this would represent a total efficiency of work, recovered from the falling water, of 51.2 per cent.

When the compressed air was pre-heated to 267 degrees Fahrenheit, before being used in the engine, 111 horse power was recovered, using 115 pounds of coke per hour, which would equal 23 horse power. The efficiency of work recovered from the falling water and the fuel burned would be, therefore, about 61½ per cent. On the basis of Prof. Riedler's experiments, requiring only 425 cubic feet of air per brake horse power per hour, when pre-heated to 300 degrees Fahrenheit, and used in a hot air jacketed cylinder, the total efficiency secured would have been about 87½ per cent.

In what follows will now be given an estimate of the probable efficiency of different methods of using the power of a water fall. First are tabulated the results that it is reasonable to expect when using turbines and transmitting power by belts and shafting; second by electrical transmission from generators connected to turbines; and finally by an hydraulic air compressor. The compressor, it will be seen, gives the apparently remarkable result of over 100 per cent efficiency. This is due to pre-heating and moistening the air, however, and not to a reversal of mechanical laws.

Given horse power of water	1,000	horse power.
Wheels at 85 per cent efficiency	850	“ “
Shafting, pulleys and belts at 80 per cent	680	“ “

or a total net result of 68 per cent, wheels being at full gate and allowing the minimum loss for friction of shafting.

With wheels as usually run at part gate, the results would be as follows:

Given horse power of water	1,000	horse power.
Wheels at 75 per cent efficiency	750	“ “
Shafting, pulleys and belts at 50 per cent (average)	375	“ “

or 37½ per cent of the whole power; both of the above being directly at the site of the water power.

In order to transmit power to a distance, we must take again:

Horse power of water	1,000	horse power.
Wheels at 85 per cent efficiency	850	“ “
Generators at 92 per cent efficiency	780	“ “
Transformers at 92 per cent efficiency	720	“ “
Line at 95 per cent efficiency	680	“ “
Converters at 92 per cent efficiency	625	“ “
or about 62½ per cent of the whole.		
and direct connected with motors at 90 per cent efficiency	565	“ “
or 56½ per cent of the whole, or if belted at 90 per cent efficiency	508	“ “
say 51 per cent of the whole.		

By the use of an hydraulic air compressor:

Horse power of water	1,000	horse power.
Hydraulic compressor at 75 per cent efficiency	750	“ “
Pipe line efficiency at 98 per cent	735	“ “
Pre-heating dry air adds 50 per cent. Moistening dry air adds 50 per cent. = 100 per cent	1,470	“ “
Air engines or motors at 78 per cent efficiency or 114.5 per cent.	1,145	“ “
and if belted at 90 per cent efficiency or 103 per cent of the whole as a resultant effect.	1,030	“ “

To estimate the efficiency of hydraulic compressing, taking into account the water absorbed by the air and the coal used in heating the air, we have the following:

The weight of a cubic foot of compressed air at 85 pounds and at 70 degrees Fahrenheit, equals .58.

One thousand horse power would represent 750,000 cubic feet of 85-pound air per hour; this would equal 382,000 pounds of air, and as one pound of air will absorb .58 pounds of water, we would require 221,500 pounds of water per hour. The labor represented by forcing 221,500 pounds of water per hour, equal to 3,700 per minute, against 85 pounds pressure, equals 195.5 feet would be $\frac{195.5 \times 3700}{33,000}$ equals about 22 horse power, and as pumps give an efficiency of 50 per cent, equals 44 horse power of work by pump, or 4.4 per cent of the whole 1,000 horse power, this is therefore to be deducted: The coal used in heating the air, which is about one-half pound per horse power per hour, would also represent an amount of work equal to 75 horse power, or 7½ per cent of the whole 1,000 horse power. This added to the 4.4 per cent as above would equal an amount of 13 per cent to be deducted, equals 87 per cent of the whole horse power, or 1,030 × .87 = .896, or 89.6 per cent as a final result of all, as against 56½ per cent by electricity, or 68 per cent by water wheels at their best, or 37½ per cent by water wheels at the average.

That our results are within the bounds of reason is shown by the fact that 75 per cent × 98 per cent × 200 per cent × 78 per cent × 87 per cent = 99.5 per cent.

* * *

EVAPORATIVE CONDENSER.

Since the ordinary jet or surface condenser for steam engines requires anywhere from 20 to 40 pounds, or more, condensing water per pound of steam delivered to it from the engine, it follows that a type of condenser that consumes, say, only 6-10 pound of water per pound of steam should possess a considerable economical advantage where water rates are high. The July issue of *Power* contains a description of what is called an evaporative condenser in which a spray of water is drawn through the tubes of a surface condenser, together with a current of air, by a fan exhauster. The success of the device depends on the principle that the evaporation of one pound of water requires as many heat units as will be abstracted from one pound of steam when it is condensed, pressures being equal of course. So if a steam coil containing steam at atmospheric pressure (temperature 212 degrees F.) was sprayed with water, each pound of water evaporated on the exterior should in theory condense one pound of steam on the interior of the coil. In this device a portion of the heat is absorbed by the current of air and the unevaporated water. A test was made in Chicago of this condenser connected to a simple automatic engine 12½ by 20 inches running at 156 turns per minute for a period of 16 hours; steam pressure 90 pounds. The pounds of steam condensed was 24,010; total consumption of spray water, 48,000 pounds; less spray water returned, 33,600 pounds; actual amount of spray water consumed, 14,390 pounds.

* * *

The proper ratio of the diameter of a wire cable to the pulley sheaves over which it runs should be carefully observed if the maximum life of the cable is desired. Experience has shown that it should not be much less than one to forty where the cable is in constant use, as in elevators. This means that if the cable is one inch in diameter the sheaves should be forty inches in diameter or more. It makes no difference whether the cable makes a turn of 180 degrees or less, the stress on the cable is just the same so long as it is constrained to the curvature of the sheave for even a short arc of its circumference. To illustrate the effect of sheave diameter on cable life the experience of a writer in a contemporary may be mentioned. He found a plant in which two five-eighth-inch cables passed over an 18-inch sheave carrying a 700-pound counterweight. The factor of safety was thirty to one, yet the life of the cables was only two years. One-half inch cables were substituted, which reduced the factor of safety to twenty-five, but doubled the life of the cables.

CONTRIBUTED NOTES AND SHOP KINKS.

POINTING TOOL HAVING CIRCULAR CUTTER.

E. M. Lehman, Chicago, Ill., designed and used the pointing tool here shown, some ten years ago. The cutter is about two inches in diameter, which therefore gives about six inches of cutting edge that can be used and made dull before it is necessary to sharpen it. When one section of the cutting edge becomes dull, the cap screw is loosened and the cutter shifted around about 3-16 inch, thus bringing a sharp section into contact with the work, and so on around until the whole circumference is made dull.

PATTERNMAKERS' LATHE FACEPLATE.

Patternmaker writes: In pattern shops when making face plates it is common practice to take two or three boards 1¼ inch or 1½ inch thick, as the size may require, and screw the batten on back, as shown in the sketch. I go just a little farther and screw on segments of the same thickness as the batten shown at *B*. In this way you more than pay the cost when putting hand screws on work. It is annoying to find your hand screw must be put on just at the edge of batten, but with segments the back is even all round.

Lathe Faceplate.

COMBINATION ARBOR.

Robert A. Lachman, Chicago, Ill., had occasion to cut several steel pinions 4 P. and 17 T. Some of the pinions had straight holes and others taper holes. Most of the machines for which the pinions were made required two with straight holes and one with a taper hole, all being of the same diameter. Some of the machines, however, required all three pinions to have straight holes. It was desirable that the three pinions required for each machine be cut at the same setting so an arbor was made that would carry two straight-hole pinions and one taper hole, or three pinions having straight holes. The pinions were bored and faced on one side while in the chuck and the other side was faced while mounted on an arbor so that the combination arbor shown here was used only for turning the external diameter in the lathe and cutting the teeth in the gear cutter. The cut shows how a straight-hole pinion was mounted on the part of the mandrel intended for pinions having taper holes. A ring *D* was made ¾ inch thick and bored to fit the straight part of the mandrel which had been turned back of the thread. The external diameter of the ring was made the same as that of the mandrel. In this manner the end pinion was supported at both ends in a satisfactory manner. The short distance cut away from the taper bearing did no harm, as there was ample bearing left for supporting the taper hole pinions. The collar *E* was turned to the same diameter externally as the bottoms of the teeth spaces so that it could be used for setting the cutter before mounting the pinion blanks on it. This obviated all chance of error in depth of tooth space when making the setting.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published

1. Connecticut. What is the best method of reboring the boxes of engine lathes; can they be bored on the ways better than some other way? The lower half of back boxes have a screw in them to take up the end motion of spindle. 2. What is the usual allowance for making shrinking fits, as in shrinking on collars, etc.? Is it advisable under any circumstances to cool with water? 3. Small lathes are often made so that the back bearing is formed by the end of spindle running in a steel bushing (tapered usually); which should be hardened, the end of spindle, or the bushing, or both?

A. We judge from the first inquiry that you have several lathes, the main bearings of which have become worn and are to be rebored. We prefer to mount the headstock on ways and then bore with a rotating bar arranged to feed through the work, as in the case of the bar of a horizontal boring machine. If the boring is to be done on a lathe, however, such an arrangement is not easy to rig up. You might find it feasible to bore the bearings with the headstock in place. We would like to have readers submit suggestions for doing the work. 2. Allow .002 inch per inch diameter. Yes, cool with water; otherwise the center will become hot and will not cool until after the outside parts have cooled. When the center finally cools it will then contract and the fit may be destroyed. 3. When both the spindle and its seat are of steel, both should be hardened.

2. Subscriber. Please explain a method for finding gears to cut worms in a lathe to mesh with worm gears of diametrical pitch. 2. How can I find the angle of the teeth of worm gears other than by laying it out on paper? I want a method that can be used in a shop where there is no drawing to go by.

A. To start with the simplest case, suppose it is desired to cut a worm to mesh with a worm wheel of one diametrical pitch, and that the lathe has a lead screw with one thread per inch, or a screw of one inch pitch. The circular pitch of one diametrical pitch gear is 3.1416 inches, and a very close approximation to this decimal is the fraction 22—7. The worm, therefore, must have a pitch of 3.1416 inches, or 22—7 inches. This fraction, 22—7 should be memorized, as it is the only number that one need have at hand in making change gear calculations for worm threads. In the lathe mentioned the lead screw would advance the tool one inch for every revolution of the screw and would thus have to turn 3.1416 times to advance the tool 3.1416 inches. In other words, the lead screw should turn 3.1416 times as fast as the worm which is being cut. As the fraction 22—7 is equivalent to 3.1416, this result would be accomplished with a 22-tooth gear on the stud and a 7-tooth pinion on the lead screw, or gears in this ratio, say, 44 on stud and 14 on screw. Now suppose that instead of a lead screw of one thread per inch there was one with three threads per inch. The screw would then have to turn three times as fast as before, to accomplish which the gear on the stud should be three times as large, or else the gear on the screw three times as small as before. The gearing should be in the ratio, therefore, of 3 × 22—7, or 66—7. If the lead screw had four threads per inch the gearing should be in the ratio of 88—7, and if six threads, in the ratio of 132—7. Assume, finally, that it is desired to cut a worm of some pitch other than one, say, to mesh with a worm wheel of four diametrical pitch. The threads of the worm would then be four times as near together as before and the lead screw should turn only one-fourth as fast. The gear on the lead screw could thus be four times as large as in the first example, or the gear on the stud four times as small. With a three-pitch lead screw the gearing should be in the ratio of 66—28; with the four-pitch screw, 88—28, and with the six-pitch screw, 132—28. If a worm for a six-pitch worm wheel were desired, then for the three cases the gearing would be in the ratio of 66—42, 88—42 and 132—42, respectively. Of course it is understood that these fractions may be reduced to their lower terms, in order to reduce the size of the gears. Thus, for a three-pitch lead screw and four-pitch worm we found the ratio 66—28, but it would be more natural to select gears 33 and 14 instead, which bear the same ratio as the others. The foregoing calculations apply only to lathes in which the spindle and lead screw make the same number of turns with equal gears. Where the spindle turns faster or slower than the lead screw, with equal change gears, allowance must be made for this. With compound-geared lathes the simplest plan is to use equal intermediate gears and to put gears on the stud and screw, as calculated above. 2.—The simplest plan is to lay out the angle, even in the shop, as it is very easily done with a scale and try square. In making the calculation, reference must be had to a table of natural tangents. Divide the circular pitch of the worm wheel by the pitch circumference of the worm. The quotient will be the tangent of the angle made by the tooth with the axis of the gear. Where a worm gear is hobbed it is not necessary to have this angle; but if a spur gear with inclined teeth is used for the worm gear, it of course is necessary.

* * *

NUTS FOR CLAMPING BOLTS—PLANER JIG.

The nuts shown in Fig. 1 are samples of clamping bolt nuts used in the shops of the Cincinnati Planer Co. for planers and boring mills. This style of nut replaces the old-fashioned T-head bolt and is said to have many advantages over it. It may be moved along the slots to any point desired and used in connection with a common machine bolt or cap screw. It does not break away the edges of table slots and clamping bolts used with these nuts may be loosened up without the work jumping out of place, as has been the experience of many of us with the common T-head bolts. It also gives a more secure hold, as it has a longer and more rigid bearing in the table slot.

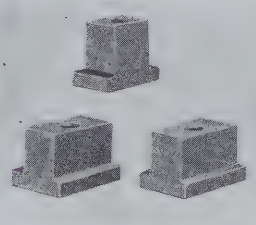

Fig. 1.

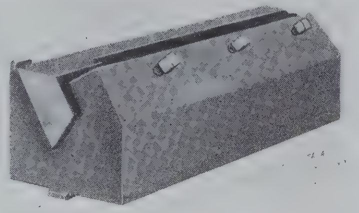

Fig. 2.

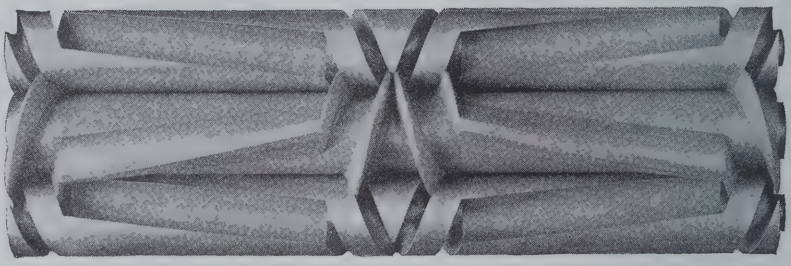
Another good scheme used in the same shops, is a simple and efficient jig for planing the edges of dovetailed strips to 30 degrees angle without swiveling the planer heads. The pieces are first planed top and bottom to the required thickness and then the edges are planed in this jig. The slot in the jig is planed out to the required angle so that the upper edge of the piece to be planed is parallel to the planer table. Fig. 2 shows a short piece in a jig ready for planing. Three set screws are provided for clamping it and a lug acts as a stop to take the pressure of the cut off the screws. There is a height gage to which the planer tool is set for finishing. All work planed in this jig is sure to be exactly of the same angle and size.

* * *

HIGH-SPEED HELICAL GEARS.

The Boston Gear Works, Boston, Mass., are devoting a great deal of attention to the construction of gear wheels to run at extremely high speeds. All of their gears for high-speed work are of metal instead of rawhide or fiber so extensively used for this purpose. While metal gears have obvious advantages over those of softer material, they must be made with great accuracy to run smoothly at high speed; otherwise the impact of the teeth makes the gears noisy. The Boston Gear Works advocate some form of helical gear and they are prepared to manufacture either spiral gears or gears of the herring-bone type which will run quietly at extremely high speeds. These gears, however, must be cut with great care and their experience is that the index arrangement supplied with standard milling machines is not accurate enough for the purpose. A first-class spur gear cut by a modern gear-cutting machine with its large dividing wheel will run with less noise than an ordinary spiral or herring-bone gear, cut on the milling machine, and spaced with its small index plate.



A Set of Three Helical Gears to Run at 5000 Revolutions a Minute.

The style of herring-bone gear recommended is one with the teeth making a much less angle (usually about 10 degrees) with a line parallel with the axis of the gear than in the old style herring bone gear having teeth usually at about 45 degrees with this line. The accompanying illustration shows three special helical gears designed for speeds of 3,000 to 5,000 revolutions per minute. These gears are for special work, of the nature of which we are not informed, except that it was necessary to have three shafts running very near together. The gears have only two teeth each and the angle made by the spiral with the axis of the gear is very small. Gears with two teeth will not run together, however, unless the faces of the gears are long enough for the spiral teeth to make about half a revolution from end to end of the gear and thus engage in the opposite tooth before the first pair of teeth are out of mesh. In this case the angle of the spiral is so small that the faces of the gears would have been excessively long under this condition. The difficulty was overcome by having the angle of the spirals change abruptly at the ends of the teeth so that there is always some portion of each tooth that is driving, no matter what position the gears are in. The difficulty in matching the ends of the teeth where the angles at the center converge and those at the ends diverge, as in this case, can well be appreciated, especially where the gears must run at such high rotative speeds.

* * *

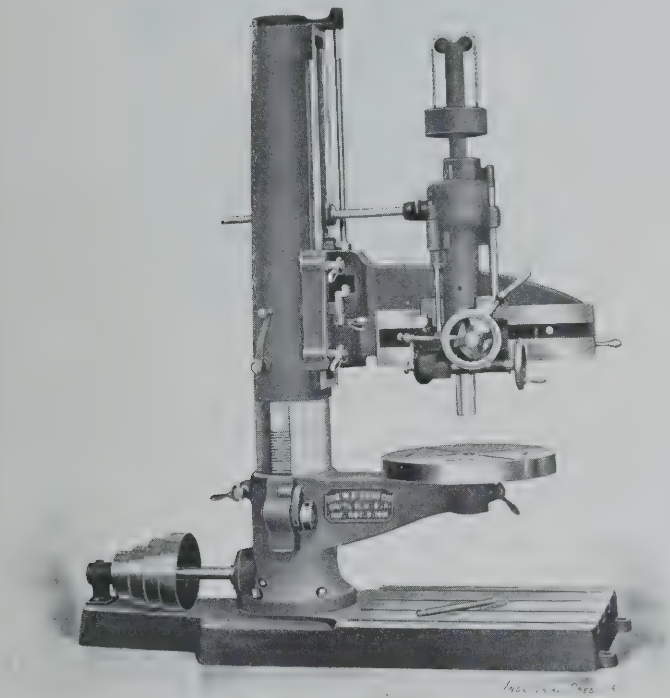
For the purpose of getting the approximate volume of a sphere, it is usually near enough, for the purpose of a rough estimate, to say that it is equal to one-half that of a cube having edges of the same length as the diameter of the sphere. Thus to get the cubic contents of a sphere 3 feet in diameter, multiply the diameter by itself two times and the result by ½; the final product, 13½ cubic feet, is the approximate volume. Thus, 3×3×3×½=13½ cubic feet. The actual volume is 3×3×3×.5236=14.1372 cubic feet.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

IMPROVED RADIAL DRILL.

We illustrate herewith an improved radial drill built by the Wm. E. Gang Co., of Cincinnati. This is a machine unique in some of its features and well adapted to the requirements of an every-day shop tool. The frame parts are well proportioned, and as evidence of their stiffness it may be mentioned that the seat of the round table is faced off with an inserted tooth mill 9 inches in diameter, fed to its cut by means of the regular gear traversing mechanism, consisting of rack, pinion and hand wheel.



Radial Drill made by the Wm. E. Gang Co.

The lower end of the column is turned to fit in the stump, allowing the arm to swing through a complete circle on its ball bearing. The upper end of the column has a flat seat for the arm, is planed with dovetail flanges at the edges of the arm seat, and back of these again are flat seats for the clamps, which hold the arm in position and also take up any wear incident to raising and lowering the arm. Two screws with handles attached, working in nuts beveled to fit the edges of the arm seat, both clamp the arm and align it vertically. Any tendency to spring the column in clamping the arm is overcome by fitting a square gib in the opening provided for vertical movements of the horizontal driving shaft.

The arm is of box section, well ribbed, and is raised and lowered by means of a stationary screw, a revolving nut and tumbler gears, the movement being controlled by the small lever shown directly between the clamping screws. The head is provided with an ample number of feeds by hand or power, a quick return movement for spindle, and is traversed along the arm by means of rack, pinion and the handwheel at the front.

To concentrate all heavy stress of driving at the spindle three large gears—for ordinary drilling, for heavy boring and tapping, and for reverse in tapping—are placed directly on the spindle. The back gears are just behind them. The upper part of the head is made to entirely surround these driving gears, thus eliminating all attached bearings, affording an excellent protection to the working parts and insuring the workman against injury. A lever at the right of the head enables the operator to quickly start, reverse, connect or disconnect the back gears.

A friction feed is provided and any desired change is obtained instantly by turning the knurled knob at the left of the head.

Any one of four styles of table—a round table, a plain square table, a plain swiveling table, or a worm swiveling table—can be furnished with this machine.

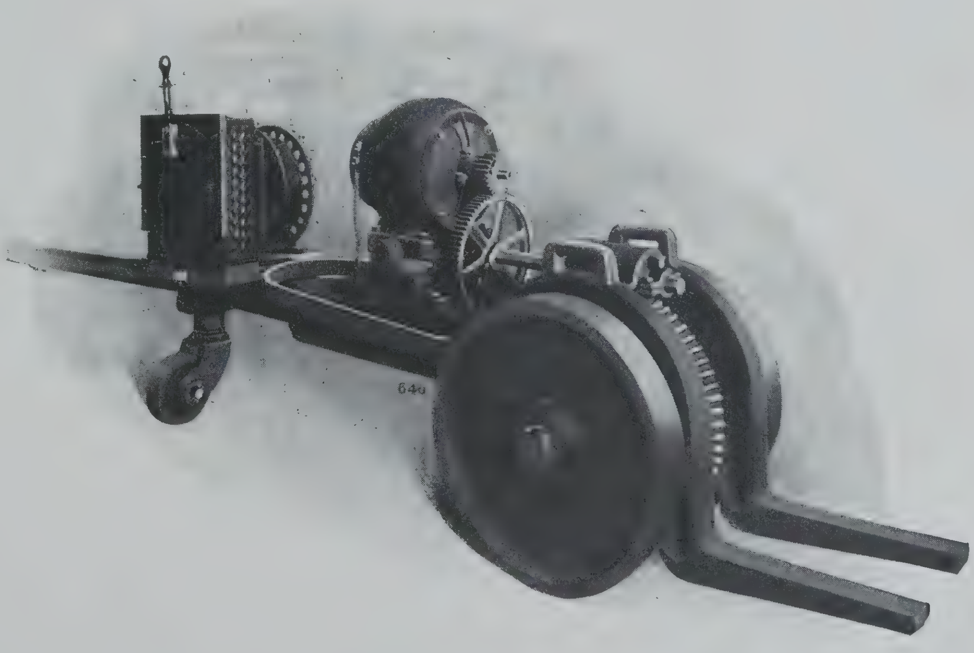
The base is so designed as to give ample strength and stiffness, to provide ample working surface and to occupy no unnecessary floor space.

The machine is provided with eight rates of spindle speed. Others may be added to cover special cases.

NOVEL FOUNDRY TRUCK.

The Northern Electrical Mfg. Co., Madison, Wis., have brought out an electrically-driven foundry truck, shown in the accompanying illustration. The first one of these was built for use in a malleable iron foundry. The old method of placing pots containing the castings in the ovens and taking them out again was an expensive and troublesome operation, requiring from six to twelve men. To remedy this, they equipped the truck here illustrated.

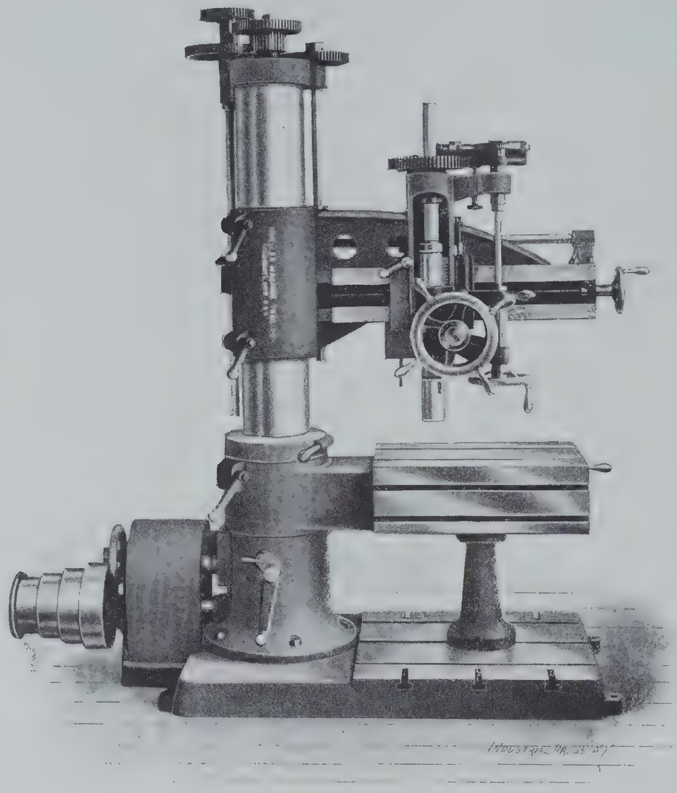
This consists of a "Northern" back-geared motor connected to the truck shaft by means of a worm and gear. On this shaft are mounted the two truck wheels that are keyed fast to the shaft. The forks on the truck are mounted on an eccentric, the eccentric being operated by a lever that is shown between the motor and the controlling apparatus. By raising this lever the forks are dropped down low enough to be shoved in underneath the pot of castings, and by pulling the lever down to the position shown in the cut, the pot of metal is raised. On the front end of the truck is mounted a reel that contains the wire that is paid out automatically as the truck is operated back and forth in the oven. On one side of the reel is mounted a reversible controller that operates the motor. This equipment is so compact and complete that one man can do the work of twelve in a great deal less time than by the old method.



Electrically-driven Foundry Truck.

A NEW TWO AND A HALF FOOT RADIAL DRILL

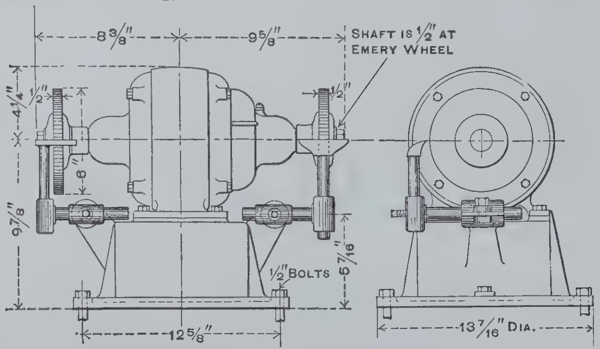
The illustrations here shown are of a new type radial drill, brought out by the Mueller Machine Tool Co., Cincinnati, Ohio. This machine has a pipe-shaped column clamped directly to a heavy well-ribbed base, thereby insuring the utmost rigidity for the arm and work spindle. The arm is supported by a top cap, resting on steel balls and both revolve easily around the column. By shifting the lower crank to right or left, and by the use of a cone pulley, twelve changes of spindle speed are instantly obtained without stopping the countershaft. These twelve speeds are equally divided between the maximum and minimum revolutions of the spindle.



Radial made by Mueller Machine Tool Co.

The lower driving shaft is the only one in motion when the spindle is not used, a feature that prolongs the life of the machine.

A depth gage reading from zero is on the head, which enables the operator to stop the spindle at any point, or it can be set to automatically throw out the feed at a certain depth. A safety stop prevents automatic feeding beyond the limit of the spindle's stroke. A single lever in front of the column operates a pair of friction clutches, and controls all starting, stopping, reversing, as well as elevating and lowering of the arm at an increased speed. Any amount of feed per revolution of spindle between .007 and .021 can be instantly obtained by a small friction wheel on the head. All tightener handles are fitted on cone-shaped screws, and by loosening the nut in front they can be set to clamp at any point in case of wear. The usual quick return to spindle and tapping device are also provided for.

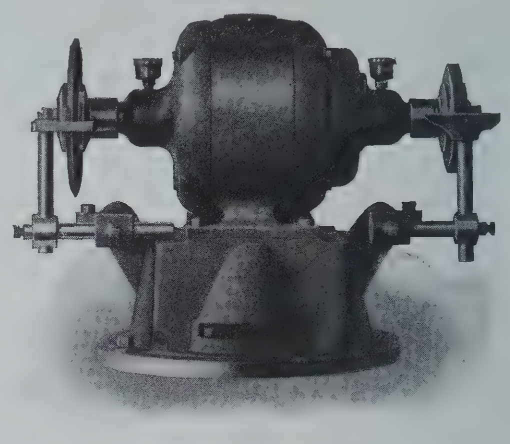


View showing Dimensions of Bench Grinder.

The net weight of machine is 3,000 pounds. It was designed by Mr. Oscar W. Mueller, formerly of the firm Dreses, Mueller & Co.

"LITTLE BADGER" GRINDER.

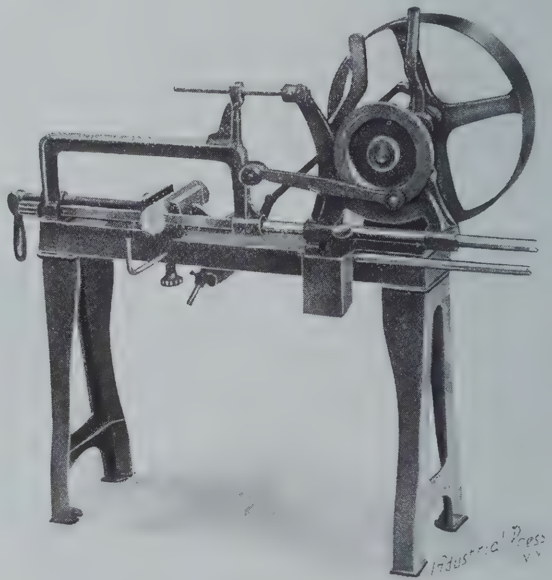
The "Little Badger" grinder shown herewith is a bench grinding machine that has been placed on the market by the Northern Electrical Mfg. Co., Madison, Wis. The dimensions are shown in the line cut, and it will be noted that it is so small that it can be easily set wherever convenient on the bench. The base is heavy enough to keep it from tipping even if not bolted down, while the machine is light enough to be readily portable. The motor is entirely enclosed and is dust-proof. Tool rests are arranged for grinding either on the face or side of the wheel. The bearings are provided with suitable lubricating devices; there is a take-up for wear and end thrust is provided for. An automatic cut-out switch is placed inside the stand, with which to stop and start the motor.



Electrically-driven Bench Grinder.

RAPID-CUT POWER SAW.

The cut herewith shows the improved rapid-cut power saw manufactured by the Robertson Mfg. Co., Buffalo, N. Y. This machine is strong, well made and will cut hard or soft metal up to 4½ inches, round or square. The saw frame is hung in a swinging carriage frame, and the action of the crank automatically relieves the drag of the saw on the return stroke, and thus the saw cuts faster and lasts longer.



Power Saw Cutting Thin Disks from end of a Bar.

The sliding balance weight enables adjustment to be made with the greatest ease for the hardness of metals. The movement of the frame is so true in line with the crank that the full stroke of saw allows the cut to be made with no friction on the saw other than that due to the set of teeth. One hundred and fifty-four cuts have been made of a 2-inch round steel bar with one saw, slicing them off 1-32 inch thick; and, for a test, cuts less than 1-64 inch thick have been taken, perfectly parallel.

When the saw has completed a cut the machine automatically stops. The frame when raised for the next cut is locked by a gravity locking lever, a most convenient device to apply to this type of machine.

The drive pulley is provided with a clutch, a countershaft not being required. The machine is furnished with a stop gage for cutting a number of pieces the same length. The floor space it occupies is 15x34 inches; the height of the machine is 34 inches; the size of pulley, 2½ by 14 inches; the length of stroke, 6 inches.

NEW MODEL MILLING MACHINES.

The Becker-Brainard Milling Machine Co., Hyde Park, Mass., have placed upon the market a new line of plain and universal milling machines from new designs and patterns. These machines, one of which is here illustrated, embody many new features, special attention being given to strength, power and rigidity in order to meet the demands of modern milling machine practice.

In the universal machines the spindle is connected with the change feed mechanism by a train of three spur gears, which eliminates the usual feed pulleys and belt, giving the positive gear drive necessary for heavy and rapid cuts.

The change feed mechanism obviates loss of time in changing gears. The feed is obtained and driven by the main spindle through a train of three spur gears on the back of the machine which drive two nests of change feed gears in the column. By compounding the gears in the upper nest, the various changes of feed are secured, giving, with the quick change in the gear case on the outside of the machine, twenty changes of feed for each spindle speed. Levers, operating the change feed mechanism, are conveniently located on the side of the feed box. All changes may be made by the operator without stopping the machine or changing his position, by the simple movement of the levers, which brings them into the position indicated on the index plate. This index plate has each feed plainly marked on its surface, showing the exact position to which the levers must be brought to give a desired feed per revolution of the spindle. For example, if a feed at the rate of .017 per revolution of the cutter is to be obtained, lever *B*, shown by the cut, is placed in the notch 3 on the lower quadrant *C* and then the lever *A* is brought to the line marked 3 opposite the space .017 on the index plate. The quick-change lever *D* on the lower side of the feed box is then moved to the hole marked "slow" and the desired speed is obtained. Should it be desired to increase the feed, lever *A* is moved so as to point to the line at 3 prime (marked with a dash below) on the index plate and .019 is obtained. If the feed is to be decreased lever *B* is moved to notch 4 on quadrant *C* and .013 is obtained. When the fast feeds are desired, the quick-change lever *D* is thrown into the hole marked "fast" and the same operation performed as described above.

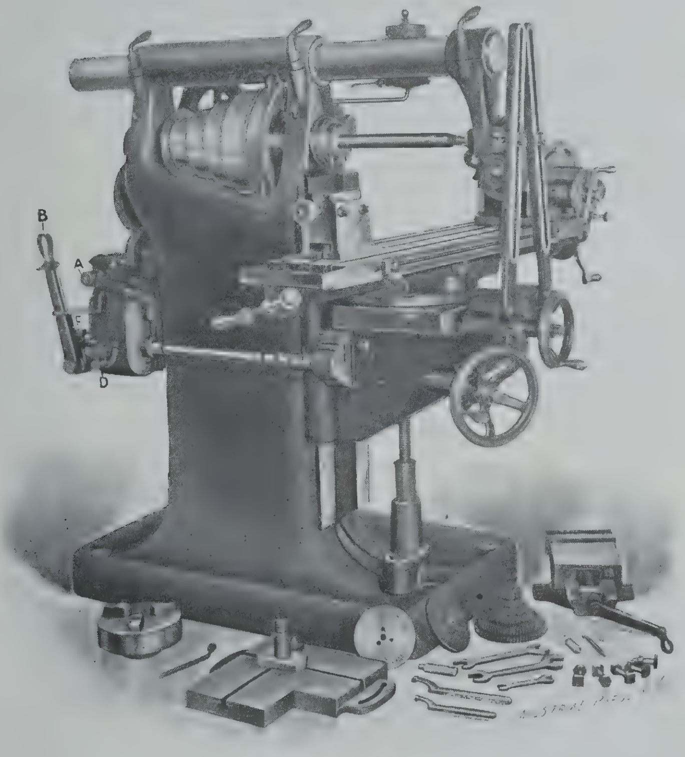


Fig. 1. Becker-Brainard Milling Machine of New Design.

Power is transmitted from the change feed mechanism through the telescopic shaft connecting by gears the longitudinal, transverse and vertical feeds, which are reversed by a lever on the side of the knee. Both transverse and vertical feeds are operated and controlled by a lever, located on the side of the knee, which, when central, disconnects both feeds and when thrown into position for one feed it is impossible to connect the other.

An important feature is a clutch arrangement enclosed in the hubs of the handwheels which operate the vertical movement of the knee and cross movement of the carriage. When either the knee or carriage has been set to the required position, the clutch may be instantly disengaged by pressing in the knob on the front of the handwheel, thereby preventing any accidental change from their fixed position and also preventing the handwheels from revolving when the automatic feeds are thrown in.

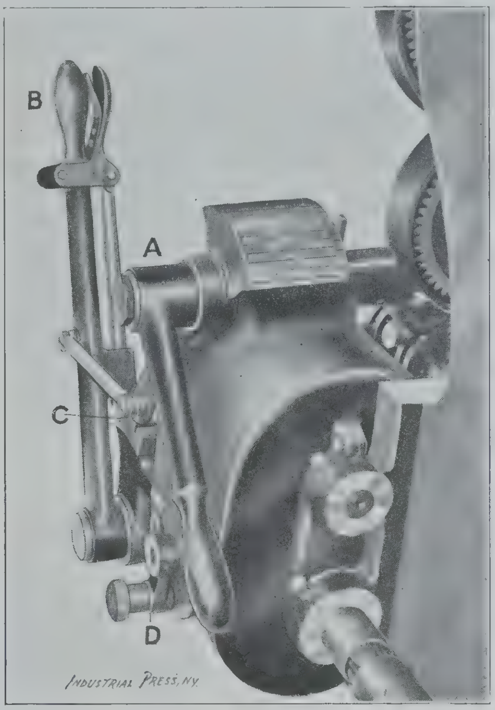

Fig. 2. Feed Box of Becker-Brainard Milling Machine.

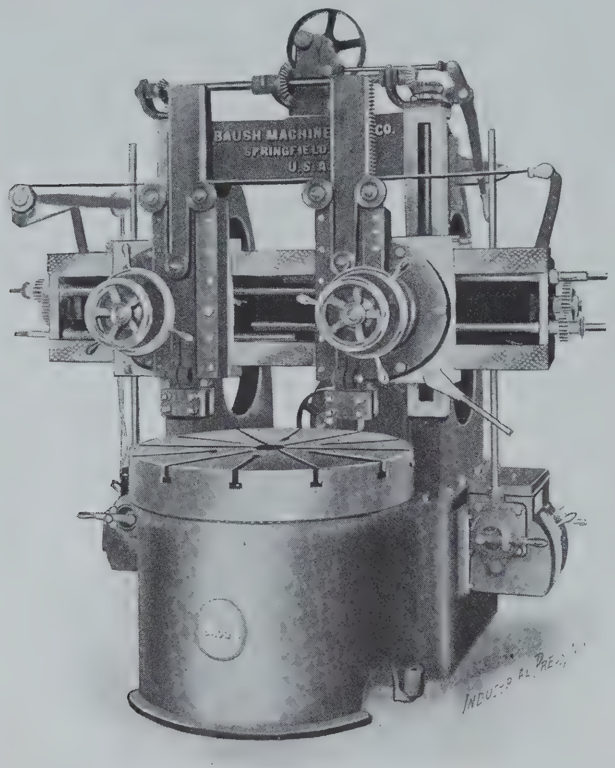
The knee, which is of the box type, provided with a telescopic elevating screw, makes holes in the floor unnecessary and allows the machine to be placed regardless of beams or foundations. The thrust of the screw is taken by ball-bearings.

The base of the machine is very solid, thereby absorbing vibration. The arm is a straight steel bar, so that any of the regular attachments can be placed in position without the necessity of removing the arm.

BORING AND TURNING MILLS.

A line of boring and turning mills in sizes 37, 41, 51, 54 and 61-inch is now manufactured by the Baush Machine Tool Co., Springfield, Mass. All sizes of the machines are equipped with a number of devices, making them well adapted for the rapid production of all classes of work within their capacities. The illustration accompanying this description is of the smallest or 37-inch size. All the mills have independent feeds operated by a device on the Hendey-Norton principle. In the 37-inch machine there are 15 changes, ranging from 1-64-inch to 9-16 vertical and from 1-64 to ⅞-inch horizontal, per revolution of table. A change from one to the other can be made almost instantly without stopping the mill. The heads can be operated independently of each other and by means of a split nut and rack and pinion can be moved back and forth very quickly. The cross rail is raised and lowered by power, the pulley being placed in the center. It is started and stopped by a lever, and the pulley is belted from below. The table can be removed and replaced by an independent or a universal chuck. It has an outer bearing with a self-oiling device which keeps it constantly lubricated. The main bearing is large and long with a hole through the center to allow the chips to pass through to the bottom of the mill without clogging, from whence they can be removed. Arrangements have been made so that the mills be driven by a motor by removing the cone and bearing and attaching the motor to the bed. The back gears are so located that they can be thrown in and out by means of a lever, without the use of a lock nut.



Thirty-seven inch Boring Mill—one of a New Series.

IMPROVEMENTS IN THE GOULD & EBERHARDT SHAPER.

Gould & Eberhardt, Newark, N. J., are applying an improved sleeve cone support to their shapers and other machine tools, which is designed to overcome the evils arising from an overhanging cone without outer bearing support. The cone *C*, Fig. 1, is supported on a sleeve bearing *B* and drives the shaft *A* through the clutch flange *D*. Connection is made between the cone *C* and the flange by means of taper pins, the pins being a tight fit in the flange and an easy fit in the cone. By employing this mode of construction the stress of the driving belt is carried entirely by the rigid sleeve journal, which is bolted by means of a flange to the side wall *E* of the shaper or other machine to which it may be applied. The driving shaft having only to transmit the torsional stress incident to driving the machine, the wear on it is reduced to a minimum, which insures the proper meshing of the driving gears indefinitely. With ordinary attention in the matter of lubrication this bearing should outlast the machine. All parts of the sleeve bearing are cast iron.

Fig. 2 shows a shaper to which the improved cone support has been applied. This machine also embodies a number of other improvements of interest. The connecting-rod to the cross feed has a friction slip joint by means of which it automatically adjusts itself to the correct length when the table is raised and lowered. The friction joint also prevents breakage of the feed gears should the feed become blocked by accident or by the carelessness of the operator.

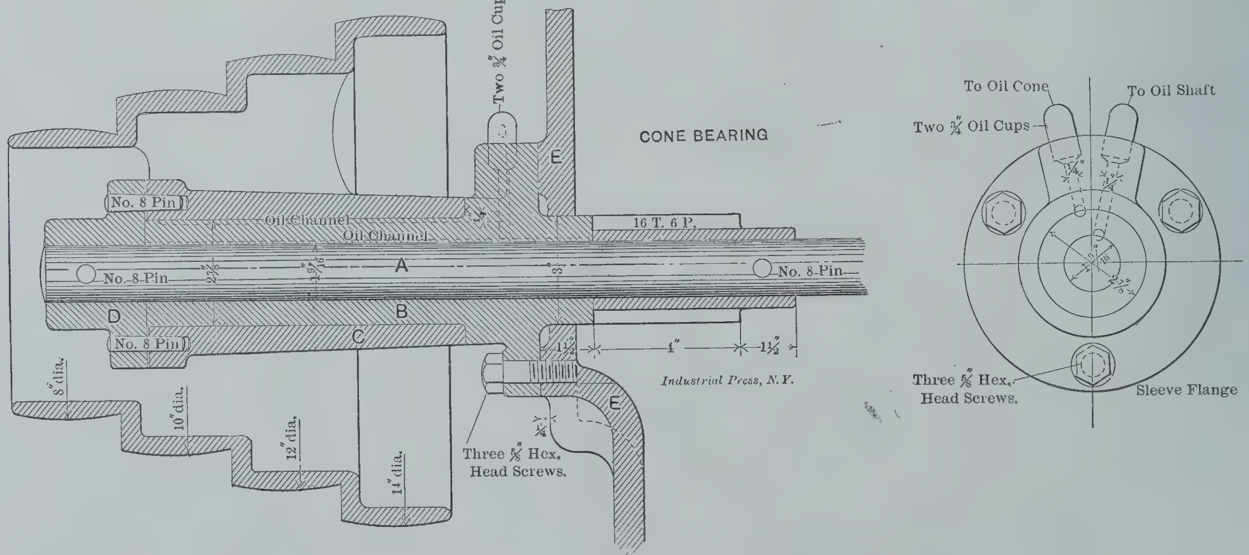


Fig. 1. Sleeve Support for Cones and Pulleys.

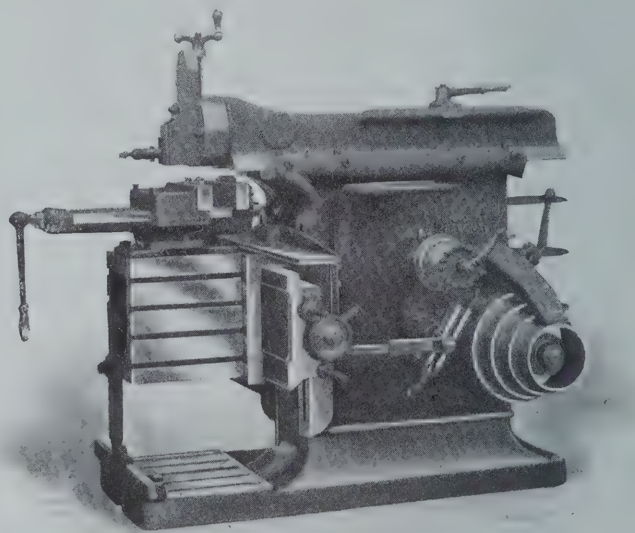

Fig. 2. Improved Gould & Eberhardt Shaper.

An arm projects over the cone, which bears numbers cast on the top corresponding to the different steps. These indicate the proper speeds for different lengths of stroke. All oil holes are provided with filter covers, which prevent the ingress of dirt, chips, etc., and filter all lubricant fed to the bearings. All the bearings are bushed where the wear is likely to become appreciable, so that all shafts may be readily brought back to their original centers. The other features, such as striking place on vise, stiffened ram, vertical graduations on vise, etc., which distinguish this tool, have been described before.

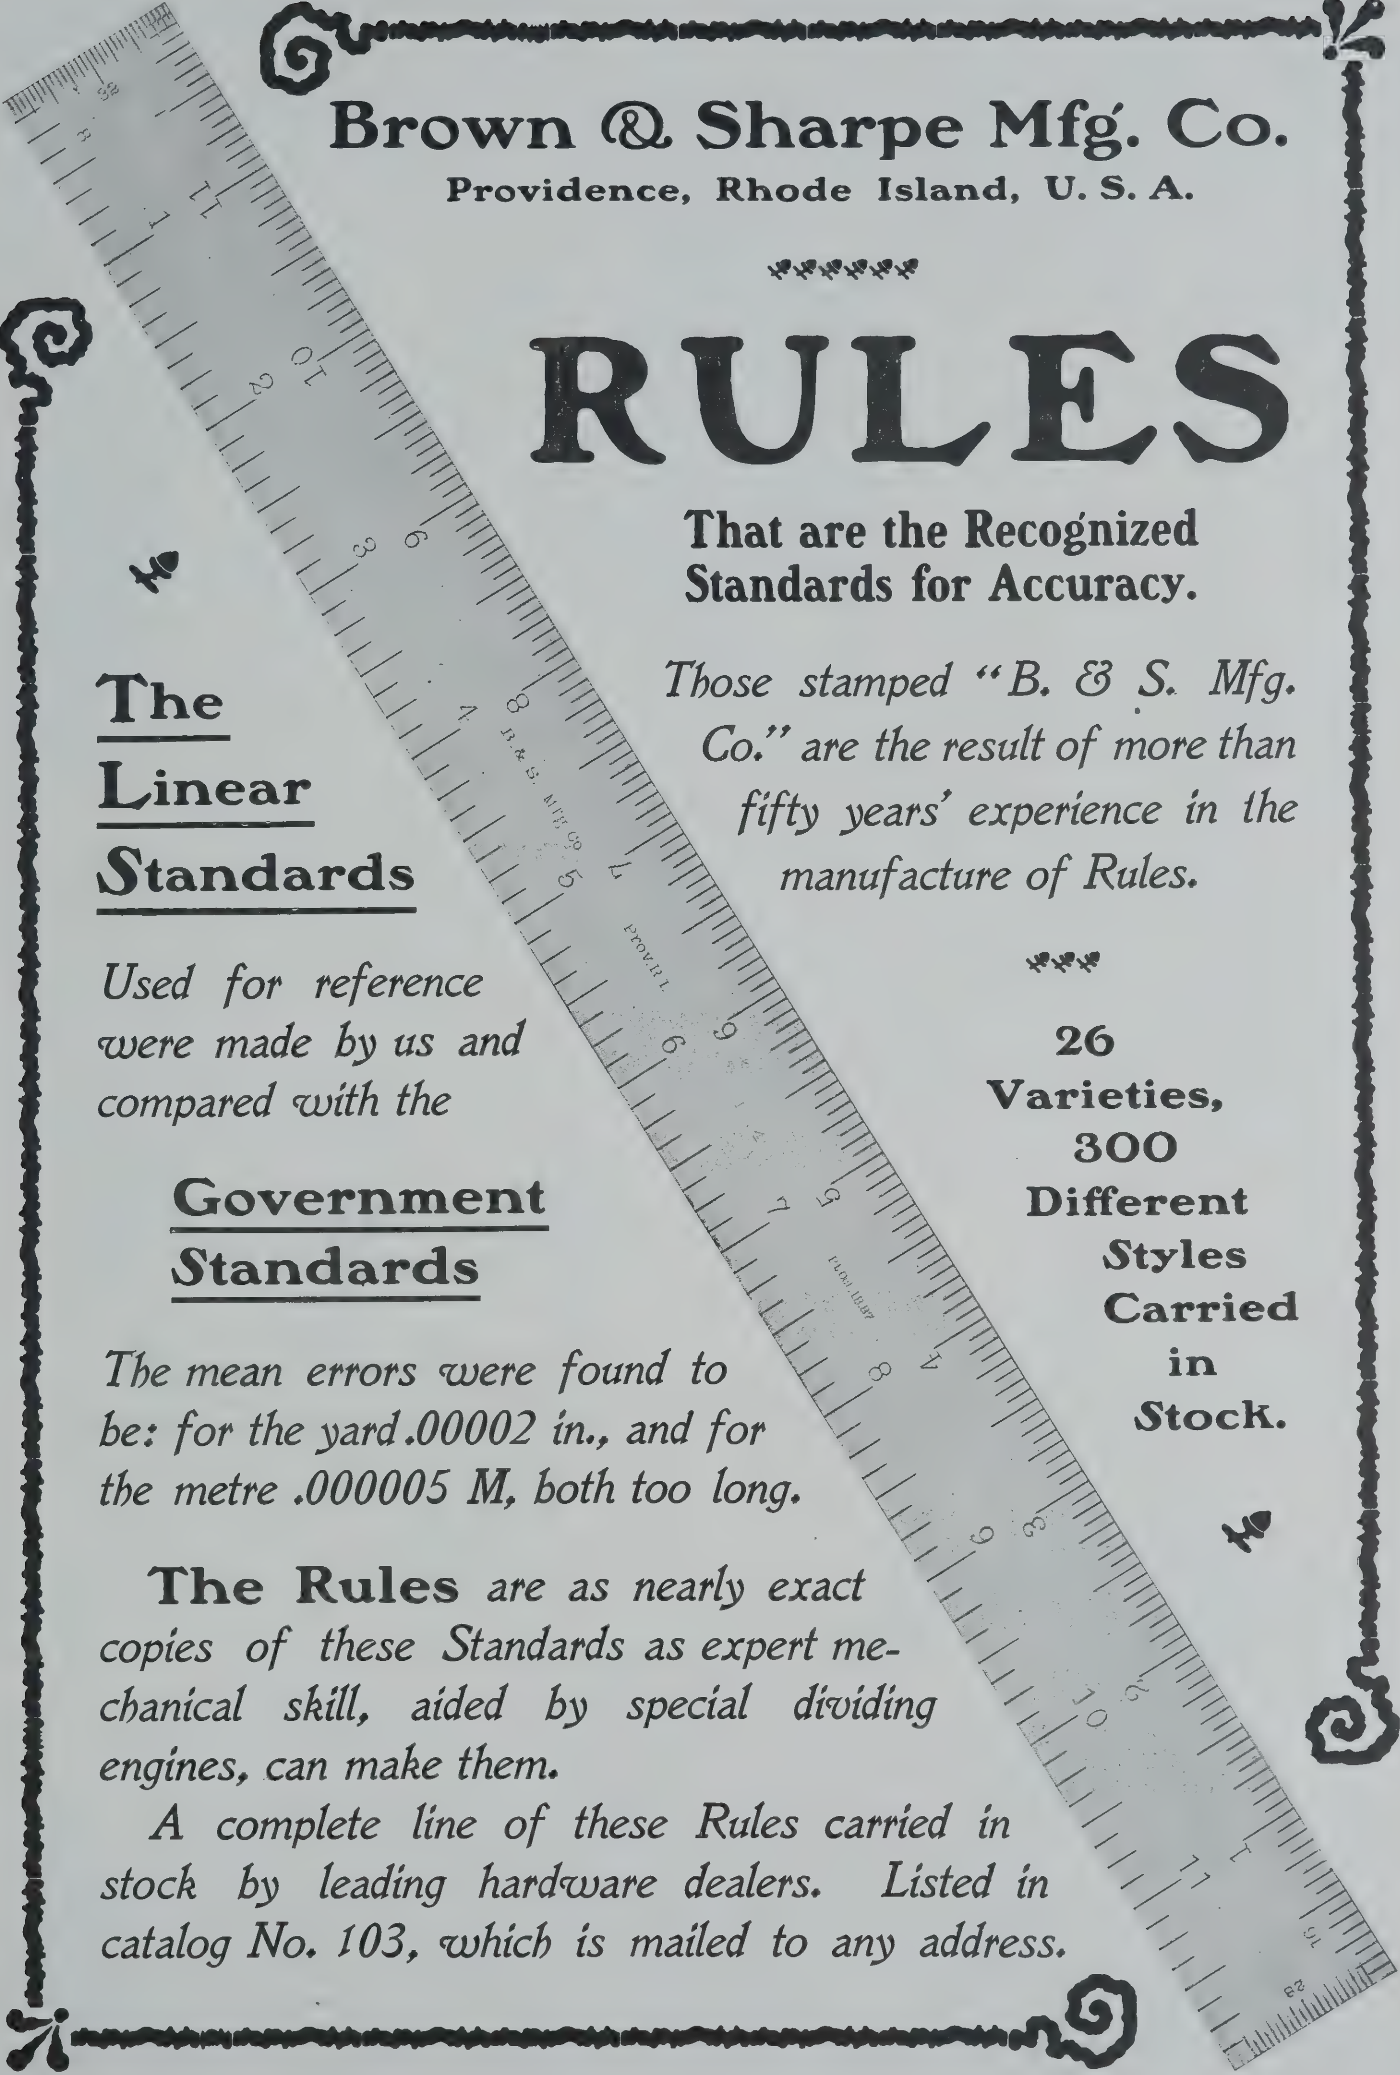
RULES

That are the Recognized Standards for Accuracy.

Those stamped "B. & S. Mfg. Co." are the result of more than fifty years' experience in the manufacture of Rules.

* * *

26 Varieties, 300 Different Styles Carried in Stock.



The Linear Standards

Used for reference were made by us and compared with the

Government Standards

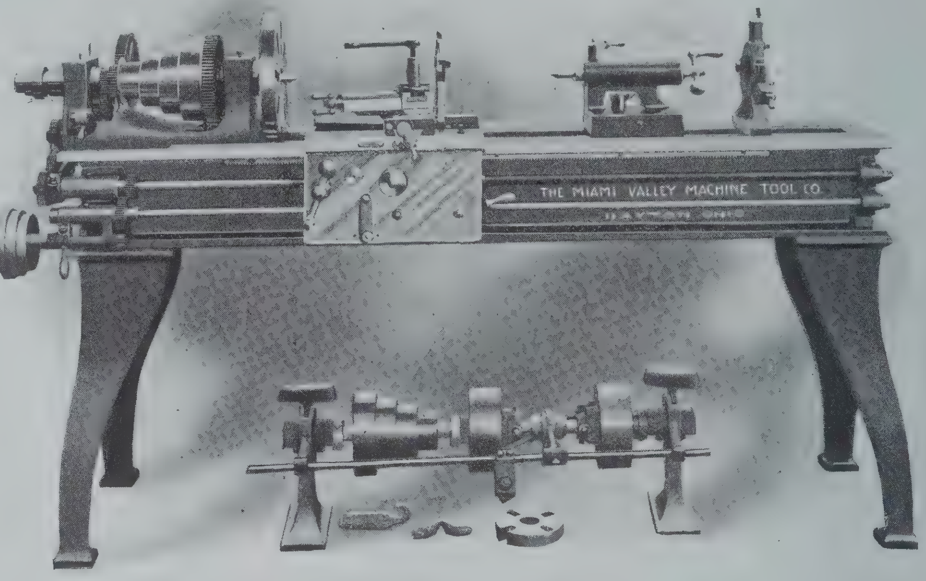
The mean errors were found to be: for the yard .00002 in., and for the metre .000005 M, both too long.

The Rules *are as nearly exact copies of these Standards as expert mechanical skill, aided by special dividing engines, can make them.*

A complete line of these Rules carried in stock by leading hardware dealers. Listed in catalog No. 103, which is mailed to any address.

NEW 13 1-2 INCH LATHE.

A new 13½-inch lathe is shown in the illustration, manufactured by the Miami Valley Machine Tool Co., Dayton, O., for whom the Patterson Tool & Supply Co., Dayton, are the selling agents. No novel features have been introduced in the design, the main considerations having been to produce a lathe with parts of ample proportions, convenient to operate, and durable and accurate in construction. The spindle is of high-grade steel, with ground journals and phosphor-bronze boxes. The cross feed is graduated. The chasing stop is always with the lathe, and it is impossible to throw in rod and screw feeds at the same time. The feed cone is provided with a swinging tightener. The centers are large, with no bushing in the spindle, but a safety plug is provided to avoid accident when the center is removed. The tailstock is of the overhanging style, with set-over. The feeds in head and apron are reversible. The head and tailstocks are fitted to the bed with a V at the rear and flat bearing in front, permitting the cross-bridge of carriage to be heavy and rigid. Besides the belt and rod-feed, a positive-feed can be obtained by engaging gear on leadscrew to the feed-rod. The carriage is provided with lock-screw. It has V-bearing in front and flat bearing in rear, and is gibbed. All sliding bearings on the V's are fitted to completely cover them, and avoid wearing a ridge in them. The power cross-feed is thrown in and out by moving a button. The countershaft has double-friction pulleys, simple in construction and easy of adjustment. Care has been taken to insure perfect facilities for oiling all bearings, especially in the apron. The compound rest is graduated in degrees.



Thirteen and One-half Inch Engine Lathe.

The front bearing of the spindle is 2 inches diameter, 3¾ inches long; the rear bearing of spindle, 1⅝ inches diameter and 3 inches long, and the hole through the spindle 1 1-16 inch. The diameters of the head-cone pulley are 3½, 5, 6½ and 8 inches. The ratio of the back gearing, 9.1 to 1. The lathe cuts threads 4 to 64, including 11½.

IMPROVED TAILSTOCK FOR LATHES.

The accompanying illustration is of a tailstock which J. G. Blount & Co., Everett, Mass., are applying to a new line of speed lathes. The tailstock has a combination wheel and lever feed and when required the lever can be readily applied by dropping it over two pins, one of which serves as a fulcrum and the other for moving the tailstock slide. Then by releasing two thumbscrews at the sides the slide is released so that it can be moved by the lever. Another important feature is the arrangement for adjusting it up or down by means of the two wedges seen in the illustration projecting between the body and base of the tailstock. These wedges can be pushed either way by tapping with a hammer, bringing the dead center accurately in line with the live center of the lathe, after which the two parts are locked securely together by means of cap screws. The tongue cast in the center of the base, which appears in the illustration, fits a dovetail groove in the base of the tailstock and keeps it accurately in line sidewise.

Tailstock with Special Adjusting Device.

THE "CHICAGO" COUNTERSHAFT.

A very simple and compact countershaft of novel design, called the "Chicago Pullet," has recently been brought out by Hill, Clarke & Co., Chicago. It is thrown in or out by merely a pull on the cord attached to a weighted lever which is set on a pivot with just enough eccentricity to throw in the friction disk driving the main pulley or cone. The weight is proportioned to hold the friction well in place, without undue pressure, and the contact roller is made of sufficient size so that it runs comparatively slow. It does not run when the clutch is out. Allowance is made for taking up any wear, so that the weighted lever will act at the best angle and give the proper throw to the eccentric.

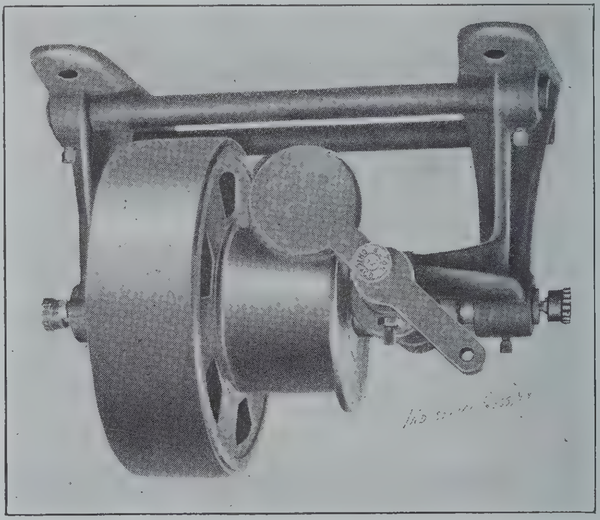

Fig. 1. Countershaft which is both Started and Stopped by Pulling an Attached Cord.

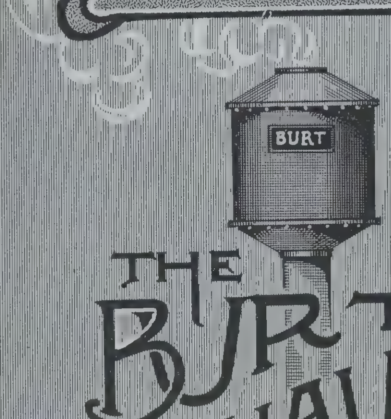
The shaft is stationary in the hanger and the pulleys revolve upon it, thus giving them a long bearing. The shaft is drilled longitudinally from both ends and grooved to distribute the lubrication, which is effected by grease cups. The contact roller also revolves upon its shaft and is lubricated in like manner. In order to accommodate different settings and directions of drive, the frame is constructed to take the "throw-over" lever at either side. The method of mounting upon heavy pipe allows the countershaft some adjustment in setting up.

THE BURT MANUFACTURING Co.
AKRON, OHIO, U.S.A.



THE BURT EXHAUST HEAD

PREVENTS oil and wet steam from escaping out of the exhaust pipe.

PREVENTS drenching your own and your neighbors' roofs.

PREVENTS dripping to the sidewalk below and forming mud in the summer and ice in the winter.

PREVENTS damage to clothing, accidents to limb and the resulting suits at law.

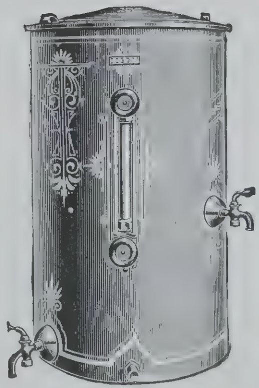
SAVES Steam, Water, Fuel, Heat, Roofs, Trouble, Accidents, Money.

Saving Waste Oil.

.... Do you not waste more oil than you use by throwing away that which has become blackened and filled with dirt and grit?

It Needs Washing

to remove these impurities, after which the oil may be used over and over again until every particle is consumed in lubricating the machinery on which it is used.

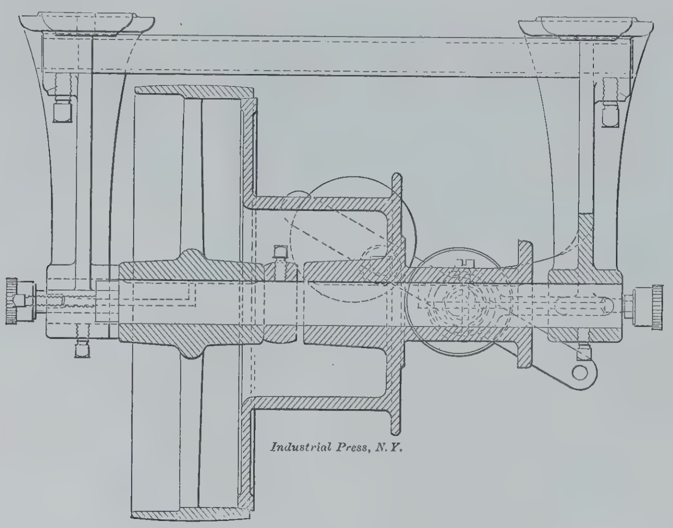


THE WARDEN OIL FILTER

is designed to purify this oil, to literally WASH IT free from all impurities. Dirty black oil, full of chips, is poured into the filter and clean new oil drawn off from the cock on the side. This filter consumes no power, requires no attention, needs no chemicals, runs day and night, asks for no time off, and never watches the clock! It is made in all sizes from 15 gallons to 300 gallons a day and will be shipped on trial at our expense.

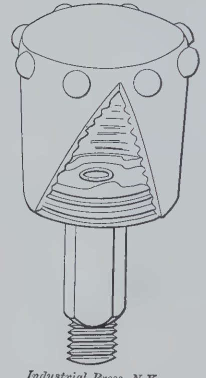
MACHINERY-NEW YORK.

This construction also allows the use either of a single driving pulley or a cone pulley of several steps, as preferred, since the countershaft does not require a shifting belt. Further particulars regarding the countershaft will be furnished by Hill, Clarke & Company, at Chicago, Boston or New York.



Details of Countershaft.

NEW GREASE CUP.



Grease Cup for Automobiles.

Now that automobiles have become a staple product in the market there are a great many fittings of various kinds manufactured expressly for use on automobiles. Among these are oil cups of various descriptions, of which one was shown in a recent number of this paper. In the illustration herewith is shown a grease cup for automobile use, made by Chas. H. Besly & Co., Chicago, Ill. It is of a design similar to that of their standard Badger grease cup, but is of double the depth and the stem is made proportionately longer. The cup is of cast iron, and the stem of bar steel drilled and threaded, so there is no danger of its breaking off. The internal thread of the cup is a round thread which will not strip, clog or cross. The round projections at the top of the cup enable one to secure a firm grip for unscrewing, and also make it possible to attach a wrench if found necessary.

FRESH FROM THE PRESS.

L. L. Cline, founder of the Trade Paper Advertising Agency, Hodges Bldg., Detroit, Mich., is now issuing a quarterly publication entitled "The Trade Press," a copy of which has reached us. This journal is to be devoted especially to the writing of advertising matter for mechanical papers and others.

Arithmetic of Electrical Measurements, by W. R. P. Hopps, and revised by Dr. Richard Wormell. Published in England and for sale by D. Van Nostrand, 23 Murray St., New York. 112 pages, 12-mo. Price 50 cents.

The chapters of the book take up joint resistances, division of current in branch circuits, strength of current with cells in parallel, in series and in opposition, electromotive force, battery power, best arrangement of cells, resistance of conductors, electric lighting, etc. The book has proved useful to students who are learning to make electrical calculations and wish to have a convenient collection of formulas and examples for practice.

Self-Propelled Vehicles, by James E. Homans, A. M. Published by Theo. Audel & Co., 63 5th Ave., New York. 632 8-vo. pages, with nearly 500 engravings. Price $5.00.

This book contains a collection of notes, data and descriptive matter relative to the various types of steam, gasoline and electrical motor carriages. The book is non-technical in character and is intended for the general reader interested in the subject of automobiles. Such a person will here find a great mass of matter, largely descriptive, reviewing the present state of automobile construction. Certain technical points are explained in a way to be understood by the general reader, such, for instance, as differential equalizing gears, different types of steering gear and the operative principles of steam, gasoline and electric types of carriage. The illustrations are largely reproduced from catalogues or articles that have appeared elsewhere, although many have been made expressly for this work, and while not so attractive as newly made cuts, are sufficiently clear and numerous to serve the purpose of supplementing the text. The author has evidently touched upon the most important subject pertaining to automobiles, and gives chapters upon the boilers, including flash boilers, boiler feeding, burners, carburetters, vaporizers, etc. The parts of the carriage itself are also taken up and there are chapters upon motor carriage wheels, springs, ball and roller bearings, brakes, etc. The explosive engine receives rather more attention than any other subject. Taken altogether it is probably the most complete American treatise on automobiles and will give one a very full and correct impression of current automobile practice.

Water-tube Boilers, by Leslie S. Robertson. Printed in England and for sale in America by the D. Van Nostrand Co., 23 Murray St. and 27 Warren St., New York. 213 8-vo. pages, illustrated. Price $3.00.

This book is devoted entirely to water-tube boilers of both American and foreign types, and the text is mainly descriptive, there being little mathematical work. It is really a collection of illustrations pertaining to the most prominent types of water-tube boilers. It traces the history of water-tube boilers, showing some of the earlier forms, and discusses modern types for stationary purposes, and contains descriptions of a number of launch boilers and marine boilers for larger vessels. The book is made up from a series of lectures upon water-tube boilers delivered by the author at University College, London.

The Prevention of Smoke combined with Economical Combustion of Fuel, by W. C. Popplewell. 203 pages and 46 illustrations. Published by Scott, Greenwood & Co., London, and D. Van Nostrand Co., New York. Price $3.50 net.

The prevention of smoke in cities and towns is always an important subject, but at the present time it is of unusual interest in great cities like New York on account of the great anthracite coal strike. New York, because of its closeness to the anthracite regions of Pennsylvania, has always used anthracite coal in preference to bituminous coal, as it is usually as cheap for the steam sizes. Consequently New York has enjoyed the reputation of being the cleanest city in the world, not so much, perhaps, because of the strenuous efforts of its officials to make it so, but because of the cheapness of hard coal. Now that the coal strike has made it impossible to get anthracite coal New York is using soft coal, with the consequence that many of its chimneys are pouring forth volumes of black smoke in a manner that rivals those of Pittsburg and of Western cities. The plants that are fortunate enough to be equipped with automatic stokers are enabled to burn the unusual fuel without serious difficulties in preventing smoke. When it is considered that property is more valuable, the death rate is lower, the moral conditions are better, the damage to fine fabrics less and conditions to a high standard of living far more favorable where smoke and carbon deposits are not known, the prevention of smoke at once becomes a subject of the greatest importance.

The book in review treats of the smoke problem as found in England. It is shown that the difficulty there is much more serious than here, as soft coal is used for almost all domestic fires. In London the volume of smoke poured out daily by these fires is probably equal to if not greater than that emitted by the chimneys of manufacturing establishments. The problem is therefore a much more serious one to combat than here where manufacturing establishments are the chief offenders. Yet the conditions are not considered hopeless and means and ways are pointed out that if adopted generally would materially abate the evil. Various forms of grates and furnaces for house use are described briefly. Chapter I. treats of fuels and combustion, chemical action, quantity of air required for perfect combustion, formation of smoke, effect of air supply on the formation of smoke. The following chapter discusses hand firing and describes forms of furnaces designed for smokeless hand firing. Then follow descriptions of various mechanical stokers, powdered fuel firing, gaseous fuel and the means of producing it, smoke observations, standard smoke tests, etc.

ADVERTISING LITERATURE.

The Sterling Emery Wheel Co., Tiffin, O. Illustrated catalogue of emery wheels, grinding and polishing machinery and supplies.

The Buffalo Forge Co., Buffalo, N. Y. Illustrated pamphlet treating of the Buffalo improved ventilators, Buffalo blowers and exhausters, etc.

Manning, Maxwell & Moore, New York. Circular No. 9, of second-hand machine tools. This circular will be sent to anyone upon application.

The American Blower Co., Detroit, Mich. Catalogue No. 141 of the A. B. C. pressure and volume blowers. The company's products are fully described and illustrated and price lists are also given.

The Massachusetts Tool Co., Greenfield Mass. Catalogue No. 3 of fine precision tools, including micrometer calipers, micrometer gages, surface face gages, steel rules, center squares, depth gages, dividers, etc.

The L. S. Starrett Co., Athol, Mass. Supplement to catalogue No. 16 of fine mechanical tools. This pamphlet illustrates the tools manufactured and calls attention to some new sizes of squares and calipers now being made by the company.

The Standard Tool Co., Cleveland, O. Catalogue of twist drills, reamer chucks, spring cotters, taps, flat spring and riveted keys, milling cutters and special tools. This catalogue is very complete and will prove interesting to the prospective purchaser.

The Norton Grinding Co., Worcester, Mass. Illustrated catalogue 6 x 9 of the Norton plain grinding machines. The catalogue also contains specifications of the 12-inch x 72-inch plain grinding machine described in our August issue.

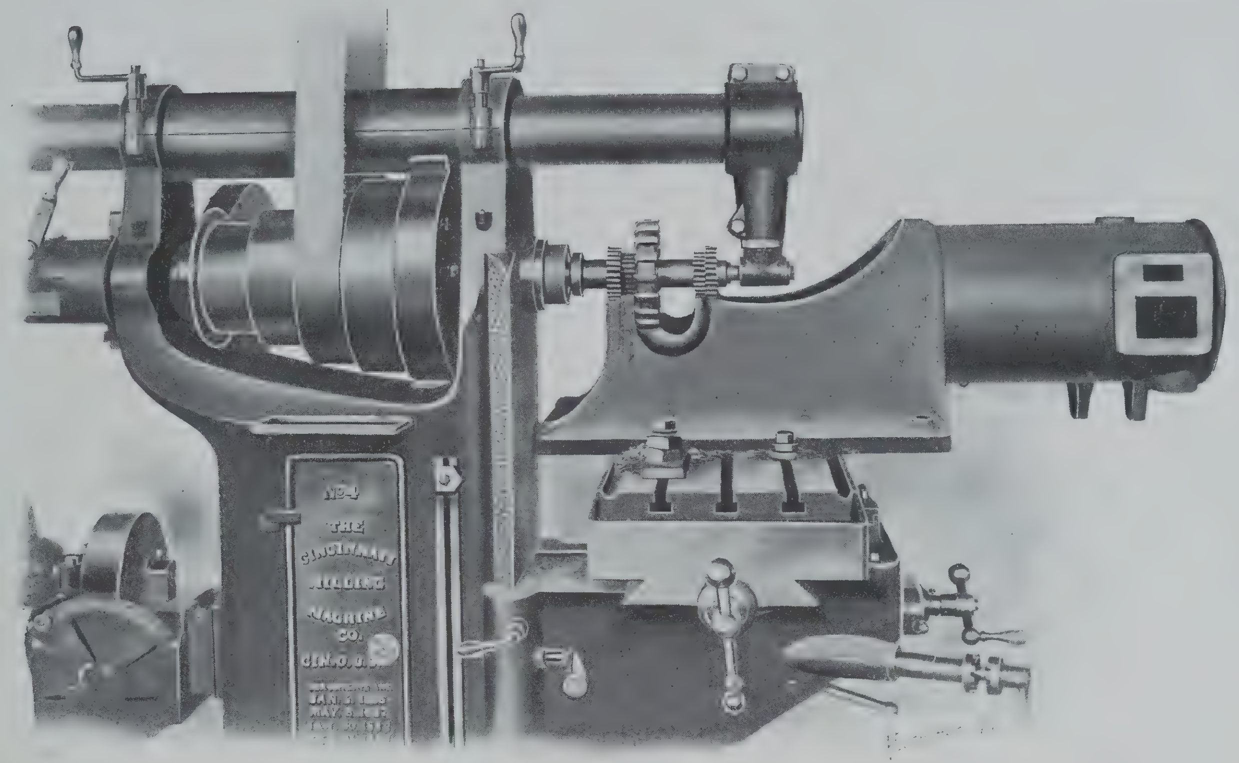
The Skinner Chuck Co., New Britain, Conn. 1902 catalogue and supplement of the Skinner patent chucks. These include lathe, drill and planer chucks and faceplate jaws. The company are also prepared to make special chucks to order. The catalogue contains a large number of cuts of chucks and also a price list.

The Bignall & Keeler Mfg. Co., Edwardsville, Ill. Standard size catalogue of pipe-threading and cutting-off machinery. The various styles and sizes of these machines are illustrated by excellent halftones and the machine parts are described in detail. These machines are built to operate by hand or by power.

The Garvin Machine Co., Spring & Varick Sts., New York. Illustrated catalogue No. 8 of screw machines, monitor lathes, forming machines and double turret screw machines. This is one of a series of 14 catalogues issued by this company dealing with the machinery manufactured and handled by them.

The American Tool Works Co., Cincinnati, O. Circular calling attention to some of the lathes manufactured by this company, and containing letters received from purchasers of "American" lathes expressing their satisfaction therewith. The company issue a "Lathe Book" which gives full details of their lathes and which may be had upon application.

The R. K. LeBlond Machine Tool Co., 4620 Eastern Ave., Cincinnati, O. 1902 illustrated catalogue of engine lathes. These range in size from 10 to 30 inches. The LeBlond engine lathe with interchangeable turret on the carriage is described and illustrated, and turret lathes, roughing lathes, stud lathes, bed lathes, etc., are also shown.



Just twenty-eight minutes

are required for machining the bearings in an 8 H-P. engine frame in the shops of The Root & VanDervoort Engineering Co. when the work is done on a No. 4 Plain Cincinnati "Geared-Feed" Miller. The best time they ever made on a planer was 1 hour and 35 minutes. The time in each case, includes handling and chucking the work. The miller saves more than 70 per cent. of the best planer time. Through the light part of the cut, i. e. when the cutter enters and leaves the work the machine is fed .102 in. per turn, and through the heavy part of the cut the feed is .080 in. per turn. The change from the fast to the slow feed and then back to the fast feed again is made by simply shifting a lever and is done by the operator while the cut is going through. The space traversed in entering and leaving the cut about equals the length of the heavy part of the cut. That means that for one-half of the entire table travel the work is being done 27 1-2 per cent. faster than would be possible on a miller requiring the manipulation of change gears or transposing cone pulleys and belts, to secure the feed changes. This illustrates one of the points we have in mind when we talk about the advantages of a "quick feed changing device" on our miller. Will be glad to take up other points with those interested.

Our 1902 Catalog tells some things worth knowing and can be had for the asking. We will show you another way to mill at a money-saving rate next month.

THE CINCINNATI MILLING MACHINE CO.

CINCINNATI, OHIO, U. S. A.

EUROPEAN AGENES—Schuchardt & Schutte, Berlin, Cologne, Vienna, St. Petersburg, Brussels, Stockholm and New York. Adolph Janssens, Paris. Chas. Churchill & Co., London, Birmingham, Manchester, New-Castle-on-Tyne and Glasgow. The Niles Tool Works Co., 23-25 Victoria St., London, S. W.

MONTGOMERY & Co., 105 Fulton St., New York. Catalogue No. 21, entitled the "Tool Catalogue." This treats very completely of the large line of small tools, factory supplies and light machinery carried by this company. The catalogue contains 704 pages and is very profusely illustrated. A complete index is given, and the catalogue will be most valuable to anyone interested in this line of goods. The pamphlet entitled "Confidential Prices," accompanying catalogue No. 21, gives the discount on all the articles manufactured.

THE RAND DRILL Co., 128 Broadway, New York, have issued a timely pamphlet showing the progress of the work on the New York rapid transit subway. The book is designed primarily to advertise the fact that the Rand air compressors and compressed air drills are used extensively by the different contractors in excavating for the tunnel. In addition to a general description of the tunnel and of the work so far accomplished, there is a brief review of the various attempts at rapid transit in New York City, including the surface and elevated roads, as well as the attempts to start the great underground system. The illustrations are mainly from photographs.

THE FOSDICK MACHINE TOOL Co., Cincinnati, O. June, 1902, catalogue, standard size, of the radial drills and drilling machinery manufactured by this company. This is a handsome catalogue, containing many fine half-tone illustrations of the various sizes and styles of the company's drills, together with complete descriptions of same. There is also a half-tone showing the company's works and one giving a view of a part of the shop where the radials are built. Space is also given to a large number of copies of letters from different firms expressing their approval of these radials. Catalogue will be forwarded when applied for.

MANUFACTURERS' NOTES.

PAWLING & HARNISCHFEGER, Milwaukee, Wis., send us a statement of orders received from 15 well-known firms in this country for cranes and hoists of their manufacture.

THE BURT MFG. Co., Akron, O., have received an order from the Detroit Copper Mining Co., Morenci, Ariz., one of the largest copper mines in the world, for two 50-gallon Cross Oil Filters, making ten of these filters in use in their mines.

THE CLEVELAND PNEUMATIC TOOL Co., Cleveland, O., have recently opened up an office at 411 Park Bldg., Pittsburg, Pa., represented by Chas. L. Nelson, and at 34 Lemoine St., Montreal, Canada, represented by N. J. Holden.

THE COLBURN MACHINE TOOL Co., Franklin, Pa., manufacturers of high-grade machine tools, state that work on their new plant is progressing very nicely and they are getting in their equipment and shall have their machinery installed and works in full operation in from about thirty to sixty days.

THE U. BAIRD MACHINERY Co., Pittsburg, Pa., has been incorporated under the laws of the State of Pennsylvania, the new name of the company being the Baird Machinery Co. The officers are Messrs. C. A. Wolfe, H. A. Reed, W. B. Wolfe, O. P. Meckel and J. L. McCartney.

THE NEWTON MACHINE TOOL WORKS, 24th and Vine Streets, Philadelphia, will shortly issue a new catalogue 6 x 9 consisting of about 250 pages. The company would be pleased to have the addresses of all those desiring a copy and all requests will be carefully attended to.

THE BUFFALO FORGE Co., Buffalo, N. Y., state that their products are in steady demand not only in the United States, but also in European countries. They send us a list of 16 orders received through their different branch houses for steel plate steam fans, direct-connected Buffalo engines, etc.

THE CLEVELAND PNEUMATIC TOOL Co., Cleveland, O., inform us that the contracts for their new plant have been awarded to Messrs. J. A. Reaugh & Son, of Cleveland, O. It is expected to have the plant completed and ready for operation within 90 days. The plant will be equipped with the most modern machinery and appliances for turning out the largest amount of work in the shortest time.

THE AUTOMOBILE & CYCLE PARTS Co., Cleveland, O., since August 1st have transacted and will continue hereafter to transact their business under the name of the Federal Mfg. Co. This change of title will not affect the management of the company or the business of their factories. The company inform us that their products are so diverse that a comprehensive name became a necessity.

GEORGE WILLIAM HOFFMAN, 295 E. Washington St., Indianapolis, Ind., sole manufacturer of the "U. S." metal polish and "Bar Keeper's Friend" and other specialties, sends us a circular treating of these specialties. This polish may be had in powdered or liquid form, as desired, and is used to remove stains, grease, smut and tarnishings from plated or polished metal, marble, porcelain, glass, wood, etc.

THE BUFFALO FORGE Co., Buffalo, N. Y., have been awarded the contract for the installation in the mines of the Continental Coal Co., Glouster, O., of three 250-inch fans for the purpose of ventilating and exhausting fumes, smoke and dangerous gases. This plant is similar in many respects to that of the Modoc Coal Mining Co., located at the same place and recently installed by the Buffalo Company.

THE FALKENAU-SINCLAIR MACHINE Co. is a new company organized for the manufacture of machine tools and located at 109-115 North 22nd St., Philadelphia. This company has taken over the entire plants and business interests of A. Falkenau and of the Philadelphia Machine Tool Co. Besides the building of machine tools and special machines, and contracting for machines in large quantities, the company's full lines of presses and machines for working sheet metals, hydraulic machinery and testing machines will be continued and extended.

THE ROYERSFORD FOUNDRY & MACHINE Co., Royersford, Pa., report a very active business in the sale of their punch and shears. Several of their machines have just recently been shipped to Manning, Maxwell & Moore, New York, N. Y., and a carload to the Marshall & Huschart Machinery Co., Chicago, Ill. They have made the Marshall & Huschart Machinery Co., 62-64 So. Canal St., Chicago, Ill., their exclusive agents for the sale of their machines in the States of Illinois, Indiana, Michigan, Wisconsin and Ohio, the city of Cleveland excepted.

THE PHILADELPHIA PNEUMATIC TOOL Co., Philadelphia, Pa., report an unprecedented rush of business, their manufacturing capacity being taxed to the utmost to keep up with orders. The increasing demand for the Keller rotary drills is particularly noticeable. They state that four of the large eastern steel companies have recently purchased Keller tools to the aggregate number of 237. One of the western trunk line railroads has recently made a contract with this company to purchase at least 1,500 Keller tools within the next eight months, and a cable order for Keller tools was received last week from Bilbao, amounting to several thousand dollars.

THE AMERICAN SCHOOL OF CORRESPONDENCE, Boston, Mass., has recently made an arrangement whereby the students are admitted to the classes of one of the prominent technical schools without further examination, and their work counts toward a degree of B. S. Ambitious young men who cannot afford to give four years to study for a college degree can now do part of this work at home and finish at a resident technical school. The Trustees of the American School have been offering a limited number of free scholarships; after September 30th the offer will be withdrawn. There is still an opportunity, therefore, to obtain, free, a course in mechanical, steam, textile and sanitary engineering and mechanical drawing.

PAWLING & HARNISCHFEGER, Milwaukee, Wis., makers of electric cranes and hoists, have just acquired the Gardiner Campbell Co.. property adjoining their works. This property is 200 by 150 feet., and the three-story building is being remodeled to supply additional machine shop facilities, and to provide extra pattern storage. The foundry is being changed over, and added to. In the entire building will be placed a modern foundry equipment. Among the improvements will be two P. & H. electric traveling cranes. Their present power plant is also being enlarged and new boilers, engines and another generator will be provided. They state that these improvements will considerably shorten the time required to complete a crane or hoist.

IN the editorial columns of the engineering edition of MACHINERY for this month reference is made to the fact that the Standard Welding Co., Cleveland, O., are now turning out electrically-welded parts for automobile construction. They write us that they are also enlarging their plant by the erection of new buildings to enable them to increase their stock of manufactured tubing in sizes from 2½ inches diameter and smaller. This tubing is uniform in gage, of the best open-hearth steel and is particularly adapted to places where the tubes are to be plated with nickel or other similar finish. The company also wish to announce that they are prepared to contract for various classes of work. They will either electrically weld stampings and forgings furnished them by manufacturers, or will do the whole work complete.

THE NEW PROCESS RAW HIDE Co., Syracuse, N. Y., have recently made arrangements with Messrs. Geo. Angus & Co.. Ltd., Newcastle-on-Tyne, England, prominent manufacturers of leather, whereby the English concern is to establish a plant in England for the manufacture of rawhide gears and other products under the patents and secret processes of the New Process Raw Hide Co., using the latter company's trade mark. This plant it is expected will take care of the company's business not only in Great Britain, but throughout Europe, Messrs. Angus & Co., having offices in nearly all of the principal cities. The English company will shortly place orders with American firms for the latest gear-making machinery and will proceed at once with the fitting out of the new factory which will be located at Newcastle-on-Tyne.

THE DERRY COLLARD Co., with offices at 256 Broadway, New York City, has been organized for the purpose of publishing and selling educational books, charts, models, etc., for readers of technical literature. One of the first books to be brought out will be a treatise on hardening, tempering and annealing steel, by our contributor, Edw. R. Markham, the consulting expert. A locomotive valve model will also soon be ready. A new policy has been adopted by this company for the sale of technical books, in that they will send books to any person for examination before he pays for them. If he finds them satisfactory he can then remit, and if not, the books can be returned. Detailed information will also be furnished about the technical merits of any book, whoever the publisher, either by circular or by written letter. The office of the Derry Collard Co. is fitted as a reading room and any mechanics visiting New York will be welcome there. The president of the company is Mr. Fred. H. Colvin, who was formerly editor of MACHINERY.

MISCELLANEOUS.

Advertisements in this column, 25 cents a line, ten words to a line.

The money should be sent with the order.

A MANUFACTURING CONCERN in Northern Ohio thoroughly equipped with entirely new plant for turning out light or medium weight tools of any character suitable for machine shop trade, would like to correspond with parties desiring same manufactured on royalty. Address MANUFACTURER, 9-15 Murray St., New York.

AGENCY WANTED for high-class engineers' and woodworkers' tools by thorough engineer with own workshop. Power in showroom. Good connections in England. Established in 1876. W. ROBERTSON, Engineer, Eccles, near Manchester, Eng.

FOR SALE CHEAP.—Two colored charts, A. and B., for scientific tool tempering, explaining tempering in oil, water and tallow and telling what each tool will stand. Also, 40 new steel working methods for forging and welding different kinds of steel and five of the best steel welding compound receipts on earth. All new and up-to-date. Send for free samples. The two charts and the 40 new methods for $1.00. Address W. M. TOY, Sidney, O.

INVENTOR'S MODELS built and perfected, special machinery designed and built, small parts duplicated. Let us quote prices. F. J. STOKES MACHINE CO., Philadelphia, Pa.; New York representative, FRANK P. WISNER, 46 Cliff St.

MANHATTAN TYPEWRITER FOR SALE—Same size and keyboard as Remington No. 2. Used about two years and in good running order. Price $25. Address INDUSTRIAL PRESS, 15 Murray St., New York.

SPECIAL TOOLS, models, fine light machinery and foundry work wanted. MURRAY MFG. CO., Richmond Valley, Staten Island, N. Y.

TO EXPORTERS OF MACHINERY TO RUSSIA.—The Toula Manufacturing Company, Limited, at Toula, in Central Russia, beg to inform American makers and engineers, who might be desirous of having their products manufactured in Russia itself, that they are prepared to undertake any orders that might be intrusted to them. The Toula factories include a cast-iron and steel foundry and newly fitted-up works with all the most modern appliances, including a large quantity of American machine tools, for constructing machinery of every description. The arrangement enables the company to undertake, under the most favorable conditions, the manufacture of all descriptions of machinery, machine tools, agricultural machines and specialties of all kinds. Address communications to: LES ATELIERS DE TOULA, SOCIETE ANONYME, 299 Chaussée d'Anvers, Brussels, Belgium.

WANTED.—Air Compressor, duplex 16 x 12, 110 revolutions, about 15 lbs. pressure, 610 cubic feet free air per minute. Address, H. SCHERER & CO., Detroit, Mich.

WANTED.—Engine Lathe manufacturer, or some other party with money, to take interest and furnish capital to patent an attachment every up-to-date engine lathe ought to have. Address E. W. W., care Machinery, 9-15 Murray St., New York.

WE DESIGN and make automatic machinery and special mechanical devices. Do all work in connection with the development of mechanical inventions. Engineering, designing, drafting, machine construction, models, tools, and also attend to job work and repairs. Address CHAS. E. HADLEY, Mechanical Engineer and Machinist, 584 Hudson St., New York, N. Y.

MACHINERY.

October, 1902.

SHOP CONSTRUCTION.—1.*

GENERAL PLANS FOR A MODEL PLANT.

Oscar E. Perrigo.

The "eternal fitness of things" requires that in whatever we design, build, equip and arrange for producing our portion of the product of the world's vast commerce, we shall strive to make it the best of its class; also, the best adapted for the special uses to which it will be put, the kind of goods to be manufactured, the circumstances, conditions and surroundings under which we work, etc.

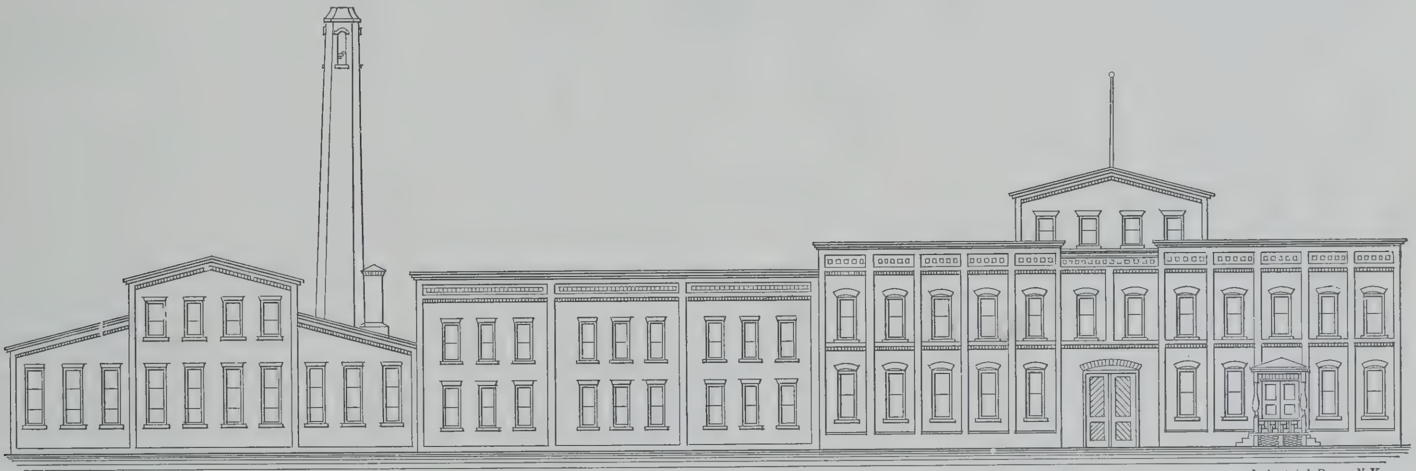
In a great majority of cases the manufacturing plants of this country have been the result of *growth*, more or less rapid. Often they began with meager accommodations, which, as means allowed and necessity required, have been gradually added to. And thus the establishment became an aggregation of buildings of various sizes and forms, ofttimes representing in a general way the worst arrangement for economically producing work. At the same time it represented the total expenditure of a much greater amount of capital than would have been necessary to erect and equip good buildings, well suited to the practical necessities of the business.

There are numerous establishments in this progressive country to-day occupying antiquated and rambling structures that have cost money enough for the building of modern works properly designed for the economical production of a much higher grade of goods than it is possible to manufacture in old plants.

The world moves, and nowhere is this more apparent than in manufacturing. That which would answer the purposes of a business even five or ten years ago is among the "back numbers" to-day. The constant striving for the best was never more in evidence than at the present time among our up-to-date, progressive manufacturers, who are able to look beyond first cost to the greater advantages to be gained later on. The aim of this series is to discuss, from a practical standpoint, what is the best design, arrangement, equipment and management of manufacturing plants erected for the production of a medium-sized class of machinery, from the reception of the raw material to the shipping of the finished product. With this in view cuts showing the general plans for suitable buildings of a size and capacity for the usual work, arranged in compact form, of modern construction and supplied with conveniences for handling material and product, accompany this article. The entire plant, shown in Fig. 1, requires a site of somewhat less than 300 x 450 feet.

Fig. 2 shows a compact design to meet cases where the amount of land is limited and illustrates how all the buildings may be so grouped as to render the handling of materials and transportation of them as simple, direct and economical as possible. A railroad track should pass near the works, and from it a branch should be brought closely past the rear and to one side of the collection of buildings. Such an arrangement results in a great saving in the expense of hauling both material and product, and permitting the general arrangement and development of the plan herein proposed.

The main building, or machine shop, is 100 x 375 feet, divided lengthwise into a central portion 40 feet wide and 52 feet high, with side wings or bays each 30 feet wide. The central portion is open clear to the roof and has a traveling crane of ample capacity moving over its entire length. The side wings are divided into a main floor, on a level with the central portion and a gallery, or second floor; the first being 16 feet and the latter 14 feet high in the clear. This gallery is also built across 18 feet of the front end, thus connecting the two galleries and furnishing a platform by way of which the traveling crane may transfer material and product to and from the main floor. Along the center of these galleries and across the front end runs a tram track, provided with light push cars for facilitating the transfers. Stairways are provided at each end and in the center for conveniently and speedily reaching any part of the shop from floor to galleries and *vice versa*.



Industrial Press, N.Y.

Fig. 1. Front Elevation of Shops for a Model Plant to build Medium Sized Machinery. Scale, one inch equals forty feet.

At the front end of the machine shop proper are the offices connected with and forming a part of it, consisting of two structures 50 feet square, with a driveway space of 20 feet between them. On the first floor of one of these are the offices, storeroom, etc., and in the other the tool-making room, a room for storage tools and fixtures and a stock room for small finished parts. On the second floor is located the drawing room, while over the driveway is the pattern shop. The offices are only those particularly connected with the manufacturing and shipping, and not the general offices of the company. A wing connects the front buildings with the foundry. The ground floor of this wing is used as a storage room for pig and scrap

---

* This is the first of a series of articles upon the design and construction of machine shops, treating of the various parts of a plant, from foundation to roof, and including hints upon the arrangement of tools and the management of the completed plant. The intention will be to give such information about the special requirements of machine shops as an architect, or structural engineer who has had no shop experience, usually does not possess.

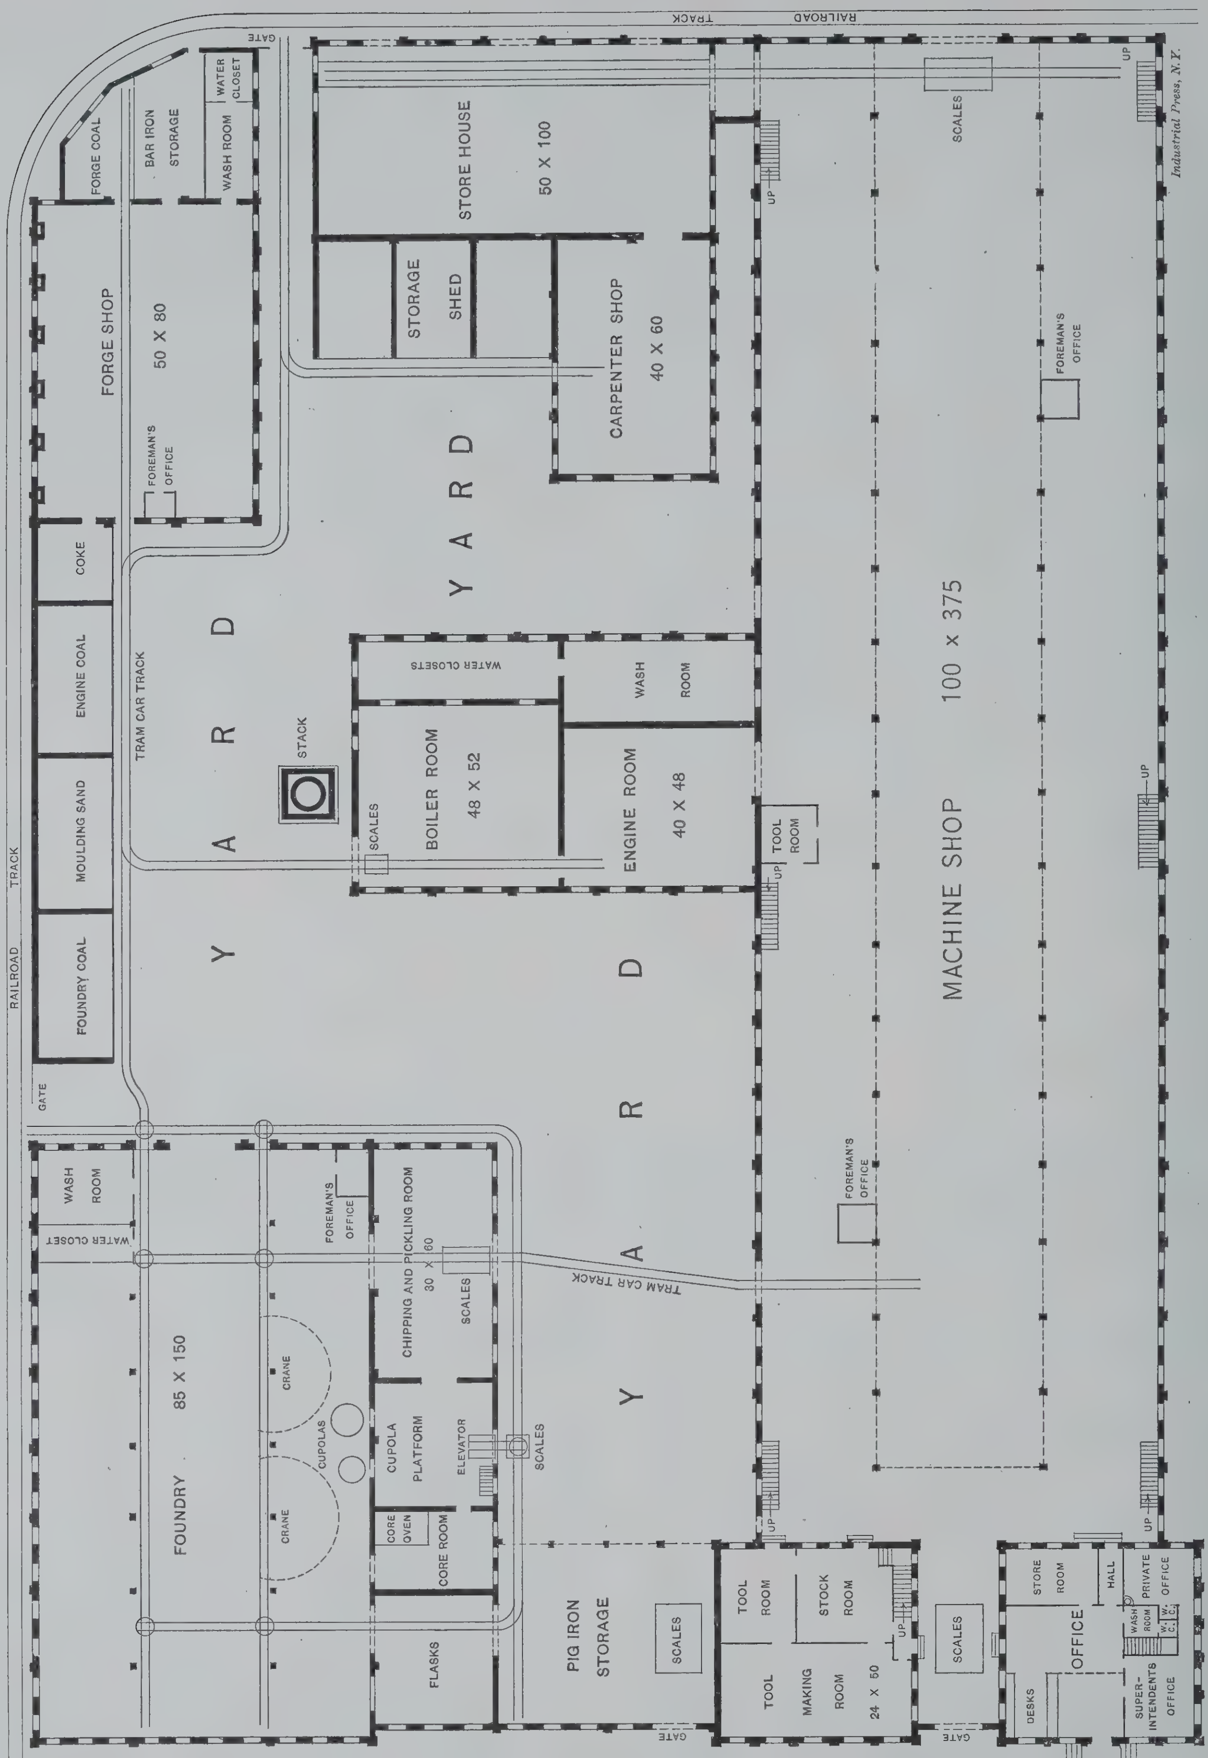


Fig. 2. Plan of Works shown in Elevation on the first page. Scale, one inch equals forty-eight feet.

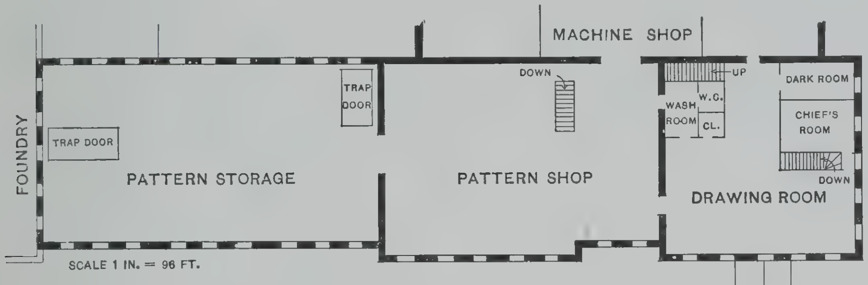
iron, and a flask room, while the second floor is a pattern storage loft, connected at one end with the pattern shop and at the opposite end with the foundry by a trap door 8 x 18 feet, directly over the train track leading through the flask room.

The foundry is 85 x 150 feet, arranged with a central part 35 feet wide and two side wings or bays, each 25 feet wide. The central part is covered by a traveling crane running the entire length. There are two cupolas, a large and a small one, served by two cranes of sufficient reach to swing into the central space covered by the traveling crane. Large work is cast in the central space or within reach of the cranes, while small work and bench molding occupy parts of the floor not covered by the cranes. On each side of the central part are tram tracks, which are crossed by one running to the flask room and one that goes through the chipping room and on across the yard to the machine shop.

A wing built on the side of the foundry toward the machine shop contains a platform upon which coal and iron for charging the cupolas are delivered by a tram car raised to that level by an elevator arranged for the purpose. This stock is weighed on track scales in front of the elevator. Beneath the cupola platform are the tumbling barrels, convenient to the cupolas for working over the slag, and to the chipping room for cleaning small castings. The flask room is located at the front, while between it and the tumbling barrel space is the core room, containing a suitable core oven. At the opposite end, facing the yard, is the chipping and pickling room, where the castings brought in from the foundry are pickled, chipped and weighed, before being sent to the machine shop. If the castings are too heavy for convenient handling in the chipping room they may be run through to the yard and there handled by a boom crane covering the tram track upon which they are run into the machine shop. Castings of moderate size, yet too heavy to move by hand, are expeditiously handled by a light overhead trolley hoist in the chipping room. At one end of the outer wings are the wash room and toilet. If more floor space is needed these may be located in a gallery placed 8 or 10 feet above the foundry floor. In the further corner of the yard, as far as possible from the foundry and engine room, is the forge shop, 50 x 80 feet, which is reached by tram cars, the track running through its length near the center. On the outer walls are the chimneys for the forges and heaters, and in the rear are the storage shed for bar iron and steel, the wash room, toilet, and space for coal. These adjuncts are in a shed built with brick walls and of such outline as to conform somewhat to the curve of the railway track, the forge shop having been so located as to admit of this arrangement.

When down-draft forges, served by exhaust fans, are used, it will not be necessary to build more than one chimney, the flue of which should be large enough to carry off the smoke and gases from all the forges.



Industrial Press, N.Y.

Fig. 3. Plan of Second Floor in Foundry. Scale, one inch equals forty-eight feet.

The power house is located midway in the length of the machine shop, so that power may be applied to the line shafting at a point that prevents much of the torsion incident to long lines of shafting driven from one end. This building is 65 x 100 feet and contains the engine room, 40 x 48 feet; the boiler room, 48 x 52 feet, and also the wash room and water closets used by workmen in the machine shop. Near the boiler room is the chimney stack, with which the smoke flues of all the boilers are connected. Coal is brought in on push cars along the tram track, to the front of the boilers, where a track scale is placed for weighing it. Ashes are removed by the same tram track to whatever point is most desirable to deliver them. Across the rear end of the yard is the storehouse, 50 x 100 feet, for finished machines, or product. This connects with the rear end of the machine shop by a tram track running from the scales beneath the traveling crane through a wide doorway and the whole length of the storehouse. The rear side of the storehouse (next to the railway track) has wide, sliding doors, through which the finished product is readily moved into the railway cars for shipment. Here, as in the chipping room of the foundry, it may be desirable to make use of overhead trolley hoists to facilitate rapid and economical handling of machinery to be shipped. A 12-foot space is left between storehouse and forge shop for a branch of the tram tracks, as a convenient means of receiving material from the railway at this point.

Adjoining the storehouse is the carpenter shop, 40 x 60 feet. Thus the men who prepare the finished machinery for shipping are near their work, and the lumber used for this purpose, and the necessary machinery for cutting it up, are close at hand and require no unnecessary handling. In the angle formed by the storehouse and carpenter shop are the storage sheds for cast iron and steel chips from the machine shop, or for similar materials.

Along the side of the yard, and extending from the forge shop to within 20 feet of the foundry are arranged the stock sheds. These hold foundry sand and coal, engine coal, coke, etc., which is delivered into them directly from the railway cars, the track being raised to the proper grade after it has passed the storehouse. It is continued the whole length of the foundry so as to deliver foundry sand directly into the windows of the foundry if desirable, keeping that in the storage shed as a reserve supply. Between the storage sheds and foundry is a gate, through which may pass a branch of the tram car track for receiving stock and material from the railway cars at this point. Details of the plans herein outlined and the progress of the work from the raw materials to the finished product will be given in future articles. The second article will deal especially with the construction of the buildings.

Whatever may be the dimensions of the building of a manufacturing plant, or however carefully provision be made for all necessities for handling materials, etc., there is always the possibility, and frequently the probability, that some day the works will have to be increased in capacity or changed in form. It is, therefore, important to consider these points at the outset, and to provide for an expansion of the business in accordance with future needs and at the same time not to disarrange or break up the general plan of the works. With these points in mind, I give the two following plans for enlarging the machine shop when more room is needed: First, the building may be extended to the rear across the railway track, the rear wall being removed and the traveling crane tracks continued through the length of the additional building. Doors are provided for the passage of cars upon the railway track, and also a specially-built car habitually used for connecting the floors of the old and new building, its platform being on a level with the two floors. Thus the machine shop capacity could be increased to any reasonable extent. Second, one, two or three wings may be built at right angles to the machine shop and on the side opposite the power house. These might be of one or two stories and of any desired length. They may contain traveling cranes to convey material to and from the traveling crane of the main shop, or have convenient trolley hoists and train car tracks, according to the character of the work to be done.

The capacity of the foundry may be increased one-third by extending it toward the power house. The same space may be obtained by using for foundry space that provided for chipping, core and flask rooms and providing space for the latter by extending the building toward the machine shop. The space occupied by the wash room and water closet will, of course, be taken also and these rooms placed in a gallery, as heretofore suggested. To obtain additional power space for these enlargements the space occupied by the wash rooms and water closets may be utilized and these rooms provided for in an addition built toward the carpenter shop.

By some one of these plans, or a combination of them, the capacity of the works may be at least doubled without seriously disturbing the general plan here described and illustrated and without impairing the general efficiency of the facilities for handling the work.

This design is in as compact a form as is advisable, with a view to sufficient yard space. Where the amount of land is ample it would be manifestly desirable to spread out the design more by increasing the distance between the machine shop and foundry at the front, and the storehouse and forge shop at the rear; or by lengthening the machine shop 50 to 100 feet and thus add to the yard room.

Either or both these plans might be employed where the extent of ground would admit of it, as it is seldom we have too much yard room.

A so-called fluid lens has been invented by a Dr. Grun, of London, which has extreme rapidity. It is stated that it will produce excellent instantaneous photographs with artificial light such as might be had for example in a theater or other well lighted interiors.

THE LODGE & SHIPLEY DRAWING ROOM.

A WELL ARRANGED OFFICE HAVING NUMEROUS FEATURES OF INTEREST.

C. F. P.

The drawing room of the Lodge & Shipley Machine Tool Co., while small in comparison with those of many other large machine builders, has had much thought devoted to its equipment. This has been done with a view to securing facilities and conveniences that might assist the draftsman in full concentration of thought and energy upon the work in hand. Many improvements in drawing room equipment have recently been added and, as much interest has been manifested therein by visitors to the works, by special request I will endeavor to describe and illustrate some of them for the benefit of readers of MACHINERY.

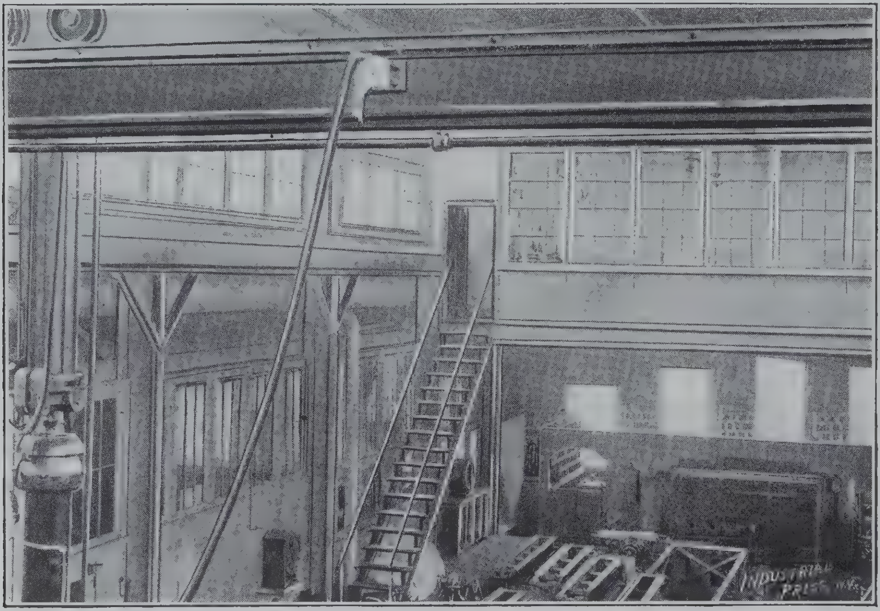

Fig. 1. View showing Location of Drawing Room at End of Shop.

Suitable quarters for the drawing room were not provided in the original plan of the building, and no room being available which would be convenient to the office and shop, it was decided to locate the necessary space 14 feet above the shop floor, at the office end of the building. This gives us a 15-foot ceiling in the drawing-room and a floor space of about 900 square feet, with light on all sides. Fig. 1 is an illustration showing the stairway to the drawing-room entrance and gives a fair idea of the location. Fig. 3 is an interior view of the northwest corner of the drawing-room, the vestibule landing of the stairway and entrance showing in the extreme left. In the center background of the illustration is shown the revolving blue-print rack, upon which is mounted a print of every standard, up-todate drawing of regular construction, indexed and arranged for the drawing-room force and shop foremen, for convenient reference. This rack, which is more clearly shown in Fig. 8, consists of 80 wings, each wing holding four 12 x 18-inch prints. The prints in the rack are so arranged as to bring together drawings of similar parts of all sizes. The details in the illustration are too small to be clearly seen, but it may be said in explanation that the rack stands open at "Reverse Plate" and shows the 18, 20, 22, and 24-inch prints; the 14 and 16-inch are on the reverse side of the left wing; the 27 and 30-inch on the reverse of the right wing, with the larger sizes following in the next wing in regular order. This system of mounting prints for reference is also used throughout the works.

In front of the rack is the card index cabinet, the upper unit of which is devoted to the indexing of all the drawings in the safe and file; all prints in the file and in the shop; all changes in regular construction; all material carried in stock, etc., etc., and is in a position easily accessible to the safe-and-file attendant and also to the drawing-room help. The lower unit faces the opposite way, and is, together with the base cabinet, devoted to the filing and card indexing of catalogues and printed matter intended for reference.

The safe shown in Fig. 3 contains 36 shallow drawers of galvanized iron, which are numbered and alphabetically labelled, an arrangement which allows the almost instantaneous locating of any drawing in the safe without reference to the card index. The fire-proof safe is used only for live drawings, and it is a rule of the room that all tracings be placed therein at night, thus insuring their safety in the event of fire.

The cabinet to the right of the safe consists of 150 shallow galvanized iron drawers, arranged the same as those in the safe, each drawing being numbered and labelled to indicate the contents. Fig. 7 shows the construction of these drawers more clearly and also the arrangement of labelling. The back of the drawer has an overlapping edge three inches wide which holds the sheets in position and prevents the back edges catching on the drawer above. No space is wasted, the drawer sliding in the grooved sides of the cabinet. The cabinet has a sliding door covering the entire front which when closed makes it dust-proof.

Fig. 4 shows the cabinet with door closed, and also gives an excellent idea of the arrangement of the tables to utilize the floor space to the best advantage. The tables in front of the windows, of which there are three, are for the use of the tracers, and each is fitted with a glass top for tracing, by transmitted light, either sun or artificial. This permits a tracing to be made even on heavy bristol board. Each draftsman is equipped with a drawing table, the construction of which is clearly shown in the several views of the room, and probably requires no further description.

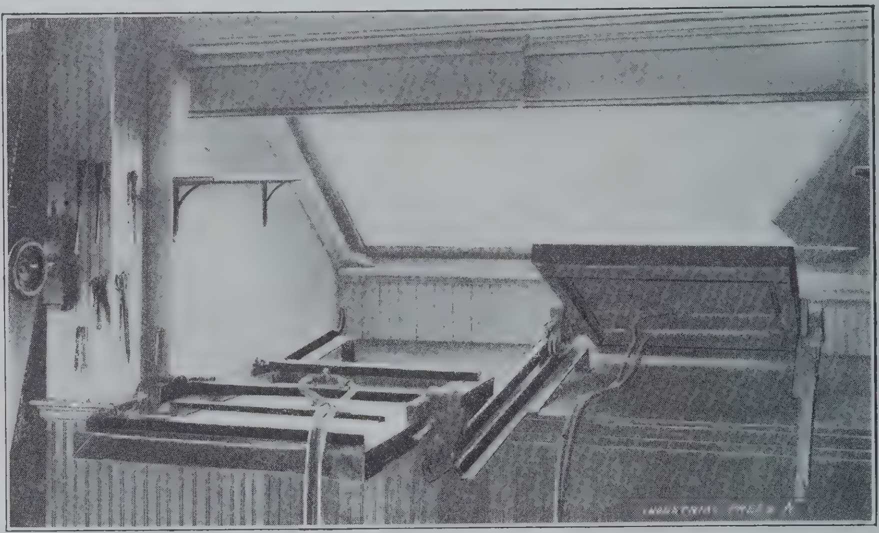

Fig. 2. Blueprint Frames and Window for Printing.

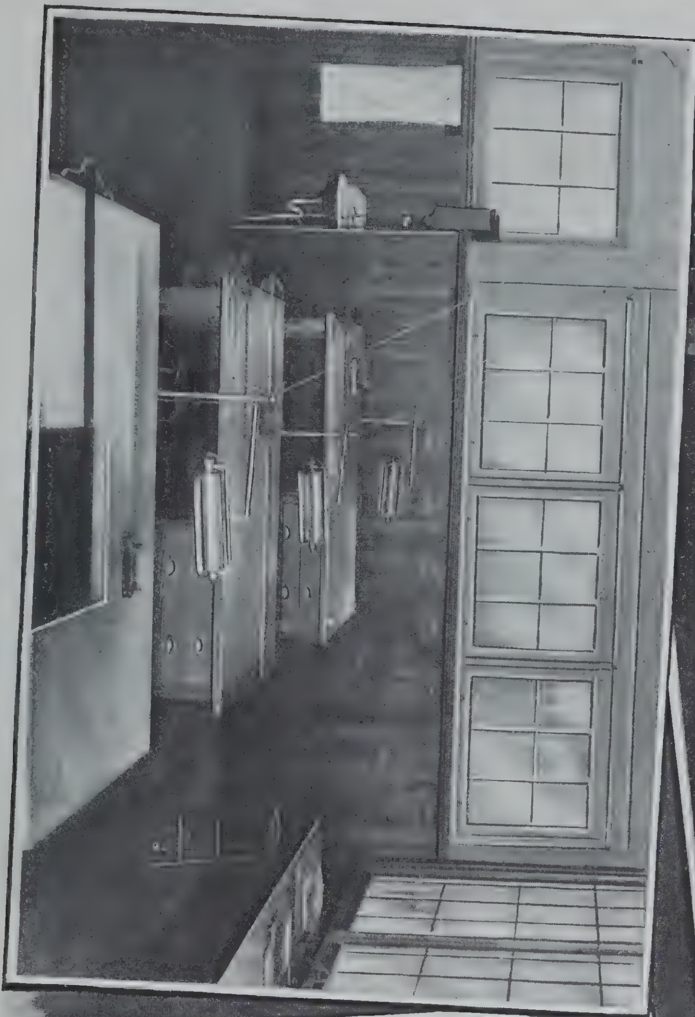
In Fig. 9 is shown in detail as well as complete the lamp we have made for use on the drawing tables. The vertical tube slips freely over the screw of C clamp; on this tube slides the cross carrying the horizontal telescoping tubes. At the outer end of the telescoping tubes is the elbow, in which swivels the T supporting the branches that carry the lamp and shade. The shade is of aluminum with wood and sheet brass ends. This arrangement allows placing the lamp in a way to get the full benefit of the light on any portion



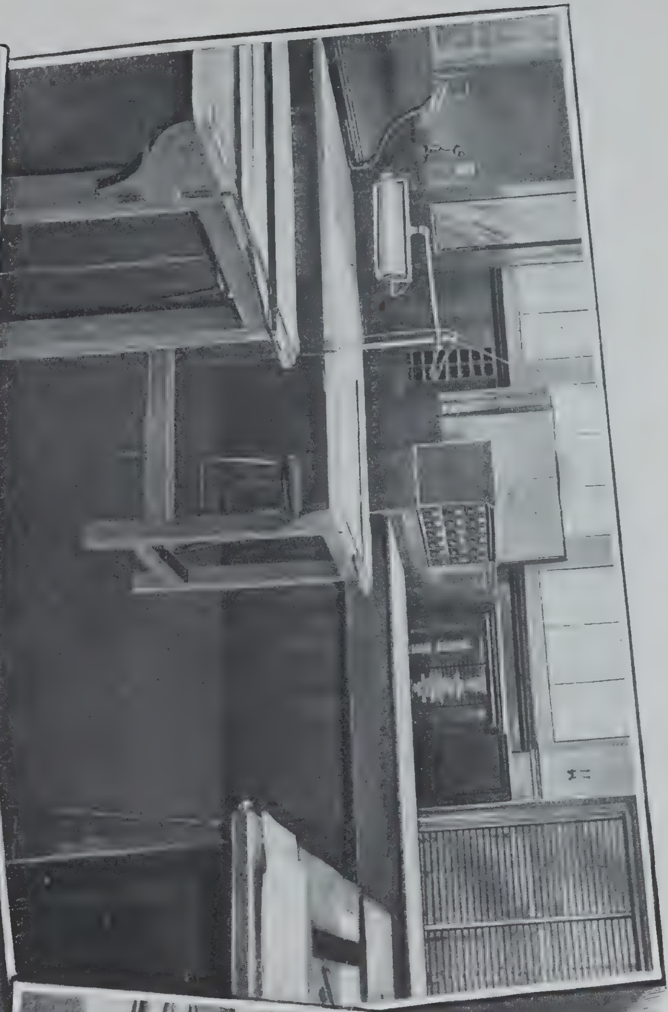


Fig. 3. Northwest corner of Drawing Room.
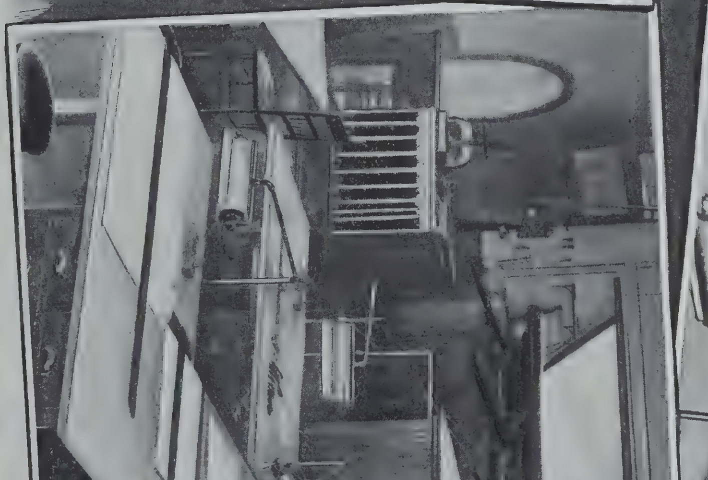
Fig. 5. Southwest corner of Drawing Room.



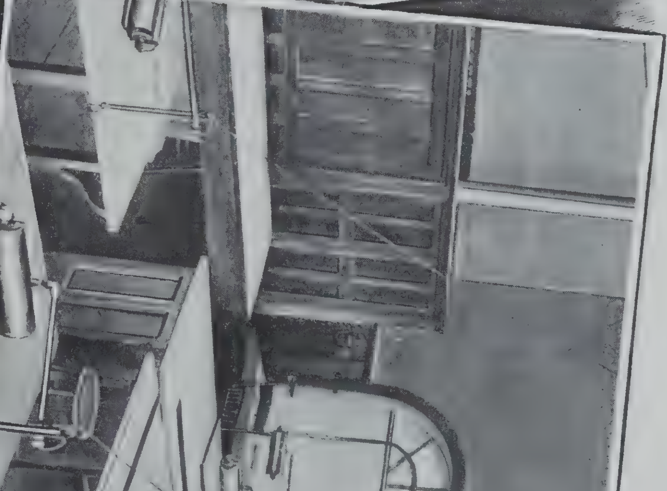


Fig. 4. Northeast corner of Drawing Room.
Fig. 6. Southeast corner of Drawing Room, showing Blueprint Department.

of a drawing on the table, and completely shade the eyes of the draftsman.

The southwest corner of the drawing room is shown in Fig. 5. Arranged along the wall under the windows is a series of lockers for the use of the employees, while to the left is ample provision for washing. At the extreme right is the reference table, provided for general reference purposes. It usually holds a supply of books, magazines, reference drawings, data sheets, etc. When this photograph was made it was being used to accommodate extra tracers.

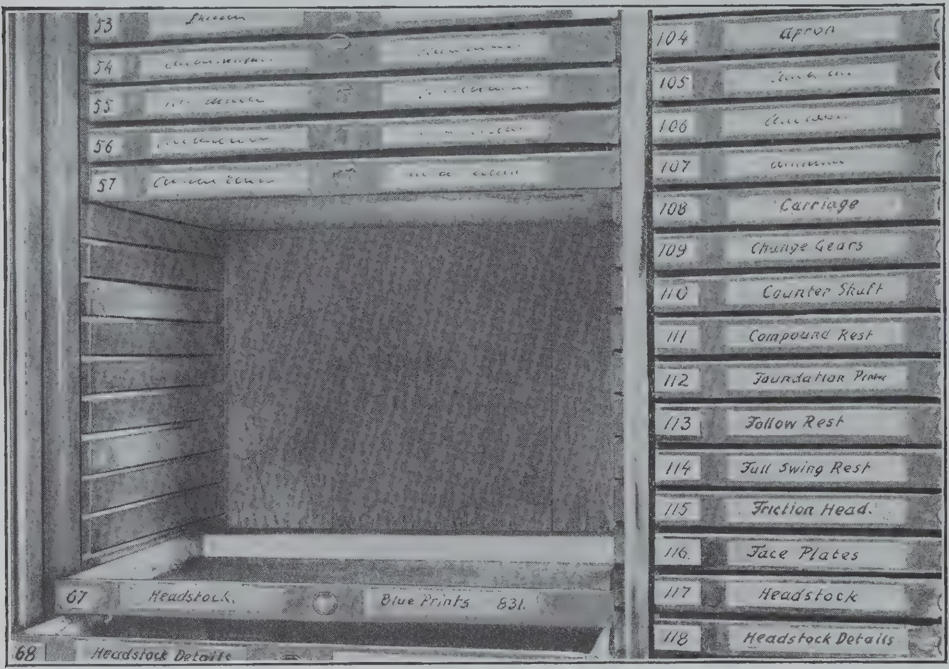

Fig. 7. Galvanized Iron Drawers of Print Filing Cabinet.

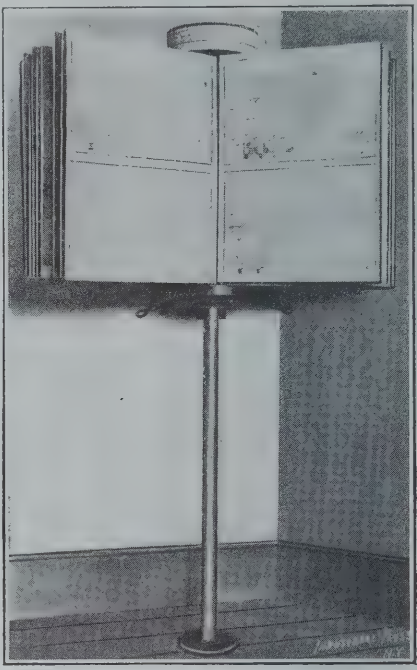

Fig. 8. Blueprint Reference Rack.

The blueprint department is located at the southeast corner, Fig. 6. In Fig. 2 is a larger view of the arrangement, which has several unique features. The blueprint frames are arranged on tracks under a plate glass roof, which allows printing in all conditions of weather when there is light enough for the purpose. The tracings and paper are held to the glass in the frame by atmospheric pressure by the use of a compressed air ejector to remove the air from between the glass and rubber blanket. This is a very convenient arrangement, and gives the most perfect prints from any kind of tracing, as the contact with the sensitive paper is bound to be absolute. One of the frames in Fig. 2 is shown in position for printing and the other for changing tracings. Shades are provided for cutting the strong light from the frame while changing the tracings. The frame carrying the rubber blanket, and to which is fastened the air hose, is hinged at the right of the glass frame and is fastened by buttons at the left. It requires but a few seconds after the blanket frame is closed for the air ejector to extract sufficient air from between the rubber and glass to allow reversing the frame. The shelves at each end of the plate-glass roof are used for small frames in cases where a single small print is required in a hurry, and for prints from negatives.

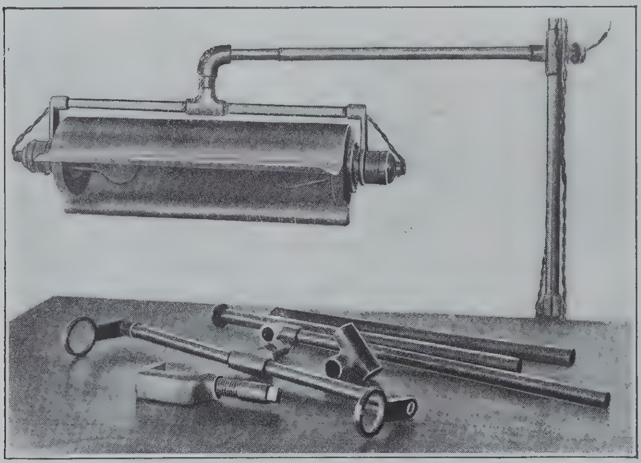

Fig. 9. Drawing Table Lamp.

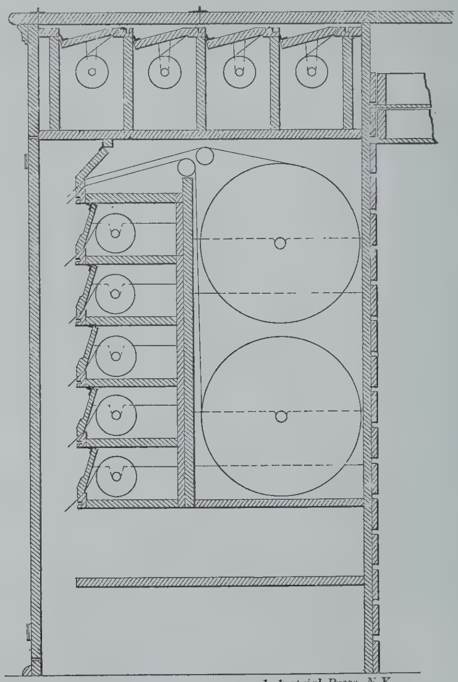
The blueprint washer and dryer is located in the corner next to the printing frames, and is designed to take as little space as possible. An endless chain carries the prints to the ceiling and back again in the drying process. The floor of this printing department is raised about two feet above the drawing room floor on account of the height of the windows on this side of the room. This height, far from being the handicap we anticipated, has proved to be rather in the nature of an advantage, keeping this department within its own limits, although decidedly limited in space.

The large cabinet of drawers in the center of the illustration, Fig. 6, is used for filing large sheets of original drawings or lay-outs, each drawer being assigned to a single size of lathe or class of drawings, and is of sufficient size to take in a sheet the full size of the drawing without folding. The top of this cabinet is partially covered with plate glass, which forms a table to be used for cutting paper, etc. The front



Industrial Press, N.Y.

Fig. 10. Sectional View of Cabinet for Storing Blueprint and Drawing Papers.

end of the cabinet is arranged in compartments for storage of rolls of blueprint and drawing papers, and a sectional view is shown in Fig. 10. The four compartments at the top, access to which is secured by raising a section of the top of the cabinet, is reserved for the print papers, four kinds of which are always on hand, and any amount of either can be drawn out without exposing the roll to the light. The compartments on the sides are used for tracing cloth and drawing papers, while the large central compartment is for detail paper and wrapping paper which we use largely for covers to protect the drawings sent into the shop. The cover of each of these compartments is held in place by spring hinges which hold it against a hardwood strip provided with a groove for guiding the knife in cutting the paper.

At the left of the view, Fig. 6, is a cabinet for the storage of extra small drawing boards. On the top of this cabinet is a shear for trimming prints and cutting paper into our standard sizes for use on the tables; also a letter press, used principally for the binding process through which all our data sheets are put. This cabinet has recently been replaced by a table similar in size and construction to the tables used by the draftsmen. Ventilation and cooling in summer is effected by several electric fans and also by a motor-driven exhaust fan mounted in the ceiling.

Visitors are cordially welcome at the Lodge & Shipley plant, and the writer will always be glad to show a Machinery reader through the company's drawing-room.

STEEL AND ITS TREATMENT.—2.

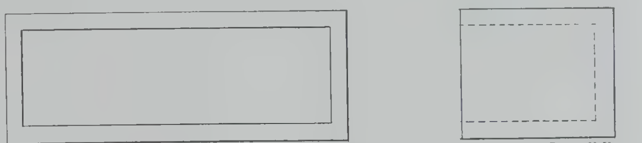
METHODS OF HEATING STEEL.

E. R. Markham.

As stated in a previous article, it is very necessary in order to get satisfactory results that steel be heated uniformly for hardening. In order to get uniform heats when hardening work in large quantities, various methods of heating are used, the method generally depending on the facilities furnished in the shop where the work is done. For instance, if in a shop ten thousand pieces of work are to be hardened, the equipment of the shop is oftener taken into consideration than the very best method of doing that particular piece if it entails an outlay of money to instal the better method. This way of doing is necessary, unless the amount of money saved by the addition of the extra equipment would pay for itself or produce an article enough better in quality to cover the expense incurred. For example, if a manufacturing concern had fifty thousand bicycle cones to harden, and their only method of heating them was an open fire, of the form of a blacksmith's forge, it would cost (estimated) 50 cents per hundred; provided the work was done by a man sufficiently experienced to get satisfactory results. The total cost for hardening the lot would be $250 for labor. Now if a lead-hardening furnace were used to heat the cones, the cost of hardening could be reduced to 10 cents per hundred or a total cost of $50 for labor, saving $200. And as a lead-hardening furnace large enough for any ordinary work can be purchased for $125, the cost of installing the furnace would be saved, with an additional saving of $75. The cost (50 cents per 100 cones) of heating in an open fire is simply an estimate and is given for the sake of illustration; while the amount of 10 cents per 100, given as cost of heating in the lead-hardening furnace is taken from a book of piecework prices paid for work when I was connected with a concern manufacturing bicycles; the men making very satisfactory wages at the rate mentioned.

Many pieces of work may be heated at one time in a large muffler furnace at a much less cost than if an ordinary open fire were used, and with much more satisfactory results. If the work is done in large quantities the price of the muffler furnace may be saved. This is to show the young hardener that the matter of equipment is generally looked at by the manufacturer from a commercial standpoint. If the manager, superintendent, or those having the purchasing of equipment in charge, can be convinced that a saving in cost of production, without a deterioration in quality of product, can be accomplished by the purchase of additional equipment, they are generally very willing to go to the necessary expense. And even if they feel they cannot purchase the equipment advocated, they look upon it as a very favorable sign when a young man is endeavoring to, in any manner, decrease the cost of production in the shop. And the manager, when he finds it necessary to put someone in a responsible position, will certainly favor the man who shows an untiring interest in the welfare of the concern employing him.

When large quantities of small pieces are to be heated for hardening and an ordinary forge is the only means obtainable, a number of pieces of gas pipe of suitable size and length may answer. One end should be closed by means of a cap screwed on, or a piece of steel or iron may be made to fit the hole in the pipe, and a piece ⅜ inch to ½ inch thick may be fastened in one end with screws or pins. The pieces to be hardened are then placed in the tubes, care being taken that no more pieces are put in at one time than can be heated uniformly. If a number of pieces of pipe are used at a time there will be a saving in cost.



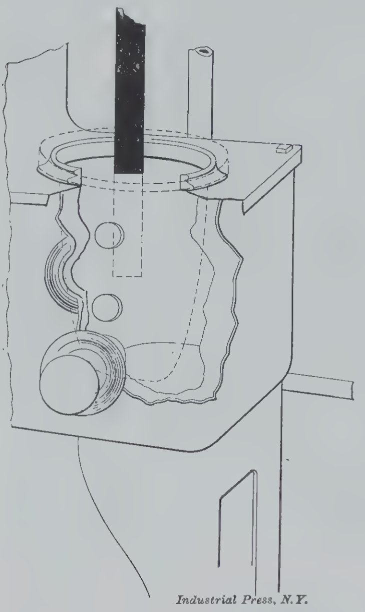
Industrial Press, N. Y.

Fig. 1.

It is possible to make an oven of the form shown in Fig. 1 for use in heating articles in the open fire. This may be placed on two pieces of brick or iron in such a manner that the fire may be under, on top, and at the back of it; the coals may also be piled up at the ends. The work which is supposed to be inside the oven and on the bottom heats very uniformly. When the work is first put in this receptacle it may be placed near one end, then as it heats it may be moved toward the center. In this way it does not heat too rapidly, neither do the cold pieces as they are placed in position at the ends chill the pieces in the center, which are red hot and are allowed to remain a few minutes in order to become heated uniformly throughout. A crucible of red-hot lead provides an excellent means of uniformly heating work in large quantities. A ladle, dish or crucible of lead may be heated in an ordinary forge and very satisfactory results obtained in heating the work. This, however, will necessarily be a slow method as compared with furnaces made specially for the purpose. But if obliged to heat the lead in this manner, bricks may be so arranged as to make a place for the crucible and allow the fire to be under it and around it, which furnishes a very uniform heat. It will be found necessary, however, to raise the crucible occasionally and poke the coals underneath it; the lead will also cool somewhat when fresh coal is placed on the fire. The very best results can always be obtained if steel is hardened at the refining heat, that is, the steel should be heated to that degree that when plunged in the bath and hardened the fracture (if the piece be broken) will show a very fine compact grain. Consequently it is necessary to keep the lead at the proper temperature, as nearly as possible, to produce the desired result. If it becomes too cool do not attempt to use it; wait until it is at the proper temperature. If it should get too hot do not continue using it, thinking it will soon cool off. Every piece heated when the lead is in this condition will not give the results it should. If the lead becomes too hot plunge a large bar of cold iron or scrap steel into it, allowing it to remain until it absorbs the extra heat and reduces the temperature of the lead to the proper degree. Then, and not till then, it is safe to go ahead with the work.

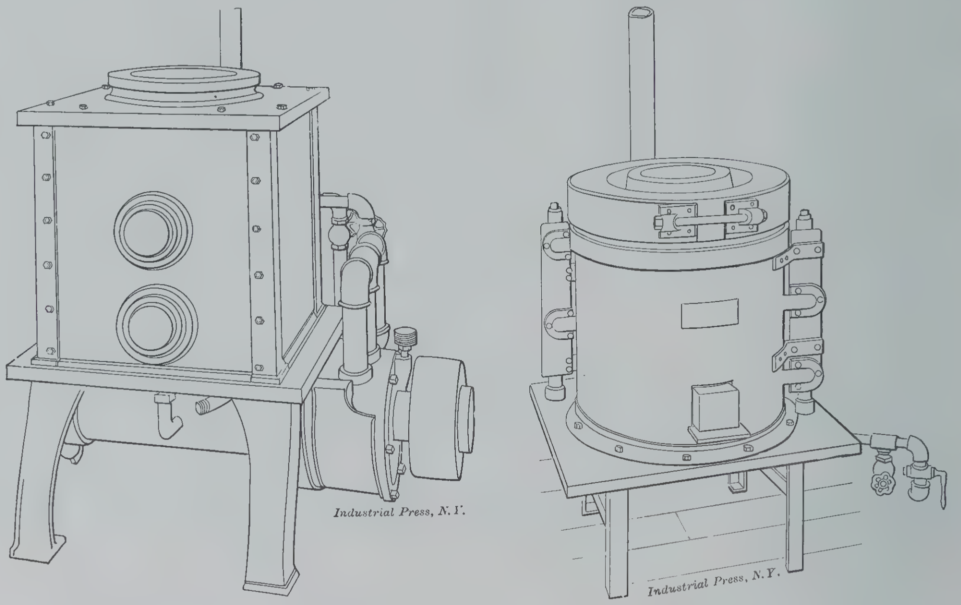
One reason why so many fail to get satisfactory results in the use of red-hot lead as a heating medium for hardening steel is because they use a quality of lead unfitted for the purpose. Steel, when in a red-hot condition, is very susceptible to impurities, and the ordinary grades of pig lead are apt to contain impurities very harmful to steel. For this reason scrap lead of an unknown quality should never be used; neither should any brand of pig lead containing sulphur be allowed to come in contact with red-hot steel. I always make it a point to use nothing but chemically pure lead in a crucible to be used for heating steel.

To prevent the surface of the lead from oxidizing from the action of the air upon it the top of the lead should be covered with charcoal, broken in pieces the size of a walnut. This also has a tendency to keep the surface from chilling as the charcoal catches fire and burns. The surface of the lead will oxidize somewhat, however, forming what is familiarly known as dross. This should be skimmed off occasionally or it will stick to the work in spite of all precautions taken to prevent it. As the surface of the lead is exposed to the air and is cooled somewhat by it, and as the tendency of the fire is to heat the lower part of the crucible hotter than the top, it is necessary to occasionally stir the lead in order to obtain uniform heats. This is especially true if long pieces projecting down into the lead are to be heated.



Industrial Press, N.Y.

Fig. 2. Heating Steel in a Lead Bath.

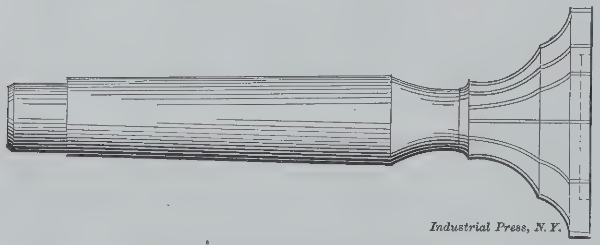


Industrial Press, N.Y.

Industrial Press, N.Y.

Figs. 3 and 4. Types of Gas-heating Furnaces.

Many mechanics object to the use of red-hot lead for heating steel because the lead has a tendency to stick to the steel, which is especially the case in heating tool steel at a low heat. The higher the heat the less tendency the lead has to stick to the steel; but it is not advisable to overheat steel simply to prevent the lead from sticking, and for this reason many have abandoned its use rather than spoil the tools they wished to harden. But there are several dips that may be used which will effectually prevent lead sticking to steel when at the proper hardening heat. Some use a strong solution of salt and water, dissolving all the salt possible in a dish of water; others use a solution of cyanide of potassium and water, dissolving one pound of cyanide in one gallon of water. The cyanide should be crushed or pounded fine and dissolved in boiling water. Great care should always be exercised in the use of this chemical as it is very poisonous. If the solution is not strong enough a greater proportion of cyanide may be added. When using either of the above solutions the work should be dipped in them and allowed to dry before putting it in the lead. For any form of moisture is converted into steam when brought into contact with the red-hot lead, and this will cause the lead to sputter and fly, and wherever these particles strike they are very apt to burn, especially if they strike in the eye. A very good plan is to place the pieces of work, after dipping in the solution, on top of the furnace or on the bricks of the open fire mentioned, allowing them to remain there until dry, when they may be placed in the lead. If a number of pieces are placed in the lead at one time and an equal number approximately are dipped in the solution and put in position to dry, then the work may be done in rotation, that is, while the pieces in the lead are heating, those on the furnace will be drying. As soon as the pieces in the lead are sufficiently heated they are taken out, one at a time, with hook or tongs and plunged beneath the surface of the lead to insure even heating. Then the piece is removed and dipped in the hardening bath. While the pieces are heating it is advisable to turn them occasionally in the lead to insure uniform results.



Industrial Press, N.Y.

Fig. 5.

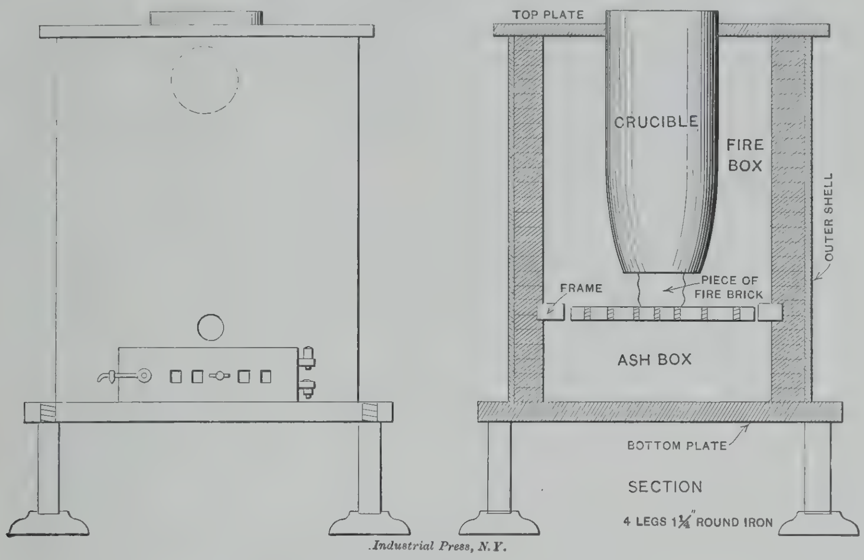
A piece of steel heated in red-hot lead in such a manner that a portion of it was not submerged in the lead, as shown in Fig. 2, should be moved up and down in the lead a trifle to avoid what is known as a fire crack. That is, the steel below and at the surface of the lead would be subjected to an intense heat, while the steel above the surface would be at nearly its normal temperature; and as the effect of the heat is to expand the steel, the point where it ceased expanding would be at or about at the top of the lead, and if held stationary in the lead the effect on the steel is liable to be disastrous. To avoid any such result the piece should be raised and lowered somewhat in the lead, distributing the strain over a larger surface and thus doing away with the tendency to crack. If pieces of irregular contour, differing greatly in size at different portions as shown in Fig. 5, are to be heated in lead, it is advisable to heat them nearly to a red in an open fire or in some manner to avoid the unequal strain to which the piece would be subjected were it to be plunged when cold into red-hot lead. It would be impossible for the large and small portions to expand equally, and the consequence would be a crack or innumerable cracks; and, unless the operator were aware of the effects of violent, uneven heats on high carbon steels, these cracks would be laid to the bath, that is, he would think the steel cracked in the cooling bath, when in reality the cause was sudden expansion rather than contraction. If the fracture were examined the walls would be found black, whereas if a piece cracks from dipping in the bath the surfaces of the fracture will be bright. They may be stained by the contents of the bath coming in contact with them, but they will not be black.

When articles having fine teeth such as rotary files, cherries, small reamers, milling machine cutters, etc., are to be heated in lead, a paste may be made that will prevent the lead sticking between the teeth, even when the dips mentioned fail to give good results. The kinds and proportions of the ingredients are given in the following table which is taken from the report of the Chief of Ordnance of the U. S. War Department:

Pulverized charred leather............	1	pound
Fine family flour......................	1½	pound
Fine table salt........................	2	pounds

The charcoal made from the charred leather should be crushed until fine enough to pass through the meshes of a No. 45 sieve.

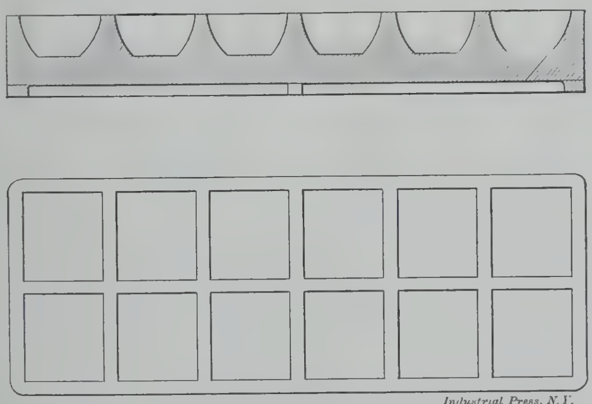
The ingredients are thoroughly mixed in a dry state, and water is added slowly to prevent lumps until the paste has the consistency of ordinary varnish. The paste is applied with a brush. The articles are placed where they will become thoroughly dry; yet they must not dry fast enough to cause the paste to crack, neither must the pieces be put in the lead until thoroughly dry or the steam generated will cause the lead to fly, as before explained.



Industrial Press, N.Y.

Fig. 6. Heating Furnace for use with Hard Coal.

If large pieces of steel or tools of irregular contour are to be heated in lead and it is not possible to heat nearly to a red in another fire with a slower heat, the article may be immersed in the lead and withdrawn, then immersed again, leaving it a trifle longer than the first time. This operation is to be repeated until the steel has absorbed enough heat to preclude the liability of cracking. Then it may be left until it is heated uniformly throughout to the desired heat.



Industrial Press, N.Y.

Fig. 7. Mold for Lead when Poured from Crucible.

The question may be asked, If pieces of the shapes mentioned can be better heated in a slow fire until nearly to a red, why not heat to a red and do away with the lead crucible entirely? The object in finishing the heat in the lead is that once the lead is brought to the proper temperature any number of pieces may be heated uniformly, provided proper attention is given the lead. According to my experience, red-hot lead provides an excellent means of heating small tools or parts of machines, etc., when the work is hardened in large quantities and when the cost of labor is a factor to be considered. For this method to be a success when considered from a commercial standpoint, it is necessary to provide some means whereby the lead may be kept at a uniform temperature throughout the entire working day, or, at any rate, such portion of it as needed for the necessary amount of work. If a furnace burning illuminating gas can be procured it will be found one of the most satisfactory and most economical methods of heating where the price of illuminating gas is not too high. Very satisfactory forms of gas-burning furnaces are shown in Figs. 3 and 4. If not situated where illuminating gas can be procured at reasonable rates, and it is not considered advisable to instal the necessary apparatus for heating by gasoline or oil, a furnace may be made to burn hard coal, coke or charcoal. While it is not generally considered possible to maintain as even a heat as with gas, yet by exercising reasonable care very uniform results may be obtained.

Fig. 6 shows a sectional view of a furnace intended for burning hard coal. The outer shell may be made of cast iron, although it is often possible to find at a junk dealer's an old boiler which can be bought for a "song." A piece the proper length may be cut from this that answers admirably for the outer shell. A round grate and the necessary frame to support it may be procured from a stove dealer. A grate of the form used in the ordinary cylinder parlor stove answers every purpose. The frame should be attached to the shell or blocked up sufficiently high from the plate which supports the outer shell to allow the grate to be turned in dumping the contents of the furnace. It is necessary to cut an opening in the front of the shell at the bottom, which should be covered with a door containing a sliding damper. This door is necessary in order to remove the ashes. The inside, from the frame to the top of the shell, should be bricked with circular fire brick, or, if possible, with a stove lining of the proper size. Over the top must be placed a plate having a hole in the center one-half inch larger than the size of the top of the crucible to be used. A smoke pipe must also be provided, to carry off the smoke and gas from the fire. This can be connected with the shell at the top on the back side of the furnace, and should also be connected with a chimney and provided with a damper for use in regulating the draft. The plate covering the top of the furnace may be cast in two pieces, having more than half the hole in the part that goes at the back. The smaller or front half may be moved forward, thus affording an opening to feed the coal to the fire. The object in having more than one-half the hole in the back part of cover is to prevent the crucible from tipping over when the front plate is moved if there were not sufficient coal in the fire to support it. It is also necessary to rest the crucible on a piece of fire brick as shown in Fig. 6. If a black lead crucible is used to hold the lead, much better service can be obtained if the crucible is annealed before using. In order to do this the crucible should be placed in some fire where it can be heated all over to a red heat. It should then be removed and placed where no current of air can strike it and allowed to remain until cold. It will then last much longer than if used without annealing.

It is necessary to remove the lead from a black lead crucible before it cools and solidifies, or the crucible will crack when heated again. When doing this it is dipped out with a ladle until the crucible is nearly empty, when it may be removed with tongs and the balance of lead emptied out. As it is necessary to put the lead in the crucible in small quantities when heating, it is advisable to have a mold made, of the form shown in Fig. 7, to turn the lead into when removing from the crucible. This mold resembles a muffin pan, and the compartments serve to cast the lead in pieces of the proper size to put in the crucible when reheating.

If the above instructions are carefully followed excellent results will follow the use of this method of heating; but if scrap lead or pig lead of an inferior quality is used then trouble will surely result. My advice would be: Rather than to attempt doing things by halves, do not attempt the use of red-hot lead for heating tool steel.

A foreign writer, Aug. F. Weiner, states that the addition of a small quantity of ferro-vanadium has the property of raising the tensile strength of mild steel by from 50 to 66 per cent.—*Sparks from the Anvil.*

EARLY MACHINE SHOPS AND MECHANICS.

HISTORICAL NOTES ON THE DEVELOPMENT OF THE MACHINE SHOP DURING THE EARLY PART OF THE NINETEENTH CENTURY.

The last century was remarkable for being a distinctly mechanical era. At its beginning the machine shop scarcely existed except in the most primitive form, and machinery of any but the crudest types was practically unknown. The clock and the watch of that time undoubtedly represented the highest development of any mechanism built for specific purposes. Agriculture and other industries were being pursued in almost the same manner as at the beginning of history. Transportation on land was effected by rude carts or wagons drawn by animals and on water by vessels propelled by sails or oars. The steam engine was just beginning to be recognized as a prime mover, but was generally unknown.

At the end of the nineteenth century, how are the conditions changed? The implements and machines for agriculture alone are almost unnumbered. The farmer sows the seed, reaps the harvest and threshes it by machinery. The steamship, locomotive and trolley car have come to be necessities for transportation. The steam engine is the prime mover of thousands of mills and factories and does the work of myriads of horses and millions of men. In every industry that then existed nearly every feature has been changed and many new industries have sprung into existence as a result of general mechanical development.

The building of machinery requires machine tools and the machine shop. The construction of the first steam engines, when the machine shop was in its infancy, were undertakings attended by almost unsurmountable difficulties. The machine shop became a necessity and has so developed that it is now an important factor in every industry and directly or indirectly influences every trade and profession.

In 1800 the pole lathe was the principal machine tool in use, although there were a very few lathes in existence having a rotating spindle driven by a band from a flywheel turned by a foot treadle, and some other minor improvements. The pole lathe was about the simplest imaginable affair to be dignified by the name of machine, being little more than the primitive lathe of the ancient Egyptians. It consisted of a wooden frame set on legs and carrying a pair of poppets which held the dead centers on which the work revolved. The work was alternately rotated forward and backward by a cord wound around the work and fastened at one end to a pole or lath (from whence the name lathe) secured overhead. The lower end of the cord was usually made into a loop through which the operator thrust his foot to exert the motive power. A foot treadle was sometimes employed instead of the loop, the end of the cord being secured to one end. The disadvantage of having the work turn first forward and then backward led to the employment of means for making the rotation continuous. The first steps in this direction appear to have been by winding the cord around the work so that the work would be turned forward on the down stroke of the treadle, and when the pressure was removed so that the pole or lathe returned to its original position, the motion of the piece being turned would continue in the same direction on account of the peculiar arrangement of the cord. This scheme, however, never became popular as a large portion of the power exerted was lost in friction of the cord. With such a tool the turning of a piece of metal with any degree of accuracy was extremely difficult, since the operator was obliged to stand on one foot and manipulate his tool against the surface of work alternately turning in opposite directions.

The first rotating spindles for lathes were made from square iron turned for the front bearing and threaded on the end for the chuck. The thread for the chuck was sometimes made internal but the usual practice was to make it external, as now holds. The tail bearing of the spindle was formed by a pointed setscrew held in the back poppet head and engaged in the end of the spindle. The spindle thus turned in a box at the front and on a pivot at the back end. This arrangement had two advantages: It afforded a simple means for taking the thrust and also taking up the end play, and reduced the frictional resistance below that which would have resulted with the shaft running in two boxes. When the latter construction was finally adopted to obtain greater stability, the back bearing was kept as small as possible to make the shaft run easily. The influence of this practice is seen in most modern engine lathes to-day when the reason for it no longer exists.

The shears of the old time lathes as well as all other parts except the spindle and centers were made of wood. The head poppet being made in two parts framed into the bed, it was almost impossible to keep the spindle in alignment with the tail center. To obviate this trouble J. J. Holtzpffal, England, made a headstock in 1794 of cast brass having its base and the front and rear bearings one integral part. This was found to be such an improvement that headstocks were subsequently made of cast iron by him. The patterns were made so that the sections of the castings were generally of uniform thickness, as is the present practice, instead of following the square shapes of the wooden parts made by the carpenter.

The most important improvement, however, ever made in the lathe and which is a distinguishing feature of every modern machine tool except the drill press, was the invention of the slide rest by Henry Maudslay in 1794. Maudslay was at this time a workman in the shop of Joseph Bramah, generally known as the inventor of the hydraulic press. This invention replaced the cutting tool held in the uncertain grasp of the workman's hand by a tool held in a hand of iron and it furnished the means of guiding the cutting point in mathematically straight lines. The slide rest made accuracy possible and enabled the production of perfect cylinders in the lathe and later the production of accurate plane surfaces in the planing machine. The slide rest at first was generally opposed and ridiculed by the workmen who nicknamed it "Maudslay's go-cart," but it was not many years before it became commonly used, as was its manifest destiny. While the invention of the slide rest was undoubtedly original with Maudslay, it appears to have been anticipated by many years in France, having been illustrated in the French Encyclopedie published in 1772. The latter device differed materially from the invention of Maudslay and as it had apparently never been developed beyond an experimental stage, or if so, had been allowed to go out of use, it is to Maudslay that we should give the credit for undoubtedly the greatest improvement ever made in machine tools.

The wood-working machinery erected in Portsmouth dockyard in 1807 under the direction of Maudslay, marked an important step in labor-saving machinery and had an important effect on the future design of metal-working tools. The machines were designed by Brunel and Bentham principally for the production of tackle blocks and when completed enabled 10 men to do the work of 110 men and in a far superior manner. These machines are said to have effected a saving to the English Government of about $120,000 annually. The making of tackle blocks was an important part of the equipment of a man-of-war, as a 74-gun ship had 1,400 blocks of various sizes.

* The illustrations accompanying this article are taken from "Turning and Mechanical Manipulation," by Charles Holtzpffal, published in 1843.

It is thus apparent that at the beginning of the nineteenth century the lathe, while yet a very crude affair, was with Maudslay's invention of the slide rest, the progenitor of the wonderful machine tools which are produced from, and in turn make possible, the modern machine shop.

The importance of the screw as a machine element and as applied to studs and bolts for fastening machine parts together, was early recognized, but no means had ever been devised for securing ease of production and uniformity of product until the invention of the screw-cutting lathe. To whom this honor is due does not appear to be exactly clear. The first mention of a lathe arranged for screw cutting is that of Jacques Berson, a Frenchman who had a primitive rig arranged for cutting spirals in wood and which was subsequently arranged to cut threads in metals. A cut of this device is to be found in some old books which give a dim idea of its operation although it is hard to understand how such a crude tool could have been operative. In 1648 engravings were published in Rome of two curious machines, called by courtesy lathes, for the production of plane, spherical and hyperbolic mirrors. The cutting tool in these machines was held in a sort of carriage mechanically controlled so that if need be the same machines could have been adapted to the cutting of helices although there is no evidence that this was ever done. Another lathe referred to by historians is that of Joseph Moxon, about 1680, for the production of "swash" work, which was then very popular. It is said that Moxon made these lathes for sale and that they were much sought after, as they were well made and generally excellent tools. Again, there is no evidence to show that they were specially adapted to the production of screws, although the tool was mechanically controlled and could have been arranged to secure the result with little more complication. A machine appears to have been used by the early watchmakers for the production of screws, working on substantially the same principle as the screw-cutting lathe, although it was adapted for the production of only one lead. The face plate on the spindle (it being a rotative spindle), was a gear and meshed in another gear mounted on a screw running parallel with the shears, as in the modern tool. The carriage was furnished with a nut engaging with the screw, so that the production of screws of various diameters but of uniform lead was possible.

Fig. 3. Allen's Device for Originating Screw Threads for Astronomical Work.

Another method which appears to have been extensively used, was that of having a thread cut on the spindle which was arranged to slide longitudinally in its bearings. The work was held in a chuck and the tool remained stationary, as in Healey's lathes of 1804. A nut being engaged with the screw on the spindle, the same lead was generated on the piece held in the chuck. One elaborate machine is illustrated in Holtzpffal's "Turning and Mechanical Manipulation," in which the idea was carried out so that ten different leads could be cut in this manner, ten screws being cut on the spindle along a portion of its length and ten half-nuts with supporting keys any one of which could be engaged as desired. It is probable, however, that this machine was built after 1800.

The various means adopted by the old-time mechanics for the production of original screws, are very interesting but can be only briefly touched on here. One was to wrap a strip of paper around the blank cylinder of metal or wood as the case might be, so that its edge would form a helix of the desired pitch. This edge gave the workman his guide for the cutting tool when the piece was mounted in the lathe. Imagine cutting threads in such a manner!

It is recorded that Anthony Robinson at the Soho works of Boulton & Watt made in 1783 an original screw seven feet, six inches long and six inches diameter with a triple square thread, pitch not given. The thread was laid out by wrapping a sheet of paper around the blank so that the edges when trimmed just met. The paper was then removed and the threads laid out as lines running across the paper at the proper angle, Robinson evidently understanding that a screw is the same as a right triangle wrapped around a cylinder so that the hypothenuse is the helix, the base the circumference and the altitude the pitch.

Fig. 4. Maudslay's Thread Correcting Device.

After the lines were laid out and inked, the paper was replaced on the blank and the lines pricked through the paper into the metal underneath. The paper was then again removed and one thread, shallowly chipped and filed out. The partly formed screw was then stood on end, being thrust through a shallow square cast iron box. The hole in this box around the cylinder being luted with clay, it was filled with melted lead, and when the lead cooled, the cast iron box formed a rude nut on the unfinished screw. A cutting tool was rigged on the face of the box with proper adjusting devices so that it could be fed into the cylinder and then the box having levers attached was handed around by the lusty workmen. In this manner the other grooves were cut of the same pitch as the first and the first finished to the desired depth. The recital of these operations gives some idea of the tremendous difficulties encountered in machine construction at the beginning of the century.

The problem of accurate screw cutting was one that peculiarly appealed to Maudslay, as he had a keen appreciation of the desirability of such a condition and of the immense advantages to be secured by its solution. Some of Maudslay's efforts in the line of accurate screw cutting after becoming the proprietor of a shop would not be half bad now if the records can be believed. He is said to have made a screw for astronomical work 60 inches long, 50 threads per inch, on which was screwed a nut 12 inches long, so that 600 threads were engaged at the same time. The old timers evidently had a keen appreciation of the law of averages, as is shown by the use of the long nut. The importance of standard planes and surface plates was appreciated by Maudslay, who supplied them in numbers in his shop and required all plane surfaces of importance to be perfected by their use. He also believed in exact measurements and had a bench micrometer called the "Lord Chancellor," as it was the court of last resort in the matter of measurement and by it the system of gages used was derived. The invention of the micrometer did not originate with Maudslay, but is claimed for William Gascoigne in 1648.

Figs. 5 and 6. Inserted Cutter Lathe Tools used in Portsmouth, England, about 1830; and Inserted Cutter Reamer of about the same date.

Maudslay's work in the production of accurate screw threads seems to have been principally along the lines of generating a thread by a tool set at the required angle for the thread and after getting one perfect helix, to reproduce it by the combined angular position of the cutting tool, together with a guide finger working in the helix already cut. He evidently considered that a mechanically operated carriage introduced an element of uncertainty which was fatal in the days of slender and inaccurate construction.

One thing is certain that although Richard Roberts brought out an improved screw cutting lathe in 1816, the art of cutting threads by a mechanically controlled carriage did not for many years become general. There are old mechanics living to-day who remember well the trials and struggles of their apprentice days when learning to use the chaser for cutting a thread. The tyro was very likely to produce a thread irregular in travel, having a wavy appearance and aptly characterized as "drunken."

The work of Maudslay in the production of accurate screw threads was followed by that of Clement and Whitworth in England and Sellers in the United States, to the latter two of whom we are indebted for the modern system of interchangeable screw threads in England and the United States.

Joseph Clement of Manchester was the first to make taps having their thread numbers in proportion to the tap diameters. He was also the originator of the form of tap having the shank smaller than the hole tapped, so that the tap could be passed through without backing out. Clement's taps were fluted by a revolving cutter similar to the method now followed. This was in 1828, but the use of the milling cutter or circular file as it was then known seems to have been known many years previously. There are records showing that the milling machine was used in this country in 1818 at Middleton, Conn., and mention is made of the use of toothed cutters in 1664 by a Dr. Hooke, for cutting gear wheels. It is also recorded by Chas. Holtzapffel that inserted cutter thread and turning tools for the lathe were in use as early as 1830. The cuts given show that they were very similar to those now used.

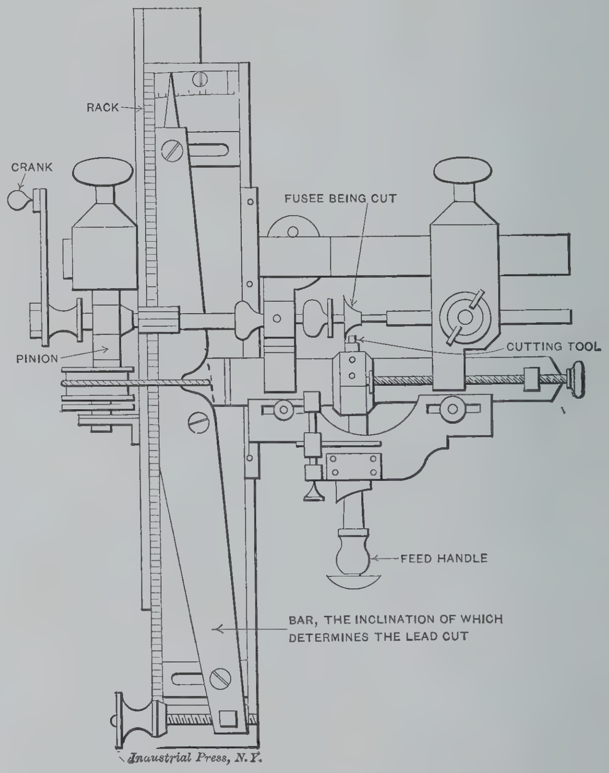
Fig. 9. Showing that Thread Rolling is not a Recent Invention

In the construction of the first lathes having beds of metal, great difficulties were met in getting the beds straight and accurate as the planing machine was practically unknown. To get a form that would require a minimum of fitting, the beds appear to have been at first made in triangular section. All fitting and accurate work was thus confined to one angle which also had the effect of holding the slide rest in position both vertically and laterally.

The invention of the metal working planer is variously ascribed to Roberts of Manchester, Fox of Derby, Matthew Murray of Leeds, Spring of Aberdeen, Clement and Rennie of London, who all appeared to have had some sort of planing machines at work from 1814 to 1820. Whether Murray's claim to the invention of the iron planer is valid or not, it is certain that he was a mechanic of no mean order as he designed and built a commercially successful locomotive in 1812 for the Middleton Colliery Tramway, Leeds, which ran for nearly fifty years before being relegated to the scrap heap. This locomotive burned coal.



Industrial Press, N.Y.

Fig. 10. Le Lievre's Device for Cutting Fusee Threads.*

Joseph Bramah patented a planer in 1802 with a revolving cutter, but it was primarily designed for wood and appears to have been used for this purpose. There are records showing that Nicholas Torq, a French clockmaker, used a metal planer in 1751 for *boring* pump cylinders, apparently being under the impression that they could be made more accurate in this manner than by a revolving cutter. It is to Clement, however, that the honor of bringing out the first iron planer on the same lines as the tool is now built, evidently belongs. He had a machine in operation for planing the triangular bars for lathes in 1820 and built a more elaborate one of which a description was published in 1825. The cutting tool was stationary relative to the work and was held in a slide rest which was fed across the table. The tool cut on both strokes. The table or platen was mounted on rollers. The planer would take six feet square through the uprights. For ten years it is said to have been the only tool of the kind in existence. For much of the time it was kept in operation night and day on piece work. The charge for its services was over $4 per square foot of area planed, but at these enormous prices the machine was able to earn only (!) $100 per day, showing an area planed of about 25 square feet. The authority for this remarkable statement is "Industrial Biography," by Samuel Smiles, but we are inclined to question the accuracy of the price received for planing. As it was possible to have surfaces chipped and filed true for $1.50 per square foot at about the same time, it is not probable that Clement could charge three times as much for the same work done on the planer.

---

* A device for cutting screws working on the same principle has recently been patented.

It is also stated that Clement used planer centers on these machines so that he was able to produce both flat and cylindrical work on the machine. Joseph Whitworth radically improved the planer by the application of the screw drive in 1839 and again Sellers of Philadelphia further improved it.

James Nasmyth, a pupil of Maudslay's, was an improver of machine tools and an inventor of a number. He is credited with the invention or adaptation of the slotter for metal work in 1836, the first machine being a modification of a machine for mortising holes in wood, designed by Maudslay. The invention of the flexible shaft for drilling in 1829, the keyseater in 1836, the crank driven shaper in the same year, the reversing or tumbler gear for changing the feed direction in lathes in 1837, the self-adjusting or spherical bearing for shafts in 1838, a tapping square for holding taps square with the work in 1840 and an end mill for keyseating shafts in 1847 are credited to him. In 1848 he made a punch for punching boiler plates having a skewed face to give a shearing cut. His invention of the steam hammer in 1839 was an important advance in the art of blacksmithing and made a radical change in forging operations, making work possible that had never before been attempted. The increase in the size of forgings and other changes in machine construction materially affected machine tools and led to radical changes in design. So decided were these changes that the machine tools made by John G. Bodmer in the few years from 1839 to 1841 contained almost every improvement of importance now found in modern tools.

It is thus apparent that the early development of machine tools took place in England, the English mechanics having anticipated practically every form of machine tool and method of working metals. The changes that have since taken place have been with few exceptions more in methods and minor changes than in radical ideas.

Early Machine Shops in the United States.

The early history of the machine shop in the United States is very uncertain, undoubtedly because the industry had never become of marked importance until well along during the past century. The first mention of a machine shop in what is now part of the United States that the writer has found is that of the Saugus Iron Works, Lynn, Mass., which were established in 1642, in which year they made the first iron casting poured in America, being an iron kettle which is yet preserved. The Saugus Works included a machine shop in which the first hand fire engine built in America was constructed for the city of Boston in 1654. The castings for this and other machines were made from bog iron ore and were made directly from the metal flowing from the blast furnace, the cupola for remelting the iron not being developed until 1790.

A machine shop was erected in the last years of the eighteenth century near Belleville, N. J., in conjunction with the Hornblower pumping engine imported from England for draining the copper mine at that place. Whether the machine shop was primarily intended to keep the engine in running order is not stated, but it apparently did outside work as we are informed that a pumping engine was built here for the city of Philadelphia in 1800. The engine when completed occupied the present site of the City Hall at the junction of Broad and Markets Sts. The steam cylinder was 38½ inches in diameter by 72 inches long, and its construction was a most difficult job with the crude and inefficient tools then in use. The boring of the cylinder took from the 9th of April, 1800, to about the middle of the following August, two men being in constant attendance night and day. This seems an incredible statement, but it is apparently sustained by the records at hand. It is highly probable that the cylinder casting, like most of the cast iron of that period, was extremely hard and very untrue, so that with the scraping cuts possible with the boring appliances used the amount of metal to be removed consumed an astonishingly long time.

In early engine construction as in other machines, as little machine work was incorporated as possible. Plane surfaces were tabooed in most shops, as they had to be surfaced by the chisel and file. The valve seat was the most important plane surface considered strictly necessary. The same general condition held in regard to bored holes. Such was the difficulty in boring true holes that on some of the early engines built, the cylinder was the only piece bored. The crank was cast with octagonal holes for the shaft and crank pin and was fitted to the shaft by thin wedges driven in so as to bring it approximately square with the shaft. The spaces unfilled with the wedges were filled with a cement made from iron borings and sal-ammoniac. The crank pin was fitted in the crank eye in the same manner. To make the throw correct for the stroke of the cylinder, it was often necessary to have the center of the working surface of the pin eccentric with the portion fitted in the crank.

The connecting rod was forged to shape and the holes for the strap bolts drifted out by the blacksmith as were the holes for the adjusting keys. The file was used for finishing.

A machine shop was started in 1801 by Robert McQueen on Duane St., New York. He was probably the first to make a specialty of building steam engines in the United States. After the success of the Clermont in 1807, Fulton established a shop in what is now Jersey City, where he built the Car of Neptune and finished steam engines, the iron castings being machined in New York by McQueen and Youle and the brass castings by James P. Allaire. What was subsequently the Allaire Works was started by Allaire in 1816. They became famous as builders of marine engines and other machinery. This firm had what is thought to be the first planer in America, built for fluting rolls and was in use in 1828. Such a then important business as the Port Richmond Iron Works, Philadelphia, Pa., had no iron planer until 1838. One of the first industries in the United States that stimulated the use and development of machine tools was the manufacture of cannon at the Fort Pitt Works, Pittsburg, Pa., which were established in 1814. A boring mill was erected at this date and cannon were bored and finished, the motive power being furnished by horses. At these works the famous Rodman cannon were subsequently made.

One of the early machine shops which had an important place in the early part of the century as machine tool builders was Silver & Gay, North Chelmsford, Mass., established in 1832. They built their first planer in 1836, having a capacity of 3½ feet square and driven by a chain. This is thought by some to have been the first planer built in America, but was not the first one in use, as shown in a previous paragraph. This planer had one V-way and one flat way set on directly on a granite bed. The table was driven by a heavy flat chain very similar to modern sprocket chains. This remarkable tool was still running in 1896. In this shop was built a 16-foot boring mill about 1840, having three heads, all of which had power feed. The center head was arranged to act as a slotter for keyseating the hubs of pulleys after they had been turned and bored. This firm built lathes, for their own use at least, having the usual chain feed mechanism commonly in vogue at that time for moving the carriage, but in addition some of them had power cross feed, one referred to in MACHINERY, February, 1896, being an example, and this was thought to have been built shortly after the firm started in business. This lathe was of about 48-inch swing and had a granite bed on which were mounted the cast iron shears. The tailstock had a set-over made on about the same plan as holds in modern engine lathes for turning tapers. Drill presses with power feed for both table and spindle, well adapted for heavy work, were built and sold by them between 1840 and 1850. They were pioneers in the building and development of the milling machine, having made them for sale as early as 1841. Frederick W. Howe afterward actively identified with the milling machine and turret lathe, learned his trade with this firm, finishing it about 1854. A spur gear cutter was built and sold to the Stark Mills by this firm in 1839 and one which was kept in their own shops in 1841. The work arbor of this machine was vertical, the index wheel being mounted below the upper part of the frame. The cutter spindle was on a horizontal axis, but was capable of being swung around sideways for gashing wormwheels and backward for bevel gears. Whether it was successfully used for cutting bevel gears is not positively known. The planing of bevel gears was taken up and a machine built for the purpose in the early fifties. The frame was made of wood with the working parts of iron and steel. The cutting tool was guided by a former and swiveled so as to cut both ways. In this machine the former was set so that the motion derived from its contour was reduced at the tool point, thereby reducing instead of multiplying any inaccuracy and also tending to make the former, which was of wood, last longer. For this machine the Silver & Gay Co. were awarded a gold medal in 1857 at the Middlesex Mechanics' Association.

* * *

HOLLOW FORGINGS.*

HOW NEW METHODS HAVE IMPROVED HEAVY FORGINGS

There are two ways of making a forging hollow. The ordinary way of getting rid of the center of a forging is simply to bore it out. After boring it is tempered, and thus the strength is restored which was taken away with the material that was in the center.

Another way of getting rid of the center of large forgings is to forge them hollow. A person who has not considered the subject carefully would naturally think that the first thing to do in making a hollow forging would be to cast a hollow ingot. There are various defects which occur in ingots, however, the most serious of which are "segregation" and "piping," and it is in the center and upper portions that those defects occur. If an ingot were to be cast hollow a solid core of fire brick or similar material would replace the center metal, and instead of one on the outside, there would be two cooling surfaces, one on the outside and one around the core, and the position of last cooling would be transferred to an annular ring midway between those surfaces where the "piping" and "segregation" would collect. This would not be satisfactory because the metal there, is what must be depended upon for the strength of the hollow forging. It is necessary, therefore, to collect the "piping" and "segregation" in the center and at the top, where metal has been added to the original ingot for the purpose. Then, having cut off the top and bored out the center, the "piping" and "segregation" are entirely eliminated, and what is left is as sound and homogeneous a piece of steel as can be obtained.

After the hole has been bored in the ingot, the next process is to reheat it, and, as before explained, this process is not as delicate a one as if the ingot were solid. The heat affects the center equally with the exterior and the two expand together and the danger of cracking is not incurred. When the ingot is reheated a steel mandrel is put through its hollow center, and subjecting the two to hydraulic pressure the metal is forced down and out over the mandrel. Thus an internal anvil is practically inserted into the forging and there is, therefore, really much less than one-half the amount of metal to work on than if the piece were solid.

When the work of shaping is completed the forging is reheated to the proper temperature and then either annealed in the usual manner or plunged into a tempering bath of oil or brine to set the fine grain permanently that has been established by the reheating. A mild annealing follows, to relieve any surface strains that may have been occasioned by the rapid cooling.

Hollow forgings oil tempered and annealed are considered the best grade of forgings made, and any forgings made otherwise, although they may be suitable for the service to which they may be applied, cannot be looked upon in any other manner than as of an inferior grade.

That steel forgings of such high grade were being manufactured for commercial purposes in this country was first brought to the attention of manufacturers generally at the World's Fair in Chicago. Here were exhibited stationary engine forgings which compared favorably with those sent over by European forges. The Ferris wheel shaft, 45 feet long and 32 inches outside diameter, with a 16-inch hole through it, represented the largest shaft made up to that time. The soliciting of orders for such forgings, however, at once aroused the latent prejudice still existing against steel forgings, and the prices demanded being somewhat in excess of those which wrought iron or ordinary steel forgings could be obtained for prevented at first the very rapid introduction of this product into the commercial field.

Difficulties Encountered in Introducing High-grade Forgings.

It hardly seemed necessary to explain to an engineer or any one authorized to purchase, and therefore presumably competent, that if he wanted material to sustain severe usage in the nature of alternating stresses, to which all forgings are subjected, he should select a material possessing a very high elastic limit. And yet it was not unusual to find that those very people preferred to use wrought iron for their engine crosshead and crank pins and shafts in preference to steel, because, as they said, "steel being crystalline is brittle and snaps off suddenly under such services as that under consideration, while iron, having fibre, is tougher and yields before breaking." Most of these men knew better, but had not given the subject sufficient thought or they would have perceived that their statements were not consistent. They said that the steel connecting rods they had tried had broken off short without any warning, while rods made of wrought iron had simply bent up, and after having been straightened out were replaced as good as new.

These people did not stop to think that a steel rod that broke off short had done so at its ultimate strength or under a stress of from 80,000 to 90,000 pounds per square inch, whereas the iron rod which had doubled up had done so at its yielding point of 25,000 to 30,000 pounds per square inch. In other words, their engines with wrought iron rods were failing all over the country under loads about one-third what they were standing up to when supplied with steel rods, yet the men were blaming the steel for helping them out of their troubles.

Then again they complained that steel shafts and crank pins heated up, while wrought iron ran cool. When it was proved to them that laboratory experiments showed the coefficient of friction of these metals to be the same and that any difference in heating was caused by local circumstances, such as poor lubrication, excessive pressure, etc., they said they did not care for laboratory experiments. They had an engine in one place with a steel shaft that never would run cool, while another with a wrought-iron shaft had never given any trouble, and they were passing judgment on their own experience. Persistent exposure of these fallacies gradually brought about a change in sentiment.

"Cold Crystallization" does not Occur.

It took a long time to persuade people who had seen broken forgings which showed a coarse crystalline section that the metal had not crystallized from shock or vibration in service, but had been forged in such a manner that the crystalline condition of the ingot from which the forging had been made had not been changed by the forging process or by subsequent heat treatment. And these are the people even now who consider themselves conservative, who would rather have their forgings made of a mild steel which is weak than of a higher carbon steel which is strong, simply because the old ideas are not yet eradicated from their minds. Tests were made at the Government testing bureau at Watertown by rapidly bending bars forward and backward within their elastic limit with the following results, and these have given engineers an idea of the comparative endurance of wrought iron, steel and nickel steel, in such service as that to which crank pins, shafts, etc., are subject:

TESTS OF STEEL UNDER REPEATED STRESSES.

---

* Extract from paper read by H. F. J. Porter, before the Engine Builders' Association.

Engineers and those whose duties it is to purchase forgings have been led to see that they should specify definitely the strength that they wish the material to possess and then to follow up the specifications by inspection to insure receiving what has been ordered.

During the past few years a series of specifications has been drawn up and adopted by the International Association for Testing Materials, which is composed of engineers, manufacturers, companies, associations, societies, and any individual or organization interested in obtaining standards. The standard specifications for forgings are herewith given for convenient reference and the physical properties mentioned are obtained from test bars drilled from a full-sized prolongation, forged to one end of the forging, these test bars being of the United States Navy standard size, ½ inch diameter and 2 inches long between gage marks.

REQUIREMENTS AND GUARANTEES FOR STEEL FORGINGS.

Class of Steel Forging		Tensile Strength, lbs. per sq. in.	Elastic Limit lbs. per sq. in.	Elongation, per cent.	Contraction of Area. per cent.
Nickel Steel.	(1)	95,000	65,000	21.00	50.00
Oil Tempered	(2)	90,000	60,000	22.00	50.00
	(3)	85,000	55,000	24.00	45.00
Nickel Steel, Annealed.	(4)	80,000	50,000	25.00	45.00
	(5)	80,000	45,000	25.00	45.00
	(6)	80,000	45,000	24 00	40.00
Carbon Steel, Oil Tempered.	(7)	90,000	55,000	20.00	45.00
	(8)	85,000	50,000	22.00	45.00
	(9)	80,000	45,000	23.00	40.00
Carbon Steel, Annealed.	(10)	80,000	40,000	22.00	35.00
	(11)	75,000	37,500	23.00	35.00
	(12)	70,000	35,000	24.00	30.00

Dimensions of solid and hollow forgings in which the physical qualities mentioned in the above table are guaranteed:

(1) Solid or hollow forgings, no diameter or thickness of section to exceed 3 inches.

(2) Solid forgings of rectangular sections not exceeding 6 inches in thickness, or hollow forgings, the walls of which do not exceed 6 inches in thickness.

(3) Solid forgings of rectangular sections not exceeding 10 inches in thickness, the walls of which do not exceed 10 inches in thickness.

(4) Solid or hollow forgings, no diameter or thickness of section to exceed 10 inches.

(5) Solid forgings, no diameter to exceed 20 inches, or thickness of section 15 inches.

(6) Solid forgings over 20 inches diameter.

(7) Solid or hollow forgings, no diameter or thickness of section to exceed 3 inches.

(8) Solid forgings or rectangular sections not exceeding 6 inches in thickness, or hollow forgings, walls of which do not exceed 6 inches in thickness.

(9) Solid forgings of rectangular sections not exceeding 10 inches thickness, or hollow forgings, walls of which do not exceed 10 inches in thickness.

(10) Solid or hollow forgings, no diameter or thickness of section to exceed 10 inches.

(11) Solid forgings, no diameter to exceed 20 inches or thickness of section 15 inches.

(12) Solid forgings over 20 inches in diameter.

SAVING FROM NEW TOOLS AND METHODS.

At a meeting of the Western Railway Club Mr. M. K. Barnum gave illustrations of the amount of money that is wasted every day by the lack of up-to-date tools. He contends that if an old machine can be replaced with a new one which will do enough more work, or do the same work with enough less labor, to represent a saving in money equal to 5 per cent. per annum on the investment, it should be entitled to careful consideration. As this is the basis on which other railroad improvements are figured, how easy ought it to be for mechanical men to obtain approval on a requisition for a machine which will save from 10 per cent. to over 100 per cent. per annum on the investment.

Several examples were instanced by Mr. Barnum of the saving through new tools and methods, which are given below. They are from "actual practice."

1.—In a railroad shop employing about 160 machinists there were no horizontal boring machines for such work as boring driving box brasses, rod brasses, rocker boxes, air pump cylinders, etc., and all such work had to be done in lathes, milling machines or drill presses.

After repeated conferences and much argument accompanied by estimates of savings that would result, permission was obtained to order a No. 2½ horizontal boring and drilling machine with 4-inch bar and latest attachments. It has been in use about 18 months and shows earnings by money saved as follows:

Original cost of machine installed ready for work..	$1,696.00
Average savings per year as compared with old manner of doing same work	900.00
Interest on investment	53 per cent.

It formerly required three hours to bore a driving box brass for a 9 x 12-inch journal in a milling machine and about four hours to do the same work in a lathe, whereas they are now bored in one hour in the horizontal boring machine. Rocker boxes, tumbling-shaft boxes, etc., are done in one-half the time formerly used.

In boring air pump cylinders it was formerly necessary to take the pump apart and set and bore each cylinder separately, requiring from two to three hours each. In the new machine it is possible to bore all four cylinders of a New York pump at one setting, without taking them apart, which requires but an average of one hour for each cylinder. In addition to the saving in time, much greater accuracy is insured. It is very conservative to say that this machine does double the work of the old ones, thereby saving the wages of one machinist at $3.00 per day for 300 working days, or $900.00 per year.

2.—An old car-wheel borer was replaced by a new, heavy 42-inch borer with hub-facing attachment, power crane for handling wheels, etc., which cost, installed, $1,710.90. This wheel borer saves the wages of one helper three hours a day and does more than double the work of the old machine, making a total of $2.45 per day, or $735.00 a year, which amounts to 42½ per cent. on the investment.

3.—A new heavy double head car-axle lathe, costing $1,665.00 installed, turns out one-third more work than the old one on account of taking a heavier cut and heavier feed, thereby saving about $250.00 a year, or 15 per cent. on the principal.

4.—It formerly required about four hours for eight men with screw jacks to take a 10-wheel engine weighing 132,000 lbs. off its drivers, at a cost of $5.14, and about one-half that time for four men to do the same work with hydraulic jacks; but using four pneumatic jacks, it is now regularly done by four men in one hour at a cost of 66 cents. However, to be strictly up-to-date an electric crane should be used and the time reduced to ten minutes.

5. A pneumatic ram was recently made at a cost of $168.55 for breaking staybolts to remove worn-out fire boxes, which earns very large interest on the investment. It formerly cost $45.60 to cut out the crown bolts and staybolts of a 10-wheel locomotive with 9-foot fire box, using three men, but with the pneumatic ram it is done by two men for $15.20, thereby saving $30.40 on each fire box. If only one fire box was removed each year this tool would earn 18 per cent. on the investment, but as this shop applies 30 new fire boxes a year the saving amounts to $912.00, or 541 per cent. per annum on the amount invested.

6.—In a certain shop which makes general repairs to about 160 locomotives a year the average length of time required to put each engine through the shop was reduced from 34 days in 1898 to 30 days in 1900. This represents a saving of 640 days for one locomotive, which, at a rental value of $10.00 a day, gives $6,400.00. As this was done with the addition of only a few new machines in a shop full of old and worn-out tools, many of which had been in service from 25 to 35 years, you can readily understand how much greater saving could be effected had the shop been fully equipped with up-to-date machinery.

* * *

The hottest place (on earth) is said to be at Mammoth Tank, Colorado desert, where the temperature has risen to at least 128 degrees.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

OCTOBER, 1902.

NET CIRCULATION FOR SEPT., 1902,—26,185 COPIES.

The index to volume eight of MACHINERY is now ready for distribution and will be sent to any reader upon receipt of postal card request.

* * *

With the establishment of the Engineering Edition of MACHINERY there is more room available in the dollar, or Shop Edition, for letters and short articles upon shop methods and devices and kindred subjects. Much of the general matter, such as has occasionally been published in MACHINERY, will now be transferred to the Engineering Edition, which will give additional space in the Shop Edition for articles dealing directly with shop practice. We intend to have these articles in greater variety than ever before, and readers of MACHINERY can materially assist in this by giving us the results of their experience and observation in the form of brief contributions, accompanied, if possible, by sketches or photographs. For the benefit of those who have not contributed, we will add that all sketches are redrawn in the process of engraving, no matter how good or how poor they may be, and that manuscripts are re-written in this office if necessary. While manuscripts and sketches should always be prepared as carefully as possible, a contribution will not be rejected simply because it needs considerable revision. It is the *idea* that we want, and if the idea is a good one it will always have careful consideration. All accepted contributions are paid for upon publication. There is probably not a machine shop in the land but that might supply something of value to many of our readers. All live mechanics are interested in something pertaining to shop work, and it is this something that we want to hear about.

BLACK DIAMONDS FOR USE IN THE ARTS.

Some months ago the writer visited a well-known shop in Brooklyn (National Meter Works) and was shown some interesting examples of the use of black diamonds or carbons for lathe and other machine tools. Some of the working parts of water meters built by this company are made of hard rubber, which has to be machined after being molded. It will probably surprise some mechanics who have never worked this stuff to learn that it is one of the most difficult substances known to machine with steel tools. In fact it is impossible to work it accurately with ordinary steel tools, or any steel for that matter. Some peculiar property of hard rubber, developed by the combination of ingredients necessary for vulcanizing, causes it to blunt the edge of the finest and best steel so quickly that it is rarely possible to go over the surface of a small piece even and have it pass the inspectors' limit gages, the wear of the tool being so great. Consequently it is necessary to use diamond tools for turning hard rubber and they are generally used for this purpose.

In these shops, however, the use of carbon tools has been extended to the regular machine shop departments, making them the finishing tools for turret lathes, for boring gas engine cylinders, and for many other purposes to which ordinary steel is usually applied. The results in the matter of accuracy are very gratifying and if it were not for two or three drawbacks the black diamond tool would undoubtedly become a common lathe tool accessory in many machine shops once its advantages were recognized.

One difficulty is that of holding an irregular mass of carbon so as to present the cutting edge advantageously and still hold it firmly enough to prevent its being dragged out by the pressure of the cut, and lost; but this is not very serious, since the proper function of a diamond tool is finishing and not removing heavy stock. There are a number of methods employed for mounting carbons in holders, the particular one to be used depending somewhat on the size and shape of the carbon and the use to which it is to be applied. Another and more serious trouble is grinding the correct shape of cutting edge for metals. This takes considerable time; again the grinding of carbons is said to be a trade secret not known to many of the regular cutters who work on white diamonds. The most serious drawback to the use of diamond tools, however, is their great cost. It is so great that it renders their use practically prohibitory except where the nature of the substance makes them positively necessary. This condition vitally affects the prosperity of a number of industries. Diamond dies are largely used for drawing the finer wire sizes and the diamond drill is extensively used in prospecting when it is desirable to secure a solid section of rock from depths.

The only place in the world in which black diamonds are found in sizes large enough to be of commercial value is in the state of Bahia, Brazil. A recent report made by Mr. H. W. Furniss, U. S. Consul at Bahia, Brazil, makes public considerable interesting information regarding the mining of diamonds and the reasons for the excessively high prices that prevail. Mr. Furniss says that contrary to what is generally believed to be the case, there is no combination of interests or syndicate that controls the output of carbon; the limited supply and consequent high prices may be attributed to the lack of proper machinery for mining.

Diamonds were first discovered in Bahia, Brazil, in 1821, but it was not until 1844 that they were mined to any extent. All diamond and carbon-bearing lands belong to the State, but it is possible for a person of any nationality to take out mining claims by complying with the State regulations, which do not appear to be rigorous. The climate, however, is very bad, fevers and other diseases being prevalent. The miners do not work systematically and the character of the tools used is very crude. Diving machines are used to a limited extent to get the precious stones from the river bottoms, and naked divers also work these beds. The geological formation of the district is volcanic. The diamonds are found in sandstone pebbles containing a very hard matrix. These pebbles are mixed throughout the granite and when exposed to the weather they disintegrate and expose the diamonds and carbon hidden within. The quantity of the granite containing diamonds is enormous and the production could be multiplied many times provided proper machinery and modern methods of mining and handling rock were employed.

The present output of carbon from the diamond district averages about 2,500 carats per month of all classes—porous, crystalline and good. The most valuable sizes are those weighing from one to two carats. Larger sizes have to be broken up to be used, which causes loss; and the smaller sizes are not in great demand. The largest black diamond ever found was discovered in the Lençoes district (where the best ones come from) in 1895. It weighed 3,150 carats and sold to the exporter for $24,500. The next largest in size was found in the same district in 1901 and weighed 577 carats. This was sold by the miner for $17,380. The average size of carbons is six carats. Almost the entire product of diamonds and carbons is shipped to London and Paris.

DANGER FROM GAS EXPLOSIONS.

The formation of explosive gas is a danger that cannot be too well guarded against as it often occurs in the most unlikely places and under what may seem to be normal conditions. We are, of course, only too familiar with danger arising from gasoline and benzine vapor. A tank full of gasoline is not nearly so likely to explode when approached by a light as when partly full or as an empty barrel which has contained gasoline, but an explosion in an empty steam boiler, is another matter. The *Locomotive* tells of an engineer at Menominee, Mich., who was severely injured by an explosion in an empty steam boiler which had been laid up for repairs. The repairs had been made and the engineer found it necessary to open a hand-hole to examine the interior. Finding it necessary to insert a candle, he did so and thrust it into the open handhole. Immediately an explosion occurred, accompanied by a blinding flash and loud report. The explosion appears very mysterious on the face, but it is attributed by the *Locomotive* to the use of petroleum or kerosene to loosen scale. Whenever a boiler is opened after such solvents have been used, great care should be taken to thoroughly ventilate the interior before inserting a light. A still more puzzling class of explosions is reported to have been occurring recently in the wheat fields of Washington. Many grain threshers have been wrecked and burned by gas explosions taking place while threshing. These were at first attributed to smut in the wheat, but it is pointed out that smut is no more plentiful this year than in former years. Apparently a more likely cause is the use of California petroleum for lubricating oil, which has been the practice lately. A hot bearing would, of course, gasify the petroleum and give off an explosive vapor which would only require a spark from the engine to cause an explosion. In fact the heat of the bearing alone might be sufficient.

* * *

NEW VARIABLE SPEED MOTOR FOR RAILWAYS

What may prove to be the most important event of the month in the field of constructive engineering is the announcement by the Westinghouse Electric and Manufacturing Co. of the perfection of an alternating current traction system for interurban railroads. A road with this equipment is to be constructed between Washington and Baltimore, a distance of 40 miles, with a branch running to Annapolis, a distance of 15 miles, by the Washington, Baltimore and Annapolis Electric Ry. Co.

For operating the ordinary street railways at the present time the direct-current motor is used, almost without exception. Where the distances traversed are great, however, the plan is sometimes adopted of using high-voltage alternating currents for distributing the power to points along the line; and then, by means of transformers and rotary converters, the current is supplied to the trolley wire as direct current at the usual railway voltage of from 500 to 650 volts. The rotary converter substation, however, has always been an undesirable feature, chiefly on account of the cost of the apparatus and building and the attendance required. While the plans that have been proposed to do away with this are numerous, none have appealed to railway engineers.

In Europe the polyphase induction motor has been used to some extent, but it has required the use of two or three overhead wires, and we understand that the induction motor has not been found entirely satisfactory in points of starting torque and in efficiency at other than the normal speed. The Westinghouse Company propose to employ a single-phase alternating current, to be transmitted at 15,000 volts to substations containing stationary transformers at suitable intervals. From these stations current will be fed to a single trolley wire at 1,000 volts. The motor used will be a single-phase, variable-speed motor, and it is in this motor and its connections that the greatest interest is attached. Particulars are not yet to be had, but the builders are confident that it marks a long step in advance, which has been awaited by railway engineers.

Two months ago we called attention to the electro-pneumatic car system recently perfected by Mr. Bion J. Arnold, Chicago, for the use of alternating current on railways. In this case the motor on the car is employed to propel the car and to charge an air reservoir on the car. The air compressor operates either as a compressor or motor, and is connected directly to what corresponds to the stator of an alternating-current motor, the stator in this case being so constructed that it can rotate instead of remaining stationary as usual. The speed variation in the motor is obtained by varying the speed of the stator through running the air engine at different speeds. The rotor, which drives the car, must necessarily keep in step with the stator and so propel the car at the corresponding speed.

The Arnold system is to be applied to an important line in the West, and this, with the Westinghouse line between Washington and Baltimore, may mean the beginning of a rapid change from steam to electric locomotives on suburban lines and even on through lines, where the conditions are suitable.

* * *

NOTES AND COMMENT.

REVIEW OF CURRENT EVENTS, TECHNICAL AND MECHANICAL.

In the article on the Cincinnati Machine Tool District in the September paper the total floor space of the G. A. Gray Co. was given as 30,000 square feet, whereas it should have been 70,000.

Probably the largest elevator contract ever awarded was recently closed by the Otis Elevator Co. with the Metropolitan Life Insurance Co., for the additions to their building, Fourth Ave., 23d and 24th Sts., New York City. The new equipment consists of 23 high-pressure passenger elevators, 4 hydraulic freight elevators and 2 electric passenger elevators and they contemplate converting the 13 passenger elevators in the original building, so as to operate them at an increased pressure. The plant, when complete, will consist of 40 hydraulic elevators, operated from one pumping station.

A bridge which will have the longest span in the world is being constructed over the St. Lawrence River six and one-half miles south of Quebec. At this point the river is from 1,900 to 2,500 feet wide, according to the tide. The channel will be crossed with a suspended span and two cantilever structures, the latter supported on piers near the shore, and having arms 500 feet long. The span from pier to pier will be 1,800 feet long, and the total length of the bridge will be 3,300 feet. The span of this bridge is nearly 100 feet longer than that of the famous Forth Bridge, Scotland, and 200 feet longer than that of the Brooklyn Bridge. The longest cantilever bridge in America at present is the one over the Mississippi River at Memphis, Tenn. It measures 790½ feet between supports. Another one is building over the Monongahela River, Pittsburg, for the Wabash Railroad, which is to be 812 feet long.

NOVEL EXPERIMENT IN "INDUSTRIAL BETTERMENT."

The J. A. Fay & Egan Co. and the Lane & Bodley Co. are planning the erection of a building upon the site of their Bond Hill factories for the benefit of the workmen employed. This will be something in the nature of a combined boarding house and restaurant, and the purpose is to so conduct it that it will take the place of the usual saloon and boarding houses which spring up in the neighborhood of large manufacturing establishments. Everything offered by the saloon will be offered here, but in a more attractive way, and it is the intention to sell everything at a price so much less that no ordinary saloon in the neighborhood can possibly compete. The companies expect to derive a benefit by securing abundant labor of the class which patronizes boarding houses by offering attractive rooms and meals at a cost much less than the workmen could otherwise secure.

PROGRESS ON NEW BROOKLYN BRIDGE.

It is now expected that the new Brooklyn bridge will be completed one year from the present date. All of the steelwork of the Brooklyn approach has been erected, the foundations for the Manhattan approach have been laid and considerable of the steelwork put in place. The stringing of the wires for the four main cables was completed several weeks ago. Each cable consists of 37 strands having 208 wires, .192 inch diameter and of 7,000 pounds tensile strength. This gives a total ultimate strength of each cable of 7,000 × 208 × 37 = 53,872,000 pounds, assuming that all the wires are strained equally when the cables are loaded. The greater part of the steelwork for the bridge proper remains to be manufactured, or put together at the plant of the Pennsylvania Steel Co., who are doing this part of the work; but they are required by contract to finish it within eight months from the time the cables are finished, and these, with the saddles for supporting the suspender cables, are now practically complete.

REMARKABLE PATENT CASE.

A dispatch to the *New York Commercial* states that every rolling mill in the United States rolling ingots into structural shapes is infringing on the patents of John Brisbin, a janitor, and Antonie Vinnac, a roller. Brisbin and Vinnac, both rollers, invented part of the present system of carrying the ingot on a bed of rolls laterally and vertically, for which they received a patent July 20, 1886. They also secured an interest in a patent granted Patrick Hanley and Francis M. Ritchey November 16, 1886. Suit was brought against the Carnegie Steel Co., Ltd., for infringement of patents in May, 1897. Judge Buffington, of the United States Circuit Court, heard the arguments last spring. The Carnegie Steel Co.'s claim was invalidity of the patent and non-infringement. Judge Buffington held that in view of the great advance in the system of rolling structural shapes, those who have from an inventive standpoint brought about such advance should share proportionately in the gains thereof.

SINKING A LARGE WELL.

The Des Moines (Ia.) Water Co. have used a novel method for sinking a large well that is to form a part of a new water system. The well is 19 feet diameter by 35 feet deep. The character of the soil is such that the running water and the loose sand make it impossible to first dig the well and then wall it up with brick; so the circular brick wall for the well was first built upon the dry ground, and, by cutting the dirt and sand out from underneath, the whole structure was gradually lowered into position.

An iron ring 35 feet in diameter, and triangular in cross-section, with one of the angles of the triangle pointing downward, was used as the foundation for the brick wall. This iron shoe weighed 5½ tons and on top of this was laid the circular brick wall with iron stay rods at frequent intervals to make it firm. This structure first stood on the surface of the ground, but by digging out on the inside the wall was forced down into the ground by its own weight. The weight of the shoe and brick wall together was about 150 tons.

THE HARVESTER AND SEWING MACHINE COMBINATIONS

And now the humble farmer and hard-working housewife are to come under the bane of the iniquitous trust. Five of the harvester companies of the country have merged into one corporation, called the International Harvester Co., and it is announced that a large corporation is about to be formed for the purpose of taking in nearly all the sewing machine manufacturers of the United States. The International Harvester Co., as given in the *Iron Age*, includes the McCormick Harvesting Machine Co., the Deering Harvester Co., the Plano Mfg. Co., the Warder, Bushnell & Glessner Co., and the Milwaukee Harvesting Co. The sewing machine firms included in the other combination, as stated in the *New York Times*, are the manufacturers of the New Home, Household, Domestic, Demorest, Standard, White, Davis, and National machines, the Williams Mfg. Co., Foley & Williams Mfg. Co., the Illinois Sewing Machine Co., and Chicago Sewing Machine Co. The Walter A. Wood Co., D. M. Osborne Co., the Acme Harvester Co., and several smaller firms are not to enter the harvester combination. Of the sewing machine manufacturers the Wheeler & Wilson, Singer, and Wilcox & Gibbs companies are, among others, to continue along independent lines.

A GOOD WAY TO SECURE AN UP-TO-DATE EQUIPMENT.

The Lane & Bodley Co., Cincinnati, O., are planning to build a foundry, primarily for their own engine business, and secondarily as a general jobbing foundry. Preparatory to beginning operations they have adopted a plan which other firms contemplating new structures might profitably follow. They have issued a form letter to the foundry trade calling for information relative to foundry appliances and the design of foundry buildings, of which the following paragraph contains the essential points:

"If there is anything profitable to be installed in a new foundry for our own standard work or for jobbing, we want to carefully consider, and if any provision should be made in the foundry arrangement or construction to adapt it to such profitable apparatus or appliances we want to know it before and not after the building is constructed. We inclose a blueprint indicating the proposed arrangement. If you build or have for sale anything you wish to suggest for installation in this foundry we shall be pleased to have a description, together with any alterations in the plan we send you, which you would suggest to better adapt it for your proposed apparatus."

NEW ELECTRICAL LABORATORY.

The buildings occupied by the electrical department at the Massachusetts Institute of Technology, Boston, have long been inadequate for the number of students taking the course in electrical engineering, and a new laboratory building is being erected which will have one of the finest equipments of any electrical laboratory in existence. In its appointments and variety of apparatus it will surpass the German laboratories, which, at the present time, probably rank the highest in scientific attainments and facilities for investigation. The laboratory will be divided into five important working parts—the power room and main laboratory; the smaller research rooms, based upon a study of the facilities which the Germans place at the disposal of special research workers; the standardizing room; the workshop, and the lecture room. These rooms, grouped in a single large building, covering some 40,000 square feet of land and one story in height, are so lighted by skylights that each has the steady, well-diffused light of an artist's studio. The lecture room will seat 300 students and facilities will be provided for bringing machinery into the lecture room, using it to illustrate the lecture and then for conveying it again to the proper place in the laboratory.

THIS YACHT IS WELL NAMED.

Charles R. Flint's steam yacht *Arrow*, designed by Charles D. Mosher, New York, evidently holds the world's record for high speed travel on the water. The *Arrow* was launched several months ago, and has been used by Mr. Flint in going to and from his business in this city. She was designed for a 40-knot boat, and it was expected that she would surpass in speed anything afloat. Not until recently, however, was a full power trial made. At the trial she attained a speed of 39.24 knots an hour, equivalent to 45.2 statute miles. This is two miles an hour faster than the speed claimed for the British turbine yacht *Viper*, the hull of which broke in two some time ago. Two of the fastest boats in this country are the *Ellide*, with a speed of 40 miles, and the *Porter* (torpedo boat) with a speed of 33 miles an hour. The dimensions, capacity, etc., of the *Arrow* are: Length, extreme, 130 feet 4 inches; length on waterline, 130 feet; beam, extreme, 12 feet 6 inches; normal draught of hull, 3 feet 10 inches; displacement, normal, 78 tons; coal bunker capacity, 17 tons; water tank capacity, 1,800 gallons. The horse power of her engines and boilers is about 4,000. The *Arrow's* hull was constructed by Samuel Ayres & Son, Nyack, N. Y., and the boilers were built at the Crescent Shipyard, Elizabeth, N. J. The L. Wright Machine Works, Newark, N. J., turned out the main engine and auxiliaries, and W. D. Forbes & Co., Hoboken, N. J., the air and feed pump.

WHERE SMOKE WAS A NUISANCE.

Since the installation of an electro-pneumatic switch and signal station by the Pennsylvania R. R. in Pittsburg for the operation of the switches and signals of the Pennsylvania lines east, the Allegheny Valley road, the Pittsburg,, Fort Wayne & Chicago, and the Pittsburg, Cincinnati, Chicago & St. Louis, which lines enter the new Union Depot in that city, it has been found that the black, cinder-like atmosphere interferes seriously with the operation of the new system. Frequent delays in the passenger service have been occasioned from this interference.

The compressed air power is supplied, for the operation of the switches and signals, from huge compressors in the main power plant of the station. When the trouble with the switches first occurred whole sections of the conduits were torn up and carefully examined, but no fault could be discovered. A number of leading engineers were then consulted, and it was finally discovered that the dense smoke from the trains and surrounding mills and factories was responsible for the clogging of some of the switches, and it was also found that the only way to prevent this trouble was to filter the air before its compression.

The company at once began the installation of an air filtration plant, and this plant, which is located next to the dynamo room in the power plant, has just been completed, and is one of the first plants of its kind to be installed in the country for railway work.—W. G. I.

THE GREAT SAULT STE. MARIE POWER PLANT.

During the past month water was turned into the recently completed power canal at Sault Ste. Marie, Mich., and one of the greatest water power enterprises of the country will soon be a reality. The canal utilizes a fall of about 18 feet in the St. Mary River, which connects Lake Superior and Lake Huron. An attempt to utilize this fall was first made on the Canadian side of the river in 1897, when a canal 2,000 feet long, 125 feet wide and 14 feet deep was completed with a capacity for 20,000 H. P. The new canal on the American side flows directly through the city of Sault Ste. Marie, and has double the capacity of the Canadian canal. It is about 2 1-3 miles long, has an average width of 224 feet and a depth of 22 feet. A large portion of the canal is cut through solid rock, and in its course through the city crosses thirteen streets, several of which have been spanned by steel bridges. At the lower end the canal widens out into the forebay, or more familiarly the mill pond, between which and the river into which the canal empties is built the power house. This is a structure 1,368 feet long, on pile foundations, with heavy masonry walls through which are the penstocks that will eventually supply water to 320 turbines of 500 H. P. capacity each. These turbines are arranged in pairs, two pairs, or four wheels, forming a unit and operating an independent shaft to which a 375-kilowatt generator is directly connected.

An interesting feature of the canal is a movable dam at the intake to control the volume of water. It consists of four leaves, 58 feet long and 28 feet high, suspended from and operating between piers of masonry. The enterprise has been conducted by the Michigan-Lake Superior Power Co., and about 20,000 H. P. will be used by the Union Carbide Co., who have a plant at Sault Ste. Marie for the manufacture of calcium carbide. The remaining power will be utilized for the reduction and concentration of the various copper and nickel ores found in the vicinity of Lakes Michigan and Superior as well as for general power purposes.

THE CANALS AT ST. MARY'S RIVER.

In commenting upon the opening of this canal the Dubuque (Iowa) *Telegraph* gives some interesting facts relative to the commercial development of the St. Mary River, which is indicative of the growth of American commerce. The St. Mary River is about 40 miles long and has a fall of 20 feet, making its ascent difficult to any except light traffic. The first attempt to improve the river was made about 1798 by the Hudson Bay Company, who built a lock 38 feet long, 8 feet 9 inches wide and 9 feet deep. The United States troops destroyed this in 1814. The ship canal on the American side was first proposed in 1837, and a canal 75 feet wide 10 feet deep and 100 feet long, with two locks, was commenced, but through difficulties with Federal authorities it was not completed. In 1855, however, a much larger and longer canal was built through the assistance of the government. Improvements were made in 1880 and 1896, greatly increasing the capacity of the canal, the traffic of which exceeds that of the Suez canal.

IN A CLASS BY THEMSELVES.

The Largest Dome in the World.

A hotel being built at West Baden, Ind., described in the *Engineering News*, will have the largest dome in the world, its span exceeding by about 15 feet that of the great dome of the Horticultural Building at the Chicago Exposition of 1893. This dome, which has a steel framework, is nearly 200 feet in diameter and rises 50 feet above its bed plates. The framework consists of twenty-four ribs connected to the center or crown by a circular plate drum and tied together at the bottom by circular plate girder ties. The weight of the dome complete with its outer covering is 475,000 pounds. It was designed and erected by the Illinois Steel Co.

The Largest "Automobile."

What has been described as "the largest automobile ever built" is a combined harvester and traction engine in use in Southern California. The big machine consists of a traction engine capable of hauling 75 tons, and which takes the place of 60 horses; a header or mowing machine, which cuts a swath of 36 feet, and a threshing machine all complete. The threshing machine and header are run by a 30 horse power engine entirely separate from the traction engine, save that they both get steam from the same boiler. The drive wheels are 8 feet in diameter and have tires 48 inches wide, on which are ridges 1½ inches high. Under the most favorable conditions the machine can thresh in one day the grain grown on 100 acres. Eight men are employed on the thresher. Oil is used as fuel, and four horses are employed to draw the oil and water required for the boiler as it travels over the plains.

The Largest Steamer in the World.

The largest steamship in the world to date is the Kaiser Wilhelm II., which was launched August 12, 1902. She was built for the North German Lloyd by the Vulcan Co., Stettin, Germany. The Kaiser Wilhelm II. is 706 feet 6 inches long, 72 feet wide, 52 feet 6 inches molded depth, 29 feet draft, and has a displacement of 26,000 tons. She has four sets of 4-cylinder quadruple-expansion engines, the total power of which is nearly 40,000 H. P. Two of the cylinders of each engine are arranged tandem so that a three-crank shaft is required for each engine. The cylinder diameters are 37.4, 49.2, 74.8 and 112.2 inches, all having a common stroke of 70.8 inches. Steam is supplied by twelve double-ended and seven single-ended boilers at a pressure of 225 pounds. The total heating surface is 107,643 square feet, and grate surface 3,121 square feet. The estimated speed is 23½ to 24 knots per hour. Accommodations are provided for nearly 1,900 first, second and third cabin passengers.

OBITUARY.

Albert F. Prentice, vice-president of Prentice Bros. Co., of Worcester, Mass., died on September 14, at his home in that city, aged 61 years. Mr. Prentice had been prominent in Worcester for many years and had worked his way from a journeyman mechanic to the proprietor of a large business. He was born in Worcester in 1841, and educated in the common and high schools of that city. With a brother, Vernon F. Prentice, he worked in the foundry of the Cleveland & Bassett Co. for a number of years, and then the two brothers engaged in the toolmakers' business. This business was finally sold to F. E. Reed.

In 1872 the brothers began the manufacture of blacksmith drills under the name of Prentice Bros. Later they built machine tools—lathes and drilling machines being their special product. In 1889 they erected the building they now occupy, and about that time the firm was incorporated into a stock company, with Vernon F. Prentice as president and A. F. Prentice as vice-president. Mr. Prentice was a member of various societies, social and industrial.

SUPERHEATING.

THE QUESTION OF VALVES—WATER IN THE CYLINDER—TESTS—THE SCHMIDT APPARATUS.

WM. H. BOOTH.

Superheating steam enables it to live and therefore to do more work than if it were not superheated; and as less fuel need then be used it follows that the tendency of expensive fuel is to help on the practice of superheating. To expensive fuel is probably due the continued use of superheat for many years past in Alsace, where through the labors of Hirn, steam economy has been made a special object. In countries with cheap fuel there is less inducement to employ superheat and the additional appliances involved. Moreover, when superheat *did* first come into vogue in Great Britain it was soon discarded, for two reasons. One was the inability of organic lubricants to live at all at the high temperature; the other was the growth of the compound system which enabled a large economy of fuel to be secured and in an easier manner than that of superheating. And all attempts at economy have, since about 1860 to the present day, been along the lines of higher pressures and more cylinders.

But mineral oils, graphite, better construction and experience have once more brought the superheater to the front. All attempts at steam economy, so far as the engine using the steam is concerned, resolve themselves into more or less direct means or efforts to preserve the cylinder as hot as the steam which enters it. To begin with there is the saving due to increased expansion. This economy failed at a very early point. It was found not to continue beyond quite moderate rates of expansion. The reason was that the cylinder was not hot enough: it chilled the entering steam and put a short limit on further expansion with economy. Next we might cite the Corliss valve with its sharp cut-off which was erroneously credited with the economy that certainly came with this type of valve. Present-day knowledge discredits both the sharp cut-off and the valve itself to some extent, and gives credit to the position of the valve and the use of separate valves for inlet and egress of steam. To the position of the valves is especial credit due, for steam valves were so placed that they shot the moisture that entered with the steam right across the cylinder into the exhaust port, whence it was promptly ejected as soon as the exhaust valve opened. In this way the water did not partake in the processes of re-evaporation at the expense of the heat in the cylinder metal which go on in cylinders less perfectly drained.

This thought raises the question of the position of Corliss valves in cylinder heads. With the exhaust valve raised above the lower side of the cylinder of a horizontal engine, the drainage cannot be so perfect and a fault may be here introduced that will wholly or in part negative the claimed benefits of smaller clearance spaces.

Means of Overcoming the Effect of Cylinder Condensation.

One need only assume that a minute thickness of the internal surface of a cylinder follows the temperature of the steam as this enters the cylinder, expands and exhausts at constantly varying pressure, to realize that there must be great interaction between the cylinder surface and the steam. Despite the specific heat of cast iron being only a fraction of that of water, its specific gravity, is so much greater, and the weight of steam that enters a cylinder is so small a fraction of the weight of the assumed thin sheet of cylinder surface, that this surface cannot change its temperature unless it absorbs a considerable quantity of heat from the entering steam, to give it up again to the water during the exhaust stroke. This water is formed by condensing the initial steam upon the cooled interior surfaces of cylinder and piston. In early steam engineering days men built a fire under the large cylinders of the huge Cornish mine pumps. Trevithick was accustomed, in his high-pressure engines, to place the working cylinder inside the boiler steam space and this was continued in many later locomotives. Drawings of Trevithick's locomotive of 1803, which ran from the Pen-y-dareen works at Merthyr-Tydfil in South Wales, show a horizontal cylinder inside the steam space. This was the first locomotive ever run on a rail.

Jas. Watt used the jacket to keep the cylinder as hot as the steam that entered it, to use his own expression, though of course it did not fully accomplish this desirable end. Watt must have seen clearly the effect of water in the cylinder, for he could not have been unobservant of the fact that the condensation was transferred to the jacket, yet economy resulted. This of course was because, from the jacket, the water drained away unevaporated and did not enter the cylinder and it is now recognized as good practice to carry the working steam by way of the jackets if these are so designed as to be well drained. Jackets not thus supplied are too apt to become dead ends of air or mere pockets of water. But the steam jacket can after all exert but a small effect on the steam in the cylinder. The heat of the jacket must travel through the cylinder wall and the inner skin of the cylinder will still change its temperature with the steam, alternately being hotter and colder than the steam within it and evaporating or condensing it accordingly. The net result of cylinder condensation is that the heat which should do work may be said to enter the cylinder wall, step down to a level of less potentiality and emerge at the lower level without having done mechanical work.

If the material of a steam cylinder were absolutely adiabatic, neither absorbing nor giving out heat, it would matter little at what speed it were set to run. The only matters affecting economy would be those connected with the internal frictional resistances of the working parts, and the clearance spaces and their treatment. The effect of these matters could easily and quietly be ascertained, and a level of performance and efficiency would be attained from which the best made engines would very slightly depart. It is to cylinder condensation we owe the jacket. The high rotative type of engine is an endeavor to minimize cylinder effects by cutting down the time that each charge of steam is exposed to the cylinder walls. At least this is the customary erroneous way of stating a half truth. It is not that the steam is exposed for so short a time, as that the cylinder metal undergoes oscillations of temperature of less amplitude than the steam. In a very slow-running engine the inner skin of the cylinder practically follows the steam in temperature; the rise and fall have no appreciable lag. At high rotative speed the undulations of the temperature become less in amount, lagging behind the steam curve. Obviously this must be so. At an infinite rate of rotation the cylinder wall temperature would be represented by a horizontal line at a mean height on the temperature diagram of the very slow speed engine and the effect upon the steam and water in contact with the cylinder would be minimized. Another effect of high rotative speed is that water produced as mist by the conversion of heat into work is carried off before it has time to settle upon the cylinder walls.

Compound engines are another means of combating the evil. By dividing the whole range of temperature between two cylinders the condensation is reduced. All that which occurs in the first cylinder appears as steam again in the second, except for the small amount which is converted into work or lost by radiation. All the steam that enters the first cylinder must appear as steam to enter the low-pressure cylinder. The total heat of the entering steam at the first cylinder is greater than the total heat of the same steam exhausting at a lower pressure and, so far as the effect of the high pressure cylinder is concerned, upon the steam which enters it. This steam when re-evaporated at lower pressure, not having done work must be superheated. If it were possible to preserve a cylinder from radiation losses, and remove the liquefaction due to work, the exhaust of the high-pressure cylinder of a compound engine would be slightly superheated. The compound principle probably gains something by the smaller periphery of pistons and valves that are exposed to boiler pressure and by the reduction of the pressure difference on opposite sides of these peripheries of leakage.

Why Superheating Leads to Economy.

When the causes of cylinder condensation are thus understood and the immense effect on economy is realized, it is easy to foretell the benefit to be derived from additional heat. Steam cannot be superheated in presence of water. Either the water will soon be licked up or steam will become saturated. By adding heat to saturated steam not in presence of water, the steam is first made more perfect by the more thorough separation of the last remaining molecules of what has hardly yet become true steam. This done the steam becomes superheated. Steam is so light a gas (only a little more than half the weight of air—about 3-5 actually) and its specific heat is less than half that of water, that it cannot carry much heat per cubic foot for even 100 degrees difference of temperature. We can therefore not explain the economy of superheated steam by any reference to the additional heat which it carries into the cylinder. If steam be superheated by 100 degrees, this only represents about 4.8 units of heat per pound of steam at most, and one pound of steam already contains 967 units of latent heat. The addition is but ½ of 1 per cent and the smallness of the amount of heat is proved by the rapidity with which superheat disappears. About 10 degrees are said to disappear for one meter length of steam pipe under ordinary conditions. It follows therefore that the explanation requires further consideration and it will be found, if we consider for a moment, that dry steam has a very poor heat absorbing effect. If for one stroke of a steam engine we could prevent the initial steam from condensing in the cylinder walls there would be no water to re-evaporate; and if there were no water to re-evaporate, the cylinder metal could not lose heat except by radiation to dry steam that would not rapidly absorb it. As a consequence the cylinder would still remain hot for the next charge of steam. Thus except for the small amount of heat lost to the dry steam, once heating up a cylinder to the initial steam temperature would be enough to stop condensation losses for the day. Once allow a mere fraction of steam to condense and at once the action recommences. Water accumulates until it reaches such a maximum that the exhaust valve prevents further cumulation. It follows that what is wanted is just enough added heat to reduce the cumulation of wetness to the opposite effect of cumulation of dryness. Thus, if we assume an engine to be running wet, that 100 parts of water are re-evaporated at each stroke and that there is added sufficient heat to bring down condensation to 90 instead of 100, the next stroke will find the cylinder cold only to 90-100 of its former degree of coldness. Continue the addition of heat and a third stroke finds only 80 of cooling and so on. In a short time the cumulation of effect will reach a maximum and the cylinder effect will remain constant at the new figure, but will be again reduced by further small additions of heat every stroke. Ordinary degrees of superheat do not produce a dry exhaust. Some cylinder condensation still goes on, but very great benefits will accrue, not the least of which is that due to the steam being dry.

The Schmidt System of Superheating.

During the past few years several superheaters have been placed before steam users, with more or less success. Amongst the more recent is the Schmidt system which embodies the use of very high degrees of superheat. Thus in some recent tests the steam arrived at the stop valve at 709 degrees F. for a pressure of only 129 pounds. The added temperature was thus 354 degrees F., the steam being almost exactly doubled in thermometric temperature. It does not, however, enter the cylinder at this temperature, but parts with some of its heat to the steam entering the low-pressure cylinder. This reduces it to 601 degrees. It leaves the intermediate cylinder at 286 degrees and enters the low-pressure cylinder at 397 degrees, acquiring 111 degrees of temperature from the initial steam which lost 108 degrees, thus apparently confirming the temperature readings very fairly. The low-pressure steam must have been highly superheated to begin with, for it only gave an indicated pressure of about 2 pounds initially in the third cylinder, corresponding with a temperature of about 219 degrees—so that it began 178 degrees superheated which is more than we are accustomed to see at the superheater in ordinary cases. The exhaust from the intermediate cylinder was 66 degrees superheated and the general appearance of the diagrams showed dryness throughout. There was none of the filling up of the toe of the diagrams that is so grave a fault with saturated steam and shows re-evaporation at the expense of the heat in the cylinder walls. Indeed, the diagrams seem to show that about 350 degrees of superheat can be dealt with in an engine, without either wetness supervening or the exhaust being too dry. The superheat represents an addition to the total heat above 32 degrees of just one-seventh or 14 per cent—or say, 15 per cent as measured above ordinary feed temperature, but it is nearly 20 per cent of the latent heat of vaporization of steam at the pressure named—130 pounds gage pressure. The steam used per indicated horse power was 11.4 pounds per hour, which curiously enough is about 20 per cent less than a good triple-expansion engine with plain steam. This appears to be merely a coincidence. If one can look for an economy of 20 per cent with a superheat of 354 degrees an approximation to the economy at other temperatures may perhaps be made by allowing an economy of, say, 5 per cent for absolute dryness of initial steam, and a further 1 per cent for each 25 degrees F. of superheat. In running engine tests for allotment of bonus or penalty for performance in steam per k.w. hour, it is not always possible to secure the conditions of the specification, and it is necessary to agree upon the correction to be made for difference of the vacuum or of the superheat in a way to satisfy both parties. Very little is really known about the influence of superheat. Hitherto we have been contented with 100 or 150 degrees and have seen half of this amount disappear between boiler or superheater and the engine, and have been able to feel assured of little except that we were getting dry steam.

In the Schmidt engine the steam used per unit varied from 38 pounds for an output of 20 k.w. down to 18.3 pounds for a load of 140 k.w. From this it would appear that the engine used about 460 pounds to keep itself and the dynamo running, and that each unit really required about 15 pounds of steam per hour per k.w. for output or about 12.6 pounds per k.w. of engine power or about 9½ pounds per horse power, with the addition of the 460 pounds per hour spread over the whole output. This amount, of course, is much more serious on small outputs and shows how uneconomical it is to underload an engine.

The following were the figures obtained at various loads:

K.W.	Steam per Unit.
140	18.3
120	18.5
100	18.7
80	19.4
60	20.8
40	24.5
20	38.0

The formula:

$$\frac{(\text{K.W.} \times 15) + 460}{\text{K.W.}} = \text{steam per unit},$$

will be found to work out very closely in correspondence with the above figures, which therefore lie upon, or approximately upon, a straight line curve.

The Schmidt Apparatus.

Coming now to the actual apparatus used to give superheat to steam Figs. 1 and 2, page 86, show the Schmidt superheater which has a peculiarity of construction that may be particularly noted. It is known as the countercurrent and concurrent system. First, the steam from the boiler enters at that point of the superheater furthest from the source of heat; and it travels through the superheater in a direction opposite to the plane of the hot gases, until it reaches about the middle of the superheater structure. Arrived there the steam is then taken to the hottest end of the superheater and travels again toward the middle point, this time in the same direction as the gases. This is claimed to prevent the hottest end of the superheater from burning out. There is a superheater much used in this country (England) which is so arranged that the steam is taken alternately through two superheater coils and through coils immersed in the water of the boiler; and there is excellent authority for a statement that even after this treatment the steam still remains superheated. Whatever may be the case, the system has been found to give very high results in steam production. A boiler could be forced to the point of heavy priming and in combination with the superheater give a total output of dry steam of even treble its normal duty. Numerous other superheaters are at work with fair satisfaction, but none have attempted the high temperatures of the Schmidt system.

Obviously these high temperatures need care. Before closing down the heat is kept out of the superheater and it is allowed to work about an hour on the stored heat from the brickwork and in case of sudden stop provision is made to let in cold air. My own experience of superheat points to the importance of blowing through a superheater before allowing it to supply steam to an engine, if there has been a short stoppage with hot fires. The steam, after such a stop, may go nearly red hot to an engine. Also in constructing an engine for high superheat certain points especially require to be watched. It may cause trouble to have a piston valve with its outer case carried by ribs that get hotter than the seating sleeve. Such a valve will seize on points coincident with these inner ribs. Long sleeves, to keep piston rods and valve spindle glands away from the hot steam are employed; and generally when designing an engine to use very hot steam, it is necessary to consider every detail and ask if it is exposed to any special expansion effect greater than surrounding parts.

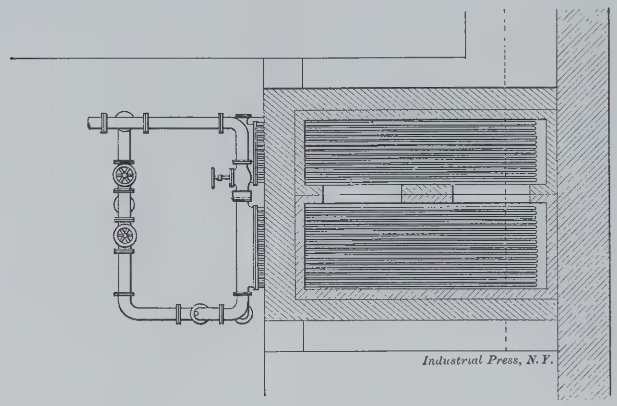

Fig. 1. Plan of Schmidt Superheater.

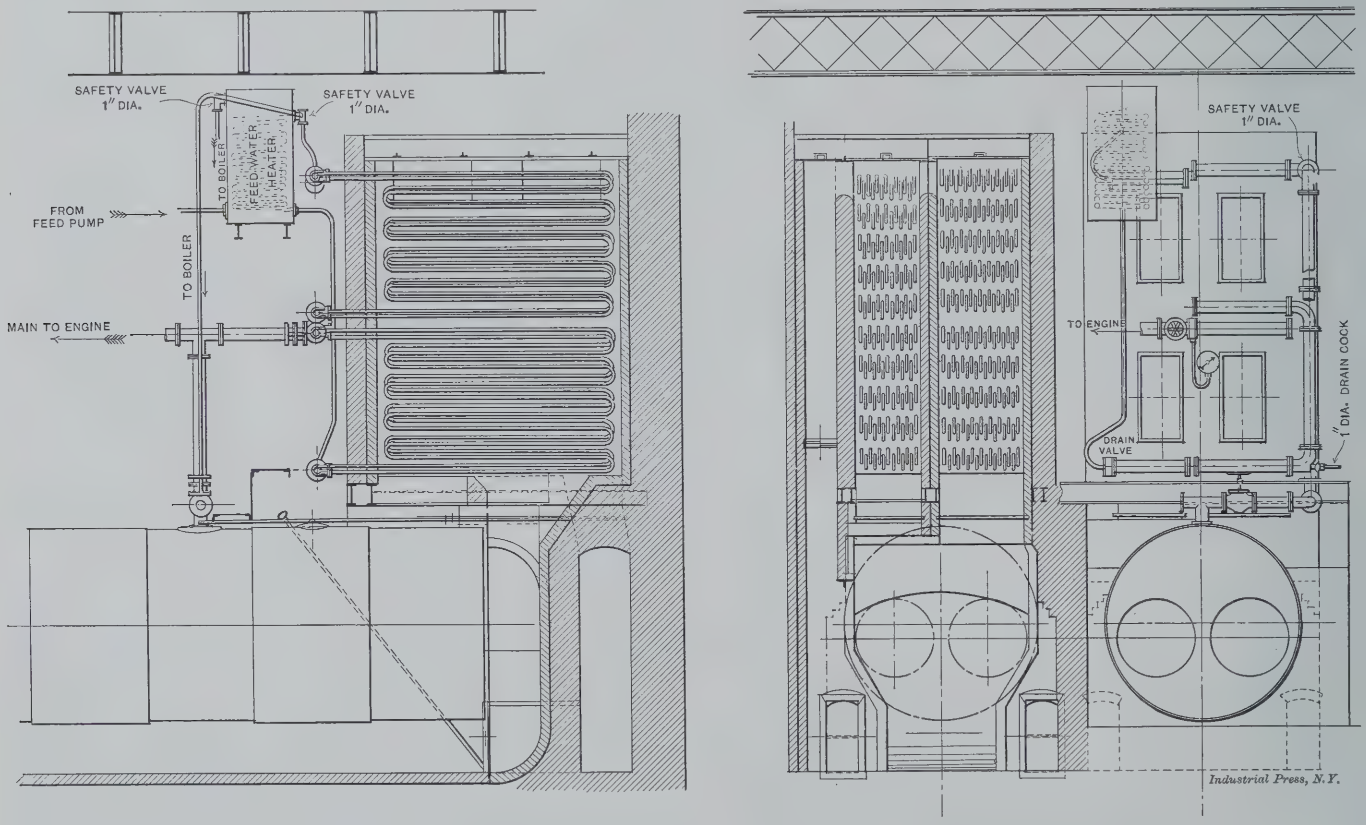

Fig. 2. W. Schmidt's Superheater and Economizer applied to a Lancashire Boiler.

In the foregoing I have taken the specific heat of steam as 0.48, but this seems very doubtful. The consensus of opinion, however, appears to be that it is not more than this figure and may be considerably less.

By means of superheat alone can a steam engine be made to approach its thermodynamic ideal. It seems likely that it will enable the triple-expansion engine to be replaced by the more simple compound or the compound by the simple engine. One thing is certain, that there would be very little difference in economy of one engine from another if it were not for the action of the cylinder metal. All electric traction men know that the very small load factors of tramways, especially of small systems of a few cars only, involve the use of steam engines which are double in size what they might be if not of the compound type. The compound engine *must* be large in order that it may take in steam enough at its first cylinder to turn its load. The first cylinder measures off the steam to the second and limits the power of the engine to what can be given by about three-fourths of a small cylinderful of steam per stroke. If by the aid of superheated steam the pernicious cylinder condensation could be checked in simple engines these could be made to give the maximum duty required without being underloaded at mean load. For the maximum load could be dealt with by three-fourths of a cylinderful of steam in the large (and only) cylinder and this could be, in cases I have calculated out, just about one-half the capacity necessary in a compound engine. The formula for steam per unit above given may be calculated out with the constant 460 and with a new constant of 230. The new constant will give much better results, especially at the smaller powers, for it represents the constant friction and radiation losses, etc., of the engine, and such losses are approximately in proportion to the size of the engine. A small engine properly loaded will in itself give better results apart from the frictional constant. I am of opinion that too much has been made of the compound principle for widely variable loads, for these compel a seriously small average load on the engine or it will not turn round at the minimum loads. Possibly by means of superheat the small single engine would do far better than the compound.

* * *

The Boston & Maine and the Boston & Albany railroads are to discontinue the practice of oiling their roadbeds to keep down the dust. While the remedy is efficacious so far as dust is concerned, there are many complaints from passengers whose clothing has been soiled because of the practice. When particles of sand and dust on an oiled roadbed are dislodged by a passing train, they are quite likely to leave an oil spot wherever they fall.

AN ADJUSTING MOTOR.

INTERESTING MECHANISM FOR STEERING GEAR AND OTHER PURPOSES.

In a recent article on marine steering gears attention was called to the fact that the engine should keep in motion only while the controlling valve is being operated upon by the steering wheel or lever, and as soon as this ceases the valve should automatically return to its mid position, while the piston immediately becomes locked in whatever position it may chance to be. It is for the accomplishment of this purpose that the controlling motor here illustrated was designed by Mr. Lincoln A. Lang, of Yale, N. Dak. This motor is not only applicable to marine steering purposes but may be used for steering motor vehicles, for controlling engines, operating power feeds, presses, etc. It may be operated by steam, compressed air, or liquid under pressure, but for steering purposes an elastic medium like steam or air is preferable on account of the liability to shocks.

The general arrangement of the motor is shown in Fig. 1. Working in a cylinder is the piston V from which piston rods extend through front and back cylinder heads and each connects to a cross-head, one of which is shown at J. A secondary cylinder or steam chest is located above the main cylinder and has connection with it by means of the ports C C'.

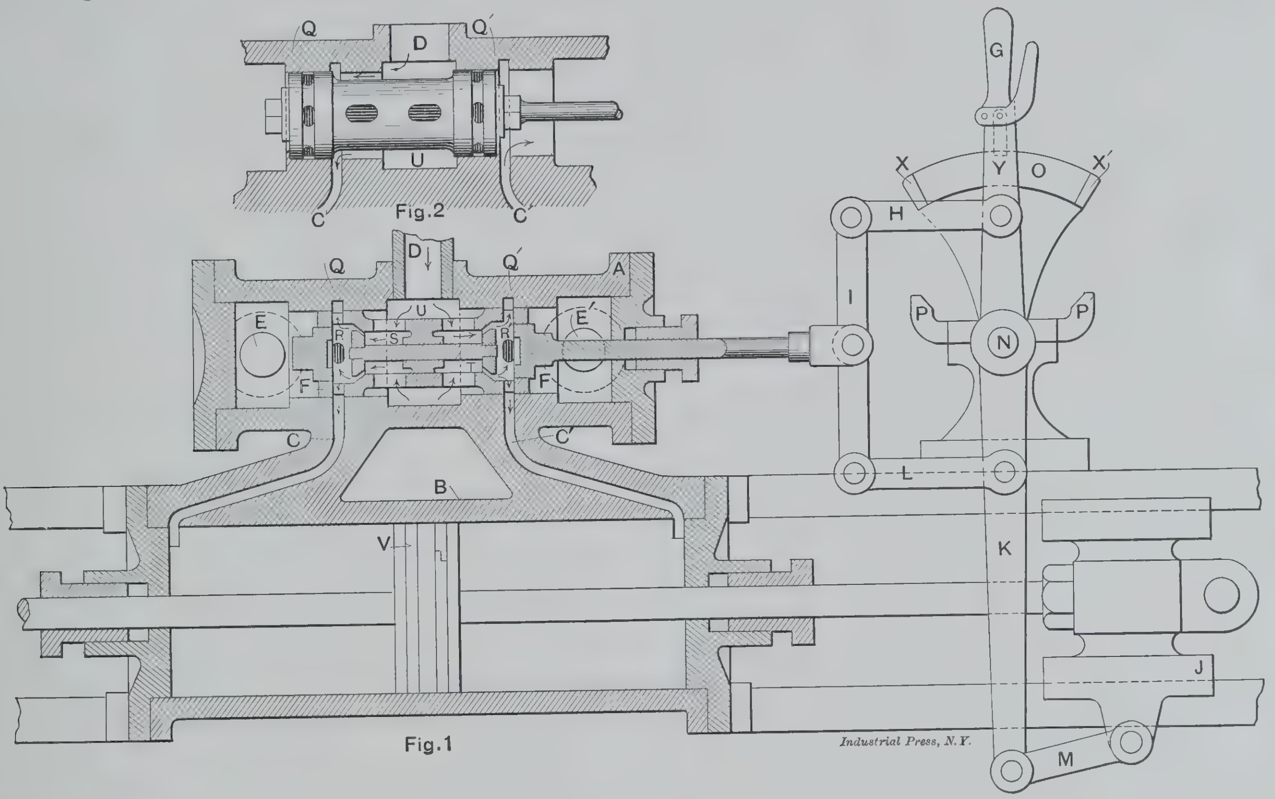

Fig.2

Fig.1

Lang's Adjusting and Controlling Mechanism.

This steam chest connects with the source of motive supply by means of the pipe D, and with the atmosphere by the pipes E E'. Working within the steam chest is the hollow piston valve F, which is actuated primarily by means of the hand lever G, the link H and the floating lever I; and secondarily by means of the cross-head J, acting through combining lever K and links L and M. The sector O and the combining lever K are integral and swing from the fixed pin N, while the lever G is mounted independently upon the same pin and is limited in movement, primarily by the stops X X' on the sector and ultimately by the fixed stops P P'.

The movable sector O is provided with a central notch Y which is adapted to engage a spring catch upon the hand lever so that lever and sector may be locked together. The hollow piston valve F is closed at both ends and its interior communicates at all times with the source of motive supply by means of the openings, as indicated by the arrows. The circular grooves Q Q', Fig. 2, through which the steam enters the cylinder, are so located as to register exactly with the ports C C when the valve is in its mid position. Mounted loosely in the bearing S, within the main valve, is the independent double-ended check valve T which is adapted to close communication between either of the chambers R R' and the interior of the valve. Assuming the piston to be in its central position, then the motive power, entering the chest by the pipe D, passes through the valve and the ports C C' into both ends of the main cylinder, thus establishing an equal pressure on both sides of the piston. Now if some external force or shock is exerted upon the cross-head, tending to move the piston in either direction, the result will be a tendency of the motive agent to circulate, which acting upon the check valve T will cause it to seat instantly, thus shutting off any outlet for the motive agent and preventing the piston from moving. Since the check valve seats itself against generator pressure it cannot pound and will fall back naturally to the balanced position as soon as the force tending to move the piston ceases to act. If we wish to shift the piston to one side of the center, to the right for example, the hand lever G is unlocked from the sector and thrown over against the primary stop X, under which conditions the valve assumes the position shown in Fig. 2. This places the port C in direct communication with the live chest U and opens the port C' to exhaust, both ports Q and Q' being thrown out of operation. The piston now moves to the right and in doing so swings with it the combining lever K. This revolves the sector O to the left and at the same time actuates the lower end of the floating lever I so as to return the valve to its original mid position, which will stop the piston and lock it in its new position. In its movement to the left, the stop X has moved away from the hand lever, so that when the mid position of the valve is regained the hand lever is again central with the sector.

Had it been desired to continue the movement of the piston to the right the hand lever, instead of being held in place, would have been kept in contact with the stop X and caused to move with it to the left. This would have continued until the hand lever engaged the fixed stop P, when the movement of the levers would float the valve to its mid position and stop the piston just at the end of its stroke.

Thus by moving the hand lever to left or right we can cause a corresponding movement of the piston, the length of whose movement can be regulated by the length of time we hold the lever against the stop X or X'. Whenever the desired position of the piston has been reached it is necessary only to stop the motion of the hand lever, when the valve will at once assume mid position, locking the piston in place.

ENGINEERING REVIEW.

A SYNOPSIS OF CURRENT TECHNICAL LITERATURE.

MAKING LARGE THREADED PIPE JOINTS TIGHT.

American Machinist, September 11, 1902, p. 1315.

"We and others," says Prof. Sweet, "have had a great deal of trouble in making and keeping large threaded pipe tight. We find that by threading the flanges ¾ inch to foot taper and the pipe ⅝ inch to foot, the joints stay tight. The reason is that after being threaded the end of the pipe is thinner than farther back. The thin portion will compress as the thread is screwed home so that it fits closely all the way. Tinning the thread of a pipe before it is screwed in, is better than any paint or smear grease."

PENALTIES FOR DIVULGING TRADE SECRETS IN FRANCE.

Cassier's Magazine, September, 1902, p. 625.

Under a French law still in force, the communication by a factory workman, clerk, or manager, of a trade secret to a foreigner, or to a Frenchman resident abroad, is punishable with a term of imprisonment ranging from two to five years, and with a fine ranging from 500 to 20,000 francs. The culprit is, moreover, deprived of his civil rights, and kept under police surveillance for a period of from five to ten years after his release from prison. A similar communication made to a Frenchman resident in France, is less heavily punished, the term of imprisonment varying in this case from three months to two years, and the fine from 15 to 200 francs. In the case of a State arms or ammunition factory, the maximum penalty must be imposed. It appears, further, that in France the proprietor of a factory has a right, without reserve, to the discoveries and inventions made within his field of work by any of his employees.

THE HIGHEST RAILWAY IN THE WORLD.

World's Work, September, 1902, p. 2516.

On the Oroya Railway in Peru, known as the Ferro Carril Central del Peru, it is possible to leave a station in a tropical climate eight degrees south of the equator and in eight hours reach a region of perpetual snow and ice. This railway is probably the most wonderful in the world, considering the difficulties encountered in its construction and the engineering expedients adopted to overcome them. Its total length from Callao to Oroya is only 138 miles, yet it cost $43,000,000 to construct, or over $310,000 per mile. At Chosica, thirty-three miles from Lima, the first switch-back is located and from this point until the summit is reached, the grade is four per cent. The summit is in the middle of the Calera tunnel (which is one and one-half miles long), and is at an elevation of 15,665 feet above the sea. This elevation is on a level with the summit of Mont Blanc in Switzerland and 1,445 feet higher than the Pike's Peak in Colorado. The railway skirts the edges of precipices thousands of feet deep where it is difficult to understand how the surveyors laid out the route. In fact in many places it was necessary to suspend them by ropes as they worked. In one place the bed of the River Remac is usurped by the track of the railway, the river having been diverted by a tunnel so it flows beneath the tracks. A car will run by gravity alone from the tunnel to the sea coast, a distance of 106 miles. The road is standard gage. The fuel used on the locomotive is petroleum.

AUTOMOBILE FOR HEAVY DUTY.

Iron Age, August 28, 1902, p. 11.

The Fischer Motor Vehicle Co., Hoboken, N. J., are now manufacturing an automobile for heavy trucking which has a novel motive power in the combination of a gasoline engine with an electric storage battery. The gasoline engine, while it is a very convenient form of motive power, has but a limited range of speed and will not carry an overload. The storage battery, while overcoming these difficulties, is but a secondary power and consequently of limited mileage. The new motor is a combination of the two systems, possessing the advantages of both and eliminating the disadvantages.

Under the fore part of the vehicle is placed a 10 H. P. three-cylinder, four-cycle gasoline engine directly connected to a 5-kilowatt 110-volt dynamo. The current from this motor is used to drive a pair of 5 H. P. motors, one of which is connected by gear and pinion to each rear driving wheel. Between the dynamo and motors are placed 50 storage battery cells, having a capacity of 90 ampere hours. When the load demands, full current goes from the dynamo to the motors, but when from slowing up or any other cause less power is needed than is furnished by the engine the current is automatically taken up by the batteries, and when, in ascending grades or starting loads extra power is required, the batteries promptly supply the deficiency.

A test of this motor was made when the ground was covered with snow. A mileage of 54 miles was made with a consumption of 12½ gallons of gasoline. At 9 cents per gallon this makes the fuel cost a fraction over 2 cents per mile under the most unfavorable conditions.

PRACTICAL POINTS REGARDING COMPRESSED AIR.

Compressed Air, 1902.

The cooling of air during compression by injecting a spray of water into the air cylinder, has been generally abandoned for the multiple-cylinder compressor in which the air is compressed by stages with intercoolers between. Water injection is bad because it causes excessive wear on the pistons and cylinders, and because of the capacity of air to take up moisture when at a high temperature. The capacity of air for moisture is in direct proportion to its temperature. Dry stage compression gives a pressure line more nearly isothermal than the injection process.

The air supply for a compressor should never be drawn from the engine room. It should always be taken from the coolest source available and that is usually the outer air. Hot supply air means thin air, and that means low volumetric efficiency. The hotter it is the more power will be required to compress a certain volume to the required pressure. After compression the air should be cooled in a condenser to abstract the moisture. Air at all times contains moisture, the average moisture being 50 per cent of what is required to produce saturation. If we can cause this moisture to be deposited in the condenser or after-cooler, it saves having it deposited on the interior of the supply pipes. Often these pipes are covered with frost on the inside, sometimes to such an extent as to choke their capacity seriously. Again moisture in the air will congeal in the ports of motors and cause great trouble. These troubles may be reduced to a minimum and even entirely overcome by a thorough system of after-cooling to abstract the moisture. Air cylinders of compressors do not require oil like steam cylinders. What is good for the one is bad for the other. A steam cylinder needs an oil of low flashing point, and plenty of it, because the tendency of the wet steam is to wash the oil out of the cylinder. Not so with air, there is no washing tendency and very little oil will last for a long time. This oil should be of the best quality obtainable and of a high flashing point. It should not be a coking oil; that is, when evaporated upon a piece of hot metal, it should not leave a carbon deposit. This is a subject which has been very much neglected, and this neglect is responsible for much waste of money and, worse than this, for explosions which destroy property and threaten lives. The actual amount of oil that should be used in an air cylinder is one-quarter that which should be used in a steam cylinder of the same size. This is the maximum, for very much less will often suffice, especially where the oil is of the best quality. Too much oil where there is a coking tendency results in choking the valves and ports. A discharge valve might stick through coking, and when stuck it will admit some of the hot compressed air into the cylinder against the receding piston, which on the return stroke is compressed and carried to a temperature beyond the flashing point. Sometimes when discharge valves give trouble, they are cleaned by injecting kerosene. This is a fatal error. Kerosene should never be used in the air cylinder, but, instead of this, fill the oil cup with soap suds, made preferably out of soft soap, and feed this into the cylinder; let the compressor work with soap suds instead of oil for a day each week and no harm is done, care being taken to feed with oil a half hour before stopping, so that the parts may not be subject to rust, which is the only danger from soap suds.

LINING THE SHAFT BEARINGS OF MARINE ENGINES.

Power, June, 1902, p. 27.

It is a matter of prime necessity that the shaft bearings of large marine engines be kept in line, but to make the proper adjustments often calls for considerable ingenuity on the part of the marine engineer. The method employed for lining shafts on the steamships of the American Line, is about as follows:

The two end bearings are chosen, between which the shaft is to be lined, and the original height of its center in each bearing above its datum plane is accurately determined. This height is given by the drawings of the engine, and is usually known and marked on the bearing. Knowing the position the center of the shaft should occupy in the end bearings, a certain height, *h*, vertically above this position is assumed, and directly behind this point is placed a box containing a candle which shines through a very small hole in the box located at the same height as that assumed, as shown at *B* in Fig. 1.

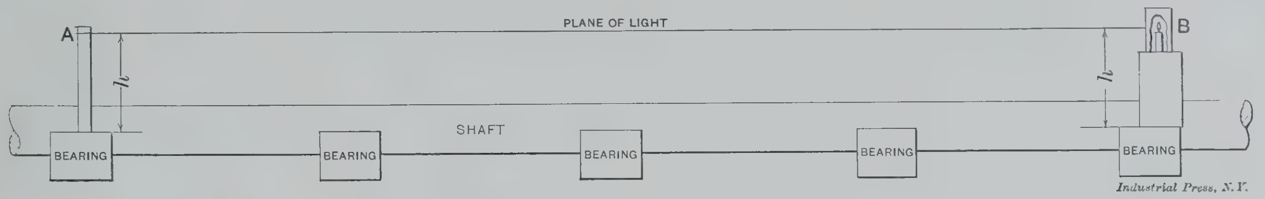

Fig. 1. Lining a Shaft by Means of a Ray of Light.

At the other bearing is placed a wooden framework which forms a very narrow horizontal slit at the same height above the center of the shaft (or where the center ought to be) as the hole in the box at the other bearing, shown at *A*, Fig. 1. The height of the light and slit should be made sufficient so that in looking at the light through the slit, the plane of sight will clear the crank webs or whatever might intervene. The height of the other bearings may now be examined by any convenient method. If the shaft is of uniform diameter, and in line vertically between the two end bearings, the distance below the plane of light, *A B*, of the top of the shaft at any point should be the same as the distance the top of the shaft at the end bearings is below the plane. A handy way to determine these heights is to use a combination of two sticks, as shown in Fig. 2, which also shows the framework forming the slit. The sticks are pivoted as shown, and the horizontal stick is moved by an assistant till it cuts the light as seen through the slit. The point where it cuts the light determines the fixed height above the top of the shaft, and by measuring accurately to the top of the shaft, will show whether the shaft at this point is too high or too low; the amount of its displacement will be h' — (h—radius of shaft). If h' equals, say 40½ inches, h equals 48 inches and the radius of the shaft is 8 inches, we know the shaft is ½ inch low. The height of the shaft, and consequently of the bearings, may be thus determined at each bearing and the results may be plotted in the form of a curve if desired. After the heights at each bearing are determined, the box containing the candle and the framework forming the slit are reversed, each being placed in the position formerly occupied by the other, and the same measurements are again made, from which the average vertical displacement of the shaft can be calculated. If it is not convenient to remove the caps of the bearings so as to determine the height of the shaft in the bearing, the heights can be measured from adjacent points outside the bearings. A small telescope with cross-hairs is sometimes used in place of the slit, but the trouble of finding the light and other points at the same time makes its use too slow for the additional accuracy gained.

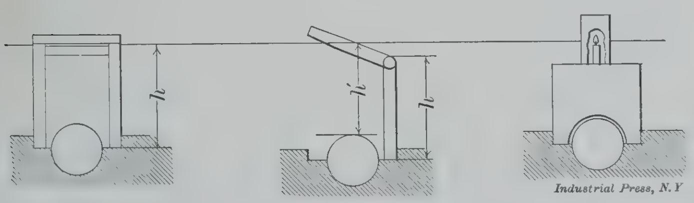

Fig. 2. Showing how to Find Displacement of Shaft.

The lateral displacement of the shaft and bearings can be determined by stretching a wire between the two points directly over the center of the shaft at the end bearings and using a plumb-bob to locate this line on the shaft.

WHY MARINE ENGINE SHAFTS BREAK WITHOUT APPARENT CAUSE.

Jour. of the Am. Soc. Naval Engineers, August, 1902, p. 721.

Marine engineers have for a number of years had to deal with mysterious fractures of shafts taking place during fair weather, and which could not be accounted for by any of the ordinary causes, such as bad material or propellers striking floating bodies.

The peculiar fact that occasionally the lines of fracture of the broken shaft resembled those caused by twisting actions pointed toward the existence of considerable twisting moments, but an explanation as to their origin could not be given. It was out of the question that the steam pressures formed the direct causes of this, as their maximum values, determined by the crank-effort diagram, rarely exceed the average value by more than 50 per cent, and would therefore create a twisting stress of, at most, 300 to 350 kilogrammes per square centimeter, the working stress allowed being about 200 to 230 kilogrammes per square centimeter.

Various authorities had already pointed out that possibly the so-called synchronous vibrations took place in the shafting, but this supposition had not been verified by direct researches. Messrs. Blohm & Voss, of Hamburg, therefore determined, in November, 1899, to study the question experimentally.

The principle of the synchronous vibrations in the shafting is the same as the principle of the vibration of a pendulum. The time required for its complete vibration, back and forth, depends upon the force and frequency of the impulse imparted to it. To be effective, however, these impulses must be in step with the pendulum, occurring regularly at the same point in its vibration. If the impulses are of sufficient force the pendulum will rise higher and higher, while if weak they will extend through a shorter arc.

In the case of the engine shaft there are torsional vibrations set up by the impulses of the steam engine corresponding in effect to the oscillations of a pendulum in a plane. The propeller on the end of the shaft affects the torsional vibration of the shaft in the same way that the weight of a pendulum affects the vibrations of the latter. Once set into vibration, the propeller would oscillate back and forth slightly at regular intervals, the frequency of which depends mainly upon the length and diameter of the shaft. The frequency of the impulses given by the engine, however, depends upon the design of the engine, those with several cranks giving different results from those with only one. An engine crank and connecting rod necessarily produce a varying turning effect on the shaft. With the different combinations possible in marine engine construction instances are not infrequent where the impulses given by the engine are in step with the natural vibrations of the shaft and may be of sufficient force to increase the extent of the vibrations to the danger point, just as the impulses upon the pendulum increase the height of its vibration.

To illustrate this point the author cites the case of a shaft in which, according to calculation, the individual number of vibrations per minute were 257.4. On a trial trip with the vessel it was possible to run at such a speed that the impulses were synchronous with these vibrations and by means of the recording instruments used it was demonstrated that the shaft became strained by a moment almost equal to three times the average turning moment, and that between these times it sprung back past the neutral line into the negative region of strain. At certain points the kinetic energy of the propeller actually drew the engine along and the shaft was strained intermittently to an extent which considerably exceeded the safe limit.

The experiments made on this subject were very elaborate and the treatment of it is highly mathematical. Directions are given for working through the problem in designing a marine equipment, and when it is found that a synchronous action is likely to occur the diameter of the shaft should be changed to make the vibrations of the shaft out of step with the periodic variations in the turning moment of the engine.

HORSE POWER OF MARINE ENGINES MEASURED BY SHAFT TORSION.

Journal of the American Society of Naval Engineers, August, 1902, p. 721.

In the tests upon the torsional vibrations of shafting, mentioned in the foregoing extract, it became necessary to measure the transmitted forces between engine and propeller. This was accomplished by accurately determining the amounts of twist of the shaft, and it is believed to be the first instance where the net or brake horse power of engines of several thousand horse power has been found. As stated below the horse power was probably estimated by this method within very close limits.

In order to calculate the transmitted forces accurately by means of the measured amounts of twist one must know the modulus of elasticity for shearing of the shafting.

As no suitable data were available from the technical literature, Messrs. Blohm & Voss determined not to start on possibly erroneous assumptions but had the modulus found by special experiment.

For this purpose three experimental shafts of 2,500 millimeters length by 60 millimeters diameter were ordered in the spring of 1900, from each of the following firms: Friedr. Krupp, Essen; Bochumer Verein, Bochum; Gewerkschaft Witkowitz, Witkowitz in Mähren, stipulating that they were to be made from the same material and treated in the same way as marine shafting proper.

These experimental shafts were subjected to exhaustive torsion tests, which showed that the modulus of the material experimented upon—Siemens-Martin steel of 40 to 47 kilogrammes breaking strength per square millimeter (57,000 to 67,000 pounds per square inch) and over 20 per cent elongation—varies by remarkably small amounts, and very nearly agrees with the average value, 828,000 kilogrammes per square centimeter (11,776,600 pounds per square inch).

This figure was then made use of to determine the effective power transmitted, and thus the ratio which it bore to the indicated horse power—i. e., the mechanical efficiency of those engines—could be found.

As far as I know, the so-called brake horse power of engines developing several thousand horse power has never been measured accurately before this. The method which, practically speaking, makes use of the shafting as a torsional spring can, of course, only be applied to marine engines having these long shafts, or to installations with long-shaft transmissions.

The efficiency in the cases examined varied between 92 and 88 per cent. Lower values, down to 82 per cent, were only found in special cases. The accuracy which may be attained in these experiments is estimated at 0.5 to 1.0 per cent. This also is about the degree of accuracy which one may, at most, expect when calculating the indicated horse power from indicator cards.

THE STEAMSHIP KROONLAND.

Marine Engineering, September, 1902, p. 429.

The largest steamship built in America to date is the Kroonland, for the Red Star Line of the International Navigation Co. The new vessel was launched last February, and only four months elapsed from the launching until the first voyage. Such remarkably rapid work has been made possible by the general improvements that have been made in shipyard tools and appliances within the past few years. Practically all the rivets in the hull and superstructure of this vessel were driven by power. While machine riveting has been generally employed in all shipyards for some years, it has always been necessary to drive a large proportion of the rivets by hand on account of the practical impossibility of adapting hydraulic riveting machinery to the many intricate parts of a ship where riveting must be done. The use of pneumatic riveters, however, has worked a great improvement in machine riveting, so that it is now possible to do practically all the riveting of a ship with these tools.

The Kroonland is 560 feet long between perpendiculars, 60 feet wide and 42 feet deep. When loaded to her full draft of 31 feet she has a displacement of 22,100 tons. Being a twin-screw ship, there are two sets of engines which are triple expansion and have an aggregate of 10,200 I. H. P. The cylinder diameters are 32½, 54 and 89½ inches with a common stroke of 54 inches. The total condensing surface is 14,000 square feet, or nearly 1.4 square feet per one I. H. P. Steam is supplied by nine single-ended Scotch boilers, each having a diameter of 15 feet 10 inches and a length of 10 feet 5½ inches. Each boiler has four Fox furnaces, and the total grate surface for the nine boilers is 643.5 square feet. The total heating surface is 22,400 square feet, making the ratio of I. H. P. to heating surface 1 to 2.2. The boiler pressure is 170 pounds.

The engines are fitted with piston valves, and the valve gear is of the double eccentric link type generally used on marine engines. The crankshafts are 16¾ inches in diameter and are made interchangeable, so that a spare crankshaft may be used for either engine in case of accident. The lineshafts connecting the crankshafts and tailshafts are 15¾ inches in diameter. They are fitted with Verity flexible couplings, two in each, to compensate for any irregularity of alignment. The tailshafts are 18¼ inches in diameter, and are protected by brass liners 1 inch thick. A feature of the engine construction is that the piston rods of the intermediate and low-pressure cylinders are flanged and secured to the pistons by six bolts instead of the usual taper fit and large nut.

HOW A LARGE PULLEY WAS TURNED TO A SMALLER DIAMETER.

Practical Engineer, August, 1902, p. 12.

A few years ago the American Cement Co. erected a plant at Jarden, Pa., in which power was transmitted from a 24 x 48-inch Corliss engine to two line shafts by means of two double 36-inch belts. One line shaft was in front of the engine and the other back of it and the belts leading up to the pulleys were both carried on the same flywheel. The pulley on one line shaft was 37½ inches face and 15 feet in diameter and the other was of the same width of face, but 15 feet ⅜ inch diameter. The slight difference in diameter made no particular difference under the circumstances.

After being installed for about twelve years, the plant was dismantled and the machinery removed to a factory at Egypt, Pa., including the old engine and line shaft pulleys. In the new factory it was proposed to belt the engine to one line-shaft and mount the two pulleys side by side, but this was about to be abandoned when the difference in diameter was discovered. A practical mechanic, however, suggested that the larger pulley could be turned down at the factory without great expense, which was done.

Both pulleys were mounted on a shaft and securely fastened to it. The shaft was provided with suitable bearings so the pulleys were free to turn. In front of them a cylinder boring bar was rigged on 10 x 10-inch timbers arranged in crib form. The bar was held in two hard wood boxes and was set square with the pulley faces. An eccentric was rigged on the shaft to give the necessary feed motion. The pulleys were driven by a belt incircling one and leading to a jack shaft fastened to the floor about twenty feet in front of the boring bar. A five horse power engine drove the jack shaft through triple reducing gears, and the 36-inch pulley on the jackshaft transmitted motion to the pulleys at about 42 feet per minute.

The larger pulley was turned off first and then a cut was taken over the faces of both, a distance of 6 feet 3 inches. Then surface was crowned, leaving a space 18 inches in the center flat. The cost of the job was only a little in excess of the freight and cartage on a new one.

ROLLING MILL ENGINE OF 6000 H. P.

Engineering News, August 28, 1902, p. 138.

The Filer & Stowell Co., Milwaukee, Wis., have recently built for the Republic Iron & Steel Co., Youngstown, O., a rolling mill engine of the Corliss cross-compound type which is rated at 6,000 H. P. when running at 65 turns per minute with a steam pressure of 140 pounds. The high-pressure cylinder is 44 x 60 inches and the low-pressure 82 x 60 inches. The frame with main bearing and guides, is formed in one great casting 26 feet 2 inches long and weighing about 45 tons. No legs or pedestals are used, the entire frame forming a flat bed-plate with a continuous bearing on the masonry foundation. The piston rods are of forged steel 9 and 11 inches in diameter. The piston rods are threaded to screw into the crossheads and the usual jam nuts are provided for locking. In addition the crossheads are split where they embrace the rods and clamping bolts are provided to tightly clamp the threaded parts of the rods. The crossheads are of cast steel with independent steel shoes top and bottom, the shoes being turned to radius of 38 inches to fit the bored guides. The shoes are faced with 7-16 inch babbitt metal. In order to prevent the great weight of the pistons wearing and scoring the cylinders, the piston rods are extended so as to form tail rods which are provided with outer bearings to carry the weight. The pistons and piston rods are thus supported on the crossheads and tail rod slippers. The high-pressure piston is of cast steel with double walls; the low-pressure piston is also of cast steel, but of single thickness. The connecting rods are 14 feet center to center. The crosshead pin of the low-pressure cylinder is 12 inches in diameter, and the crank 23 inches. The high pressure crank is 14 inches diameter. The crankshaft is made of double refined hammered iron, and is 20 feet 6 inches long, 23 inches diameter at the low-pressure crank, 26 inches diameter at the wheel fit and has two bearings 25 x 43½ inches. There are two keyways in each crank and two in the wheel hub. The flywheel is 24 feet in diameter, 19 inches wide on the face and weighs 150,000 pounds. It is of the "built-up" form and consists of ten segments each carrying a spoke. The segments of the rim are held together by steel links of the "dumb-bell" pattern shrunk into recesses in the sides. The valves are of the Corliss pattern and are operated by two eccentrics on each cylinder. The eccentrics are 44 inches diameter and 7 inches face. The throw is 10⅛ inches for the steam and 11½ inches for the exhaust on the high-pressure side and 13⅛ inches and 13¼ inches on the low-pressure side. The engine is for rolling structural shapes.

IMPROVED BOILER JOINT.

Railway and Locomotive Engineering, August, 1902, p. 336.

Mr. Samuel M. Vauclain, superintendent of the Baldwin Locomotive Works, Philadelphia, has recently designed and patented a horizontal boiler seam, which is claimed to have 96 per cent. of the strength of the solid plate. This is a very substantial increase in strength, when it is remembered that the ordinary sextuple-riveted, double-welt, butt joint has about 85 per cent. of the strength of an unperforated boiler plate. Mr. Vauclain's seam is a butt joint, with double welt, the under one being diamond-shaped. In the seam shown in our illustration there is one rivet, at the corner of the under welt, 22⅞ inches from the butt-joint. The tensile strength of the plate at this point is that of the entire sheet, minus one rivet-hole 1¾ inches in diameter. At a distance of 4½ inches nearer the seam, the plate has its full tensile strength, minus two such holes, widely spaced, plus the shearing strength of the rivet at the apex of the triangle made by half the diamond welt. On the third row, it will be seen, the strength of the plate has been reduced by three widely-spaced holes, but it is assisted by three good rivets in single shear. On the fourth row, the plate, weakened by four holes, is reinforced by the shearing strength of six rivets. On the next line, just outside the upper welt, there are nine holes, but beyond them are ten rivets in shear. When we come to the double welt itself, there are 17 holes in it, with 19 rivets in the half diamond of the lower welt. All the rivets in the row along this welt are in double shear. This means that they pass through three plates, thus giving two planes where shearing forces act. Rivets in double shear are very nearly, though not quite, equal to twice the value of rivets in single shear, or those which pass through only two plates.

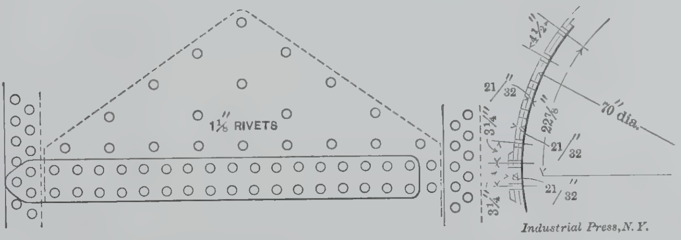

Fig. 5. Boiler Joint having 96 per cent. Efficiency.

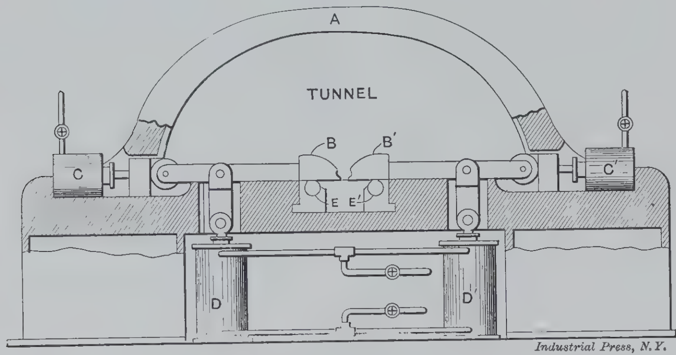
Adding together all the advantages and subtracting the disadvantages, if one may say so, or more correctly, taking the algebraic sum of all the additions to strength, and all the reductions of strength in this arrangement of plates and rivets, it has been found by test that this seam is about 96 per cent. as strong as the original plate itself. The diamond-shaped welt here used, secures this advantage, that on each line of rivets, the holes are comparatively few and far between, and as the seam itself is approached, the total number of rivets outside each succeeding line, almost makes up for the loss due to the holes punched.

A NEW PROCESS OF MAKING CUTLERY.

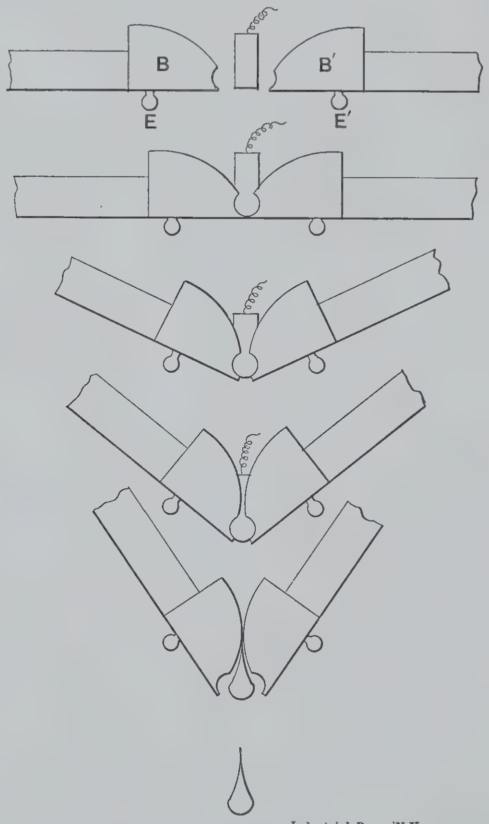
Electrical Age, September, 1902, p. 388.

The methods followed to-day in the manufacture of cutlery do not differ essentially from those followed a hundred years ago, and so far as we know, they may have originated with Tubal Cain, who is alleged to have been the first worker in iron. The making of a knife blade, for instance, requires that it first be forged to the approximate shape required; it is then ground, hardened and tempered, reground and polished. In the manufacture of knife blades in large quantities these operations may be subdivided so that each blade may pass through a score or more of hands before it is ready for the market—and the chances are about even that it will be an indifferent tool when completed owing to uncertainty of hardening and tempering.



Industrial Press, N.Y.

Fig. 6. Diagram of Forging Machine for Misko System of Forging.



Industrial Press, N.Y.

Fig. 7. The Successive Steps in the Misko Process.

Should, however, the process invented by Joseph Misko, Pittsburg, Pa., prove as successful as it is represented to be, it will very likely revolutionize the art. As might be expected, the modern wonder-worker—electricity—plays the principal rôle in the new process. The steel for blades is heated both for hardening and tempering by a powerful electric current while in a vacuum and the forging is also done under the same conditions, the air being excluded to prevent oxidization. Since the blade is not exposed to the air it may be ground before being forged to remove the scale and then shaped to the exact shape required and to a sharp edge without fear of injury.

So in the Misko system the usual process of manufacture is reversed. The grinding and polishing are done before the forging is begun. A rod of steel, say, ten feet long or of any other convenient length, is taken for the initial process. The rod is ground on all sides and polished. In this state it contains just enough material for the forming of the blades into which it is to be converted. It is now ready for the forging.

The forging machine is a tunnel of steel a little longer than the steel rod. Lying along the middle of this tunnel and with their ends separated enough to receive the prepared rod and yet not touch it, is a double row of dies *B B′* reaching almost to the full length of the rod.

Each pair of these dies is ready to form a blade, each die forming one side of it. The upper part of the tunnel *A* is an arch of steel which trusses the dies together and serves also as a guide to them in their forging operation. At each end of the dies are hydraulic presses *C C′* and there are more of these below the dies on either side, as at *D D′*.

The operator thrusts the rod of cold polished steel into the tunnel and between the die heads. He closes the door and touches a button. Powerful pumps quickly exhaust the air out of the machine. As the door closes and seals itself, electrical connections are made on either end of the polished steel rod. As the air disappears from the inside of the chamber the electric current is turned on. In a few seconds the rod is at a cherry-red forging heat. Another touch by the operator and the dies close together, forming with their ends the backs of the blades into which the rod is to be transformed. Another touch and the far ends of the dies begin to travel up the arched sides of the tunnel. As they move the inner ends close more and more with a revolving motion, squeezing down the steel between them until at the last it is forced into a sharp edge.

The operator returns the dies to their places, cuts off the current and opens the machine. The steel rod has been transformed into a series of shining polished blades. There are nicks between the blades, marking where they are to be broken apart later. As there was no air in the forging chamber the blades have lost none of the brightness of the polished rod of steel.

The next operation is the hardening. Again the rod of blades is placed in a tunnel and the air is exhausted. This time instead of dies there are, on either side of the rod, heads of metal indented to fit the blades and inside each head runs a stream of refrigerating brine, cooled to below the zero of the thermometer. The current is again applied to heat the rod of blades and when they are glowing the refrigerated heads close together, chilling the thin steel, but doing it so evenly, that it is claimed there is no tendency to produce warping or cracking.

Still the blades are bright and polished when they come from the hardening machine. To put the finishing touch to the blades, Mr. Misko has devised a refrigerated grinding and polishing wheel on which the cutlery would be kept from losing its temper though it were ground dry as is the custom. These wheels are of hollow iron with the abrasive substances cemented to their outer edges and the whole kept cool by a stream of freezing brine run through the inside of the wheel. A factory to make use of this process will soon be erected at Newcastle, Pa.

AN EXAMPLE OF THE EXTENSIVE USE OF STEEL CASTINGS IN LOCOMOTIVE CONSTRUCTION.

Railway Age, August 29, 1902, p. 202.

A noticeable feature of modern locomotives is the graceful outlines of the component parts. Sharp angles have given way to curves and fillets with a resulting improvement in the strength and durability of the parts as well as appearance. The evolution in this direction has been gradual and improved shop machinery has been responsible to some extent for the change. The introduction of heavy milling machines has made it possible to finish parts of curved contour as economically as straight surfaces can be finished on the planer. More-

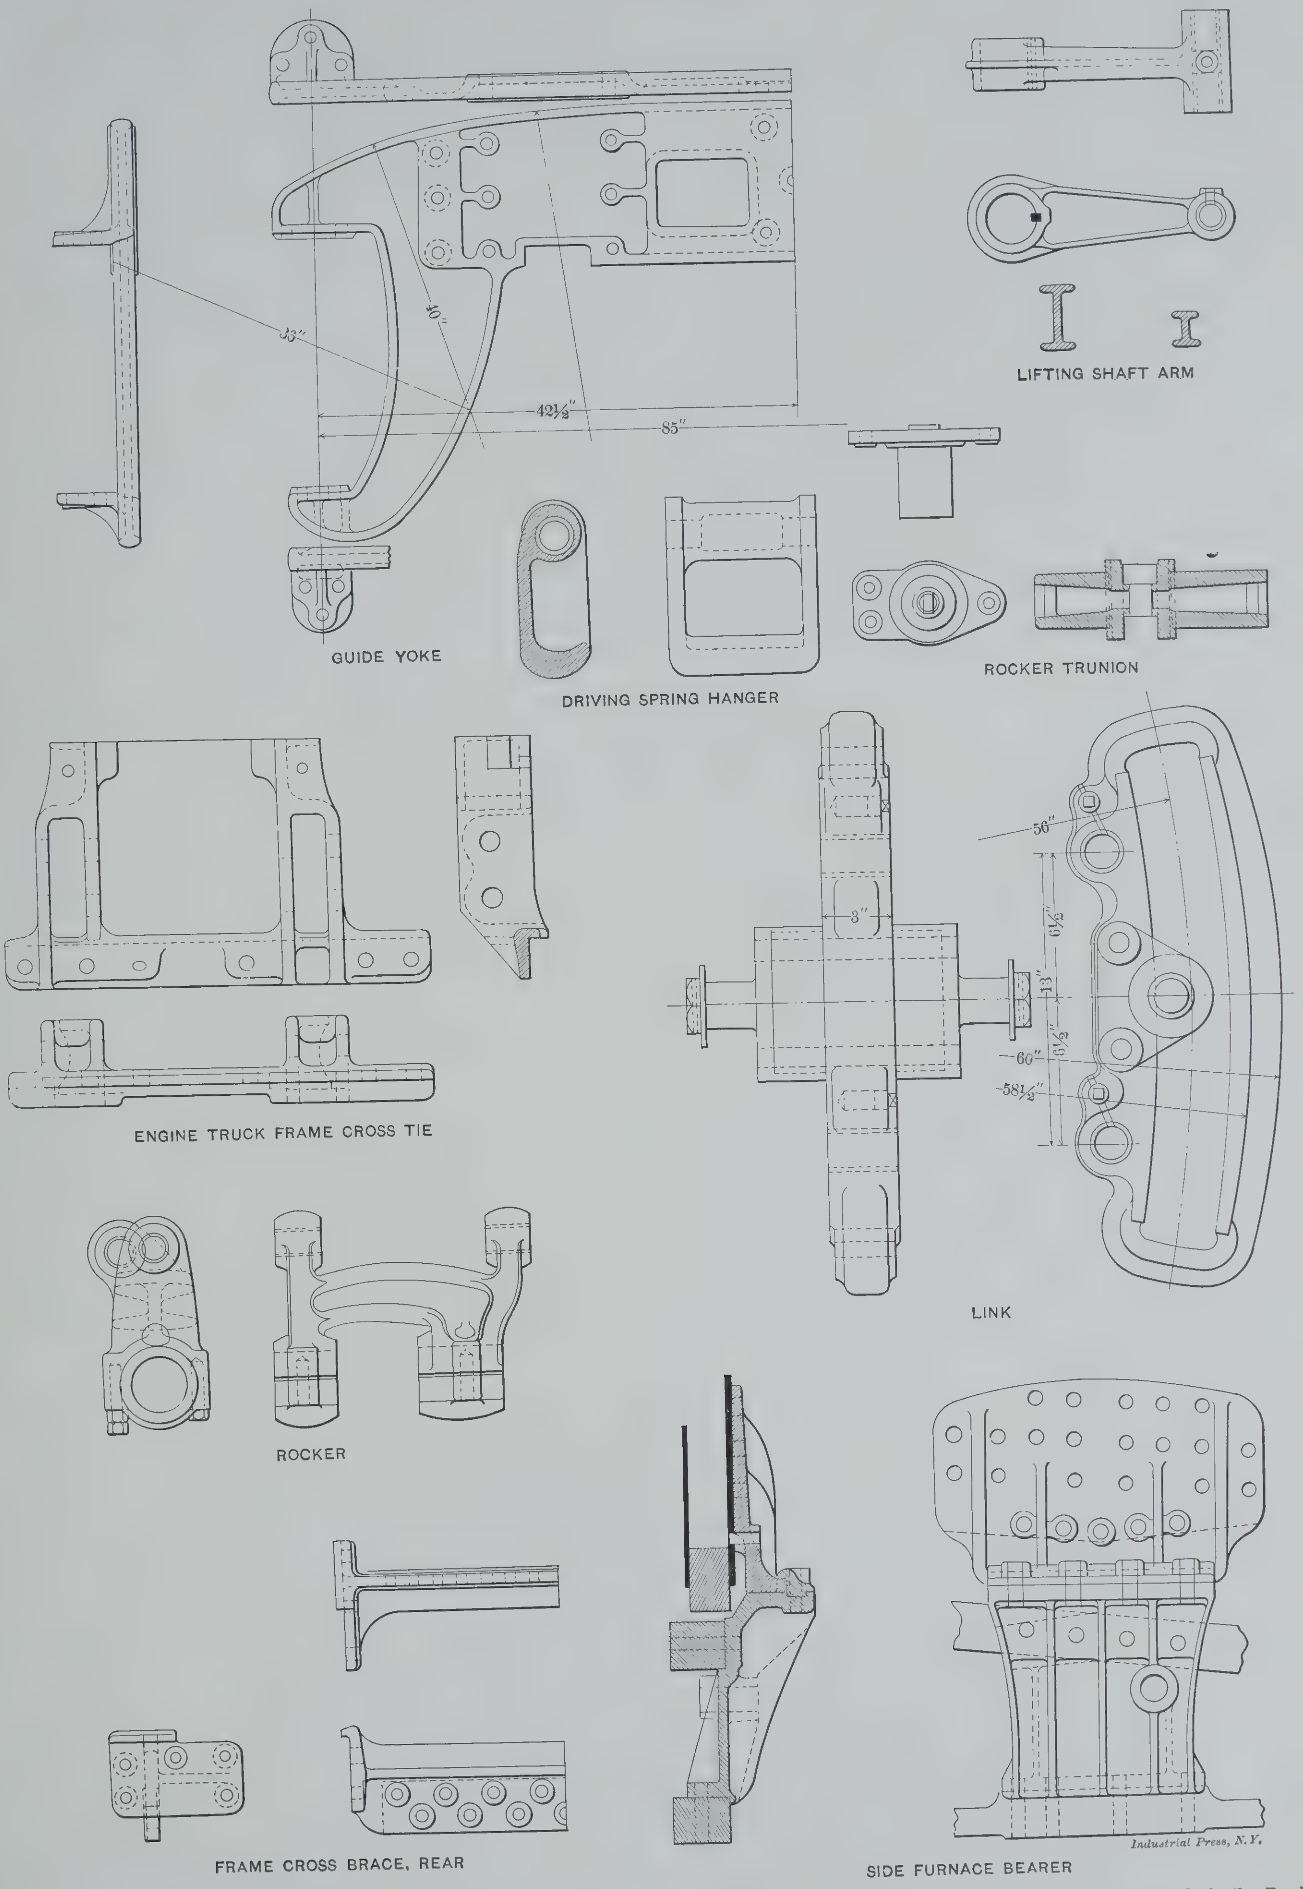


Fig. 8. Example of Steel Castings used in Modern Locomotive Construction and Illustrating the Wonderful Advances that have been made in the Production and Use of Steel Castings.

over, the development in the manufacture of steel castings has made it possible to substitute this metal for parts that heretofore have been made of wrought iron and cast iron and employ designs that embody greater strength with less weight. This change of design is more apparent in cast steel parts that have been substituted for wrought iron. An illustration of the substitution that may be carried out is found in the construction of some new locomotives recently built by the Brooks Works of the American Locomotive Company for the National Railroad of Mexico.

The illustrations show locomotive parts that have been made of cast steel only in recent years. Special mention may be made of the use of cast steel for reverse shaft lifters, the horizontal arm only is shown, but the vertical arm is also of the same material. The guide yoke evidently costs much less for machine work than when made of wrought iron and is of stronger and better design for the same weight of material. The guide blocks are cast integral with the yoke which is an example of the machining and fitting saved by the use of steel castings. The links are also steel castings. They are supported by double hangers and the saddles are both fastened to the inner arc. Case-hardened steel bushings are provided for the eccentric pins and the inner faces of the links are case-hardened in the usual manner. Oil cups are cast integral with the links and are made solid. The cavity for oil is made by drilling a ⅝-inch hole transversely to a suitable depth. This opening is tapped and closed with a ½-inch pipe plug. A ¼-inch hole is drilled from the top through the oil receptacle and into the eccentric pin hole to supply oil to the bearings. The oil cups are filled with curled hair to absorb the oil and act as a filter to prevent the entrance of dust and cinders to the bearings of the pins. The details of the other cast steel parts may be observed by inspection of the cuts.

NOTES ON TUBULAR BOILERS.

American Electrician, September, 1902, p. 438.

The Centennial standard boiler horse power is the evaporation of 30 pounds of water from a temperature of 100 degrees into steam at 70 pounds pressure, or the evaporation of 34½ pounds of water from and at a temperature of 212 degrees F. These are practically equal, since the first requires the absorption of about 33,308 British thermal units (B. T. U.) and the second, about 33,316 B. T. U. In plain tubular boilers it has been found that on an average one foot of heating surface will evaporate 2.3 pounds of water into steam when at an initial temperature of 212 degrees. This corresponds to 15 square feet of heating surface per boiler horse power, which is a conservative figure, since many authorities make it as low as 11½ square feet per boiler horse power. The amount of coal burned per square foot of grate surface

varies with the chimney draft, the kind of coal and the care given to firing, but it will be rarely less than 15 pounds per square foot grate area per hour. The rate of evaporation may vary from 8 to 10½ pounds of water per pound of coal. Professor Carpenter gives the average for power boilers as 9 pounds when the tubes are clean and the boiler in good general condition. In smaller boilers the rate of evaporation is less, the figures given ranging from 5.7 for a 5-horse power boiler to 8 pounds for a 30-horse power boiler. The grate surface required per horse power is determined by the formula:

$$\text{Grate surface} = \frac{34.5 \times \text{H. P.}}{A \times B} \text{ in which}$$

H. P. is the horse power required; A, the rate of evaporation; and B, the rate of combustion. Assuming the rate of evaporation to be 9 pounds per pound of coal and the rate of combustion to be 15 pounds per square foot of grate area, it will be found that for a 100 horse power boiler a grate surface of 25.5 square feet will be required. The cross section area of the uptake should be about 1-7 the grate area, and of the smoke pipe, from 1-7 to 1-10. The general rule for the sizes of tubes in horizontal stationary tubular boilers, is to allow one inch of diameter for four feet of length where soft coal is used, and one inch of diameter for five feet of length where hard coal is the fuel.

Table 1 gives the horse power and other data for different sizes of boiler. The number of tubes specified corresponds closely with that recommended by the leading insurance companies, but may be increased somewhat in special cases, if necessary, to secure a required heating surface within a given space. In such a case it is better, if possible, to select a larger shell and use the number of tubes specified in the table for that diameter. Two sizes of grate and smoke pipe are given for each boiler, one being computed for an evaporation of 9 pounds of water per pound of coal, and the other for an evaporation of 8 pounds, which figures correspond to average practice in power and heating service, respectively. The width of the grate is usually made 6 inches less than the diameter of the shell, while the length may be varied within certain limits to give the required grate surface. The length of the grate, however, should not exceed 6 feet in hand-fired furnaces. Grates 4 feet long and over should be made in two sections, so as to use short grate bars, which are less likely to warp than longer ones.

In the second table, below, are given the working pressures of boilers having different diameters and thicknesses of shell and different types of joints.

GIVING THEORETICAL WORKING PRESSURES FOR BOILERS OF DIFFERENT DIAMETER, THICKNESS OF SHELL, FACTOR OF SAFETY AND TYPE OF JOINT.

Assumed strength of plates, 55,000 pounds.

The assumed efficiency of joints, single lap 54 per cent., double lap 70 per cent., double butt 80 per cent., triple butt 88 per cent.

BURNING BRASS TIPS ON CAST IRON PROPELLERS.

The Foundry, September, 1902, p. 22.

A method of repairing cast iron propeller wheels is in vogue at Mort's Dock & Engineering Co.'s foundry, Sydney, N. S. W., which is said to be practically unknown in Europe and America. It is the fusion of gun-metal tips to cast iron propeller blades by the "burning-on" process. On account of cost, cast iron propellers are used to a large extent although they are, of course, much inferior to bronze in point of durability. The "tips," the portion 12 to 18 inches from the ends of the blades, are likely to be broken by striking floating debris, hidden rocks, wharf projections, "racing," etc., but the greatest source of damage in the case of steel and iron vessels, is corrosion due to galvanic action.

When a propeller blade is broken, the usual method of repair is to replace it with a new one, but it sometimes happens that a ship cannot be detained in port long enough to allow a new blade to be made and in that case a new tip is "burned on," which can be done in a few hours. The blade to be repaired is taken to a drilling machine and drilled across with holes about one-half inch apart, so that the bad part may be easily broken off. It is then taken into the iron foundry, bedded in the floor, and a cope rammed up over the portion that is to be renewed. The mold is then parted, finished, dried, closed and cast with gun metal in place of the cast iron tip which has been broken off. The gun metal having been cast against the cast iron blade, it has now to be "burned" to it.

The cope is thrown off while the casting is hot, and an "open" burn laid right across where the brass and iron join. It is then burned with iron, care being taken that the metal from the ladle falls directly onto the iron part of the blade so as to cut into it without washing away too much of the brass. If attention is given to the center, or thickest part of the blade in the process of burning, one can always make sure of a satisfactory joint. The proper way is to use a feeding rod as a guide, working it along the joint gradually as the iron dissolves. After the burn is thoroughly cooled, it is trimmed off and the blade sent to the ship. Although a blade treated in this way presents a somewhat piebald appearance—owing to the light and shade of brass and iron—there is nothing weak about it. All sorts of mechanical tests have been made in order to separate the brass and iron, without success. The bronze tip is not, of course, affected by corrosion, so the repaired blade is practically better than the original.

HEADLIGHT WITH HORIZONTAL AND VERTICAL BEAMS.

Scientific American, September 13, 1902, p. 170.

A new type of headlight which has recently been put in service by the Chicago, Milwaukee and St. Paul Railway, promises to have a very extended application among the railroads of this country. It is an electric headlight which, in addition to sending a powerful ray along the tracks in front of the engine, also projects a powerful vertical beam. The vertical beam makes a very decided illumination in the heavens, so much so that it is possible not only to detect the presence of an engine, but also in many cases to follow its path and determine in which way it is heading. An engineer is by this means placed in touch with the movements of other trains in his vicinity, and is enabled to detect their presence where, if they carried ordinary horizontal beam headlights, he would be unaware of their location.

With the vertical beam, of course, an approaching locomotive can be located when it is hidden from direct view by a curve or an intervening hill.

The headlight equipment, which is built by the Edwards Railroad Electric Light Company, consists of four parts: first, the motor, a simple-acting steam turbine; secondly, the dynamo, mounted on the same axle with the turbine and designed to yield to the arc light a current of from 30 to 33 amperes and from 30 to 33 volts; thirdly, the lamp, including the arc, the deflectors and the case; and fourthly, the bed-plate on which the whole apparatus is mounted.

The steam turbine is provided with a propeller wheel which is wholly constructed of rolled steel. It has a factor of safety of about 7, for while the normal speed of the engine and dynamo is about 2,000 R. P. M., the wheel will withstand successfully a speed of about 14,000 R. P. M. The speed of the engine is held constant, or practically so, regardless of change of load or initial pressure, by a simple and efficient governor, which is so arranged with relation to the other parts of the engine as to be easily and readily accessible, should occasion demand. The wheel shaft is journaled in ball bearings, giving a low coefficient of friction.

The novel feature of the equipment is the provision of an auxiliary plane deflector, placed outside the goggle at an angle of 45 degrees and in such a position as to intercept about 40 per cent. of the whole volume of light issuing from the parabolic reflector and direct it vertically. This vertical beam forms a constant warning signal. Reaching to a great height, and on cloudy nights striking the clouds, it can be seen for many miles. In fact, upon the Big Four road it has been seen for a distance of 21 miles, and on the Chicago, Milwaukee and St. Paul road it has been seen for a distance exceeding 16 miles. The horizontal beam is very powerful, showing up clearly three-quarters of a mile to a mile, on a clear, straight track, ahead of the locomotive bearing it.

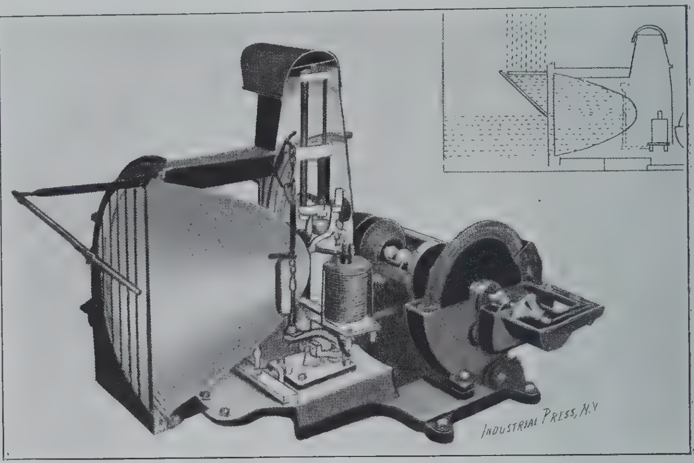

Fig. 9. Showing Arrangement of Headlight.

DOUBLE PLANER TOOL FOR MACHINING DRIVING BOXES.

Railway and Engineering Review, August 9, 1902, p. 505.

A device to be used in connection with a circular planer tool for facilitating the work of machining driving box crown-brass and cellar fits has been designed at the Marshall, Texas, shops of the Texas & Pacific Railway. For a number of years it has been the practice at the above-mentioned shop to slot brass and cellar fits, but some time ago a Pedrick & Ayer circular planer was installed and that class of work accomplished thereon. The arrangement resulted very satisfactorily as regards the quality of the work and reduction of time previously necessary in doing it, but trouble was experienced because of a lack of rigidity of the circular planing tool, making it impossible to remove all the stock at one cut on some of the larger boxes. Another disadvantage was experienced in that in machining the cellar fits only one cutting tool on the planer could be used at a time. To obviate these difficulties the device shown in Fig. 10 was designed, having two tool heads similar to a planer head working in a horizontal plane, the tools being held in a cutting position by a coil spring, this arrangement permitting them to clear on the return stroke. The tools are adjusted to any size of box by moving in or out, as occasion demands, and the mechanism has afforded a simple and inexpensive home-made tool for the work. By utilizing this in connection with the Pedrick & Ayer planer about one-third more work has been turned out than was possible during the same time by the older method.

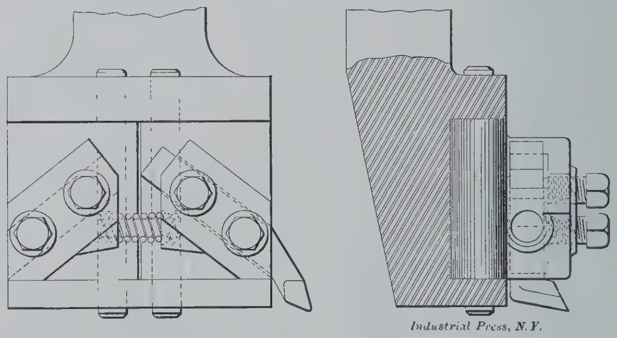

Fig. 10. Double Planer Tool for Driving Boxes

DRILLING JIG PLATES.

AN ORIGINAL METHOD FOR ACCURATELY SPACING DRILLED HOLES.

J. R. GORDON.

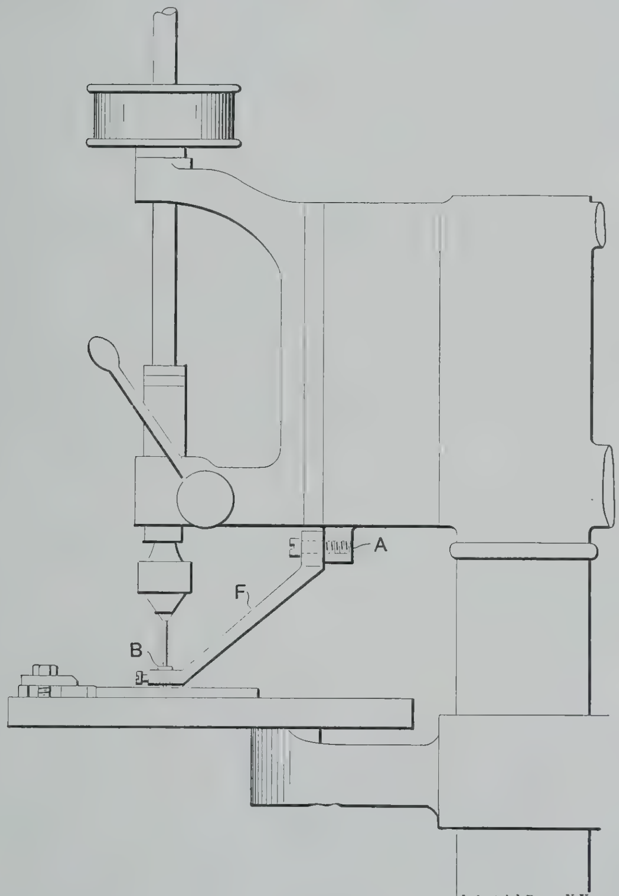
The method of drilling the holes in plates of jigs here described is to the best of my knowledge entirely new, and as I am associated with several toolmakers, of wide experience and acquaintance, who are of the opinion that the method is well worth introduction into general use, I offer it to the consideration of the readers of MACHINERY.

Having a large number of jigs to make and desiring to have the positions of the drill bushings accurate to within .001 of an inch, I removed the work table from an ordinary sensitive drill press of the usual pattern, and substituted therefor one of larger dimensions, to accommodate the size of the jig plates.

This table was first planed on the face and edges, and the stem, by which it is held in the bracket on the column of the press, was turned to fit snugly the hole in the bracket.

After planing and turning the table a series of holes was drilled, as shown in Fig. 2, and they were tapped to receive a No. 14-20 screw. Two parallel pieces *C* and *D*, Fig. 2, having straight edges and a thickness of ⅜ of an inch, were made and are to be clamped to the table in such position as may be desired or the work determine, the series of holes permitting any adjustment within the range of the table.

In order to make more room between the spindle and the column of the drill press the spindle head was blocked out, the block having a projecting lug as shown at *A*, Fig. 1, to which a bracket, *F*, was fastened to carry the bushing, *B*. This bushing is fastened by a screw and can readily be removed to insert others having various sizes of holes, if found desirable.



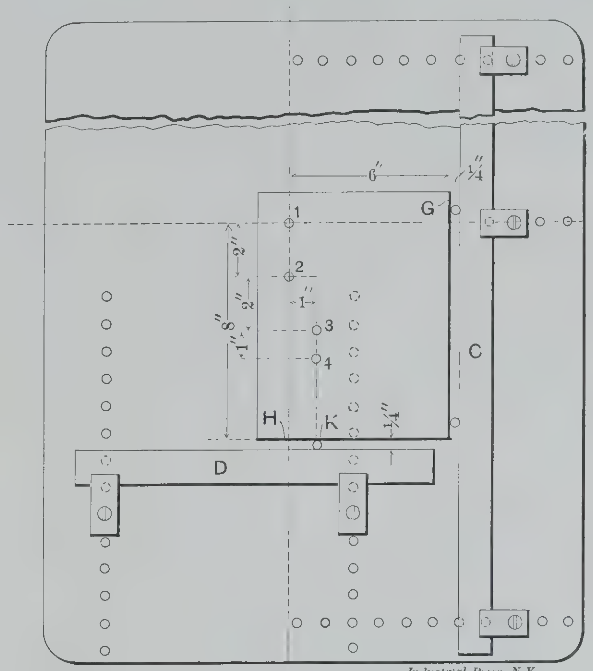
Industrial Press, N.Y.

Fig. 1. Drill Press Arranged for Drilling Jig Plates.

These preparations were all that were necessary with the exception of the gages that will be described in the operation of the method for spacing, which is as follows:

The plate to be drilled had a number of holes spaced as shown in Fig. 2, and before drilling them I marked them out as Nos. 1, 2, 3, etc., No. 1, as will be seen, being the upper right-hand hole. Its location with reference to either end or sides of the plate did not require to be very exact; but other plates may need to have the holes placed at some definite distance from the edges or ends so I will describe this one as having the distance 6 inches from the edge, *G*, and 8 inches from the end, *H*.

With these distances given I then make two gages, using vernier or micrometer calipers for my standard, and make them 6⅛ and 8⅛ inches long respectively. I then remove the bushing, *B*, Fig. 1, and in its place insert a plug having a diameter of ¼ inch.



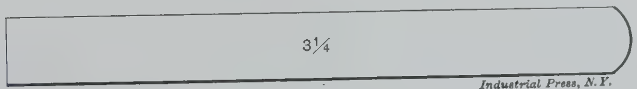
Industrial Press, N.Y.

Fig. 2. Plate in Position for Drilling first Hole.

Resting the 6⅛ gage on the table, and with one end touching the plug, the parallel piece, *C*, Fig. 2, is brought to just touch the other end of the gage and is then clasped to the table. This is not much of a trick if one end of the parallel is left free and the other end is clamped tight enough to permit the free end to move somewhat stiffly. After locating and clamping the parallel, *C*, the other parallel is clamped in position, but it must be placed square with the first parallel. This is more of a trick than the first one, but is not at all difficult if one man can be employed to clamp the piece while another holds the square and gage.

The reason for making the gages 6⅛ and 8⅛ inches long instead of 5⅞ and 7⅞ inches respectively is that it is not desirable to have the edges of the plate touch against the parallels, as chips could get between the two and destroy the accuracy of the measurements; so I allow the gage to be ¼ inch longer than the distance required and fill the space in with ¼ inch diameter gages as shown in Fig. 2.

For gages over 1 inch in length I use flat brass rods or strips about ⅜-inch wide and ⅛-inch thick and cut them a little longer than the finished length. One end is finished square and the other end is rounded as shown in Fig. 5. In making the gage, if too much metal is removed it is an easy matter to pene the stock out to make up any reasonable error. The length of the gage is stamped on it, and when the operation is completed it is put away for future use.



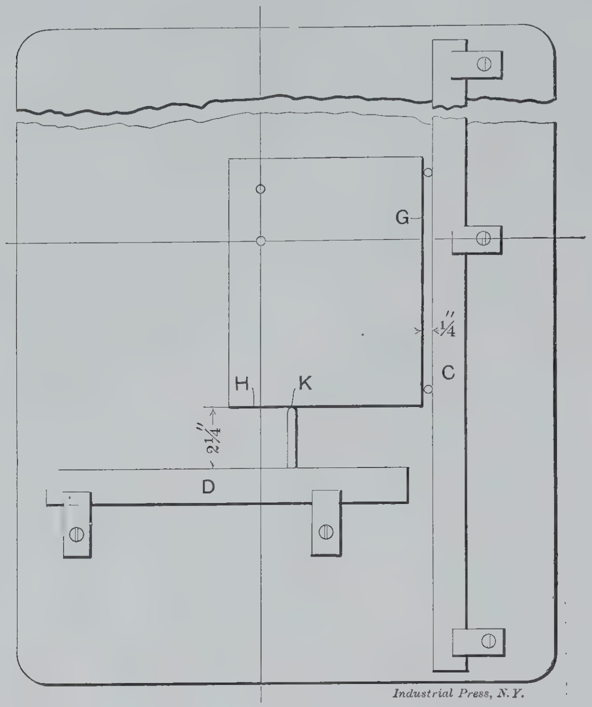
Industrial Press, N.Y.

Fig. 5. Gage.

Having located the parallels, the plug is removed from the bracket and the bushing replaced. The drill should, of course, fit as snugly to the hole in the bushing as it can and run without cutting. The bushing should support the drill to within a distance equal to the diameter of the drill from the plate to be drilled and care should be taken not to drill through the plate until all the holes have been started.

After drilling the first hole to place the plate for the second hole, distant 2 inches from the first, it is moved along the parallel, *C*, and a gage 2¼ inches long placed as shown in Fig. 3, and when so placed is ready for drilling.

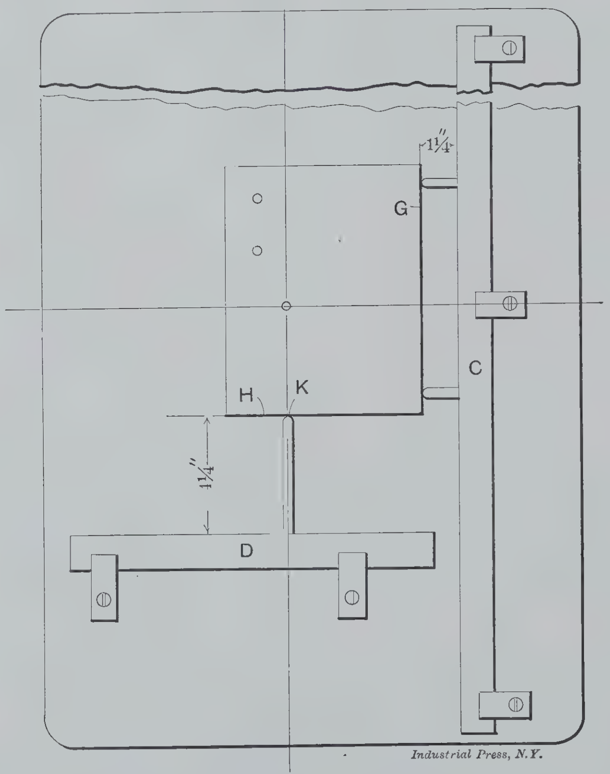
The third hole requires three new gages, since it is 1 inch off the line of the other two holes, as shown in Fig. 4.



Industrial Press, N.Y.

Fig. 3. Plate in Position for Drilling second Hole.

For holes which are to be finished 3-16 inch to ¾ inch in diameter I first use a small drill, size No. 52 to No. 30. After the holes are all drilled to this size I then enlarge them, by the use of a series of four lip counterbores, to the required size. Where extreme accuracy is required, in the place of the counterbore, a small boring bar may be substituted and the holes bored to the size desired.



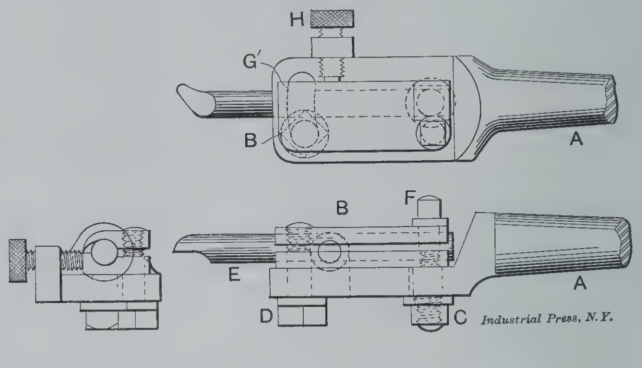
Industrial Press, N.Y.

Fig. 4. Plate in Position for Drilling third Hole.

One disadvantage of using a boring tool is that it requires a hole in the table equal to the largest hole to be bored out or that the plate shall be kept clear of the table by blocking up with parallel strips under it.

Fig. 6 shows a form of boring tool which I have found very convenient for use on this kind of work.

It consists of the shank, *A*, which is fitted to the taper hole in the spindle and a split holder, *B*, which is pivoted to the shank at *C*, and is locked to it at *D;* the screw at *D* serving to clamp the boring tool, *E*, at one end, while *F* clamps it at the other end. Adjustment is obtained by swinging the holder, the radial slot, *G*, allowing it to have quite a range and the stop screw, *H*, permitting fine adjustment. Split bushings in the holder will allow the use of boring tools of smaller diameter if desired.



Industrial Press, N.Y.

Fig. 6. Boring Tool.

This method of locating holes is not limited to the drill press but may be employed to advantage on the faceplate of a lathe. In this case the work, as soon as located by the gages, is clamped to the faceplate.

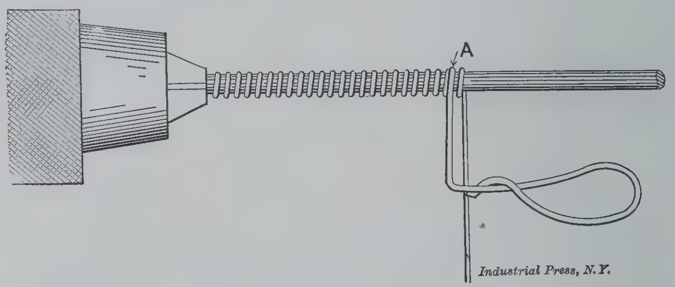
While this method was originated for drilling holes in jig plates, it may be used with equal success for drilling small interchangeable pieces. It is not necessary that the edges, *G* and *H*, be planed at right angles, as the same results will be obtained if the surface, *G*, is planed true and a finished spot provided at *K*, from which point all measurements to the parallel, *D*, are made.

* * *

WINDING SMALL SPRINGS.

P. A. Whitney sends us a little trap for winding small springs up to, say, No. 12 English standard gage, which is shown in the cut. It is accompanied by a spring, wound by this means, which is very regular and satisfactory.

The method for using the device is very simple. A drill rod, about 3 feet long, which is a little smaller in diameter than is wanted for the inside of the spring, is put in a drill chuck and a piece of wire of the size of the space between the coils of the spring is put in beside it and two coils are wound and cut off as shown at *A*. One end is twisted to form a loop for convenience of handling. Now place the spring wire in the chuck, with the rod, and after winding two coils by hand, screw the larger wire onto, or into, the coils thus wound. Then grasping the guide and the free end of the wire in the right hand, start up the lathe with the left. The free end of the drill rod should be grasped in the left hand to prevent its whipping around.



Industrial Press, N.Y.

Device for Winding Springs.

* * *

To indicate when the moving parts of the machinery have become excessively heated, a German inventor has devised a paint composed of an amalgam of the iodides of mercury and copper, which the inventor claims will change color when heated. Bearings to which it is applied are red under normal conditions, but when a temperature of 140 degs. Fahrenheit has been reached the paint becomes black.—*Electricity.*

LETTERS UPON PRACTICAL SUBJECTS.

SOME OF THE TROUBLES OF THE MACHINIST-ENGINEER.

Editor MACHINERY:

I have often noticed in the past, advertisements worded something like the following:

WANTED—An engineer. Must be used to ——— engine, and be a machinist able to do his own repairs, and repairs for the factory machines. Will pay $12 per week.

Whenever I come across such an advertisement as this (and I am sure that your readers have often done so) I wonder what kind of a *rara avis* the man who inserted that "ad" expected to get from the ranks of the unemployed. Now I have seen some mighty handy fellows in the machinists' ranks, but I speak advisedly, I think, when I say that I never saw a man who could fill both positions as they should be filled.

Let us see what is liable to be one day's work for the average engineer. He comes in before anyone else is thinking of starting to work, and putting on his overclothes begins to get up steam. In the meantime something about the engine must be fixed before it can be started, and by the time he has done that it is time to begin to oil and warm up the engine. Soon after starting, a water glass bursts and that must be replaced. Then the Boss wants his lawn mower fixed, or the kerosene stove is out or order. Then he is called to the office to fix an electric bell; and then to repair a bursted pipe or a damper regulator, and in the meantime receive a visit from the boiler inspector making internal inspection. Perhaps also he has to meet courteously two or three oil men and steam packing agents. Some time during the day he has to clean out his spare boiler, find out for the Boss how much power a certain room is using, and because it is thought he is using more coal than he has previously, it will be necessary to take some indicator cards. The Boss thinking that the present will be a good time to stock up with coal comes in and wants to know how much coal the bin will hold, and so he has to measure the bin to find that out. Fortunate is he if he keeps a journal and can refer to that when some of these questions come up. And thus it goes throughout the day. If he happens to get a few minutes to sit down and cool off, during which time he possibly studies the slide rule, or the laws of combustion, etc., some old woman or other (as happened to me) will come in and say: "Then all you have to do is to sit here and see that thing go!" (I don't quite know what she meant, as I have machinery going in three rooms and had already shoveled two tons of coal), but I told her "Yes, that was all."

Now, Mr. Editor, I have had about thirty years' experience as an engineer and some of it has "stuck," but I think the man who writes an "ad." like the above knows little of what an engineer's duty is. It has always seemed to me that an engineer must be born to love his profession, for profession it is and one to be proud of. As for myself I prefer it to anything going.

In connection with this I will tell of an incident that happened in a neighboring city. A certain firm had contracted for an engine of the cross-compound non-condensing type. In due course of time the engine arrived and also a machinist to set it up. It was duly erected (and well done too). When ready it was started up by the man who had erected it, and after it had run awhile he proceeded to take some indicator cards from it. He took some from the high-pressure cylinder and sat down on a box and began to pull his hair seeming strangely excited. The chief engineer of the plant noticing his apparent trouble interrogated him: "What's the matter?" quoth the chief. "Back pressure?" "Yes," answered our friend, "there seems to be back pressure on this high-pressure cylinder." "How much?" "About one-half inch." "Well," answered the chief, "it surely must be some 'inherent' fault of the engine, for the piping is all right." The erector who did not seem to take in the full meaning of the chief's "inherent" was sadly puzzled and informed the chief that he should write to the firm about it. I have often wondered what reception he got when he returned after complaining of back pressure on the high-pressure cylinder of a cross-compound engine.

OLD MAN.

CHUCKING PIECES.

Editor MACHINERY:

I am somewhat surprised in going into different shops to find how comparatively few use what can be called "chucking" or holding pieces, on castings which are to be finished in the lathe. While there are times when this can also be done to advantage on shaper work the application is much more limited than in lathe work.

A chucking piece is such a simple expedient and was so common in the shop where "yours truly" learned his trade that he never dreamed of its being new or novel in any part of the country, but this is the way with many other things also.

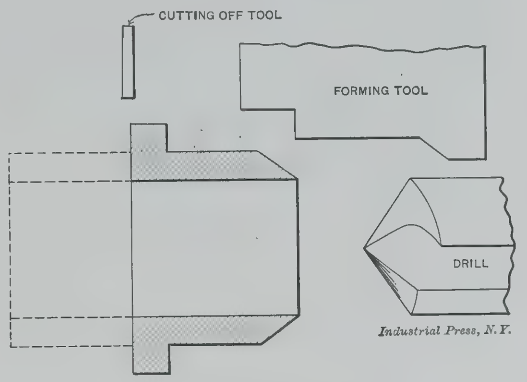


Fig. 1. Chucking Pieces.

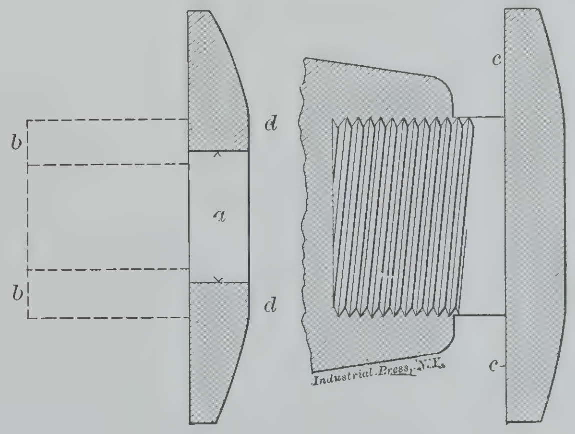
You ask a shopman if he has anything new to show you, and he almost invariably answers no, but if you ask how he does this or that piece of work you are likely to find a new method or one that differs from your own practice. It is old to them, and they never think that it may interest you. But to return to chucking pieces.

Two examples will serve to show the application to those who are not already familiar with it. Fig. 1 shows a thimble, of brass in this case, with the chucking piece in dotted line at the back. Without this it would be necessary to chuck the piece twice, with the attendant trouble of getting it true the second time and the danger of marring or springing unless it was held in a split chuck. Of course a mandrel or arbor could be used, but this has troubles of its own as well.



Figs. 2 and 3. Chucking Pieces.

By adding the chucking piece to the pattern you have a place to grip in the chuck and the whole operation can be done without removing from the chuck, thus insuring the whole thing being concentric or true, and saving considerable time. In a turret or Fox lathe this is easily done, and the tools shown give a suggestion in this line.

By threading the chucking piece in a turret lathe and holding it in a screw chuck it is handier working than holding in a regular jaw chuck, and the cost of facing and threading the piece is very little. All the metal contained in this chucking piece goes back to the foundry as chips or scraps, so there is practically no loss on this account.

Fig. 2 shows a disk for a ball joint which was first made by catching in a chuck and tapping the hole *a*, at the same time facing *d* square with it. It was then put on a screw chuck and the flat side faced off, then reversed and the ball joint finished and the outer edge turned to size.

The addition of the chucking piece shown by dotted lines (this was cored straight through, same as disk) made it possible to face and thread the chucking piece in the turret lathe and hold in a screw chuck, Fig. 3, as shown. The whole thing could then be done in one operation and cut off complete. While the work might have been held in a jaw chuck, the screw chuck is better in many ways as it gives more room to work around and there is no danger of the work slipping. A Stillson or some similar wrench takes out the piece cut off, with little trouble.

Every shop manufacturing in quantities has many places where some modification of this method can be employed to advantage. R. E. Marks.

A TAPPING RIG—DIVIDING DEVICE FOR PLANER.

Editor Machinery:

I have been reminded to-day of a rig for tapping the feed screw boss of upright frames, that was made in my young days. It had almost faded from my memory, and lest it should do so entirely I send you a description of it at once in hopes that it may do others as good service as it did our firm. The appliance is shown in Fig. 1.

The drill frames, of which *A A* show the two upper bosses were previously bored and faced. The tackle for tapping consists of the tapping bar *B* turned to slide on the upper boss *A* and in a bushing *C*, the ends being threaded same pitch as the work to be done, and fitting an internally threaded bushing *E*. Both bushes had projections to correctly locate them, and were clamped against the faced ends of the boss by two bolts as shown. The "business" end of this bar is turned down (shown at *F*) eccentrically, and carries a head *G*, which is free to rotate upon the bar, but can be held in any desired position by means of the teeth formed upon its outside face and the teeth upon the inner face of the bushing *H*. The bushing is prevented from turning by the key shown and it can be firmly clamped against *G* by tightening up the knurled nut *K*. The cutter *L* is square and fits into a square hole and is locked by the square head screw *M*. When it is in the position shown it is at its outer limit, and when exactly opposite, it is at its extreme inner position. The head is rotated by means of the handle *N*.

In practice the head would be turned to bring cutter to such a position that upon turning the bar, by means of a long handle fixed upon the square at the end, a reasonable cut would be taken. Upon reaching the recess *O*, the knurled nut *K* would be unscrewed, disengaging the teeth and allowing the head to be turned right back until the lever *N* butts against the stop pin *M*. The bar would then be withdrawn and the head turned back to the same index position and advanced a notch or two. The cutter head would then be clamped and another cut taken, and so on until sufficient depth of thread is obtained. To gage, the bar is withdrawn altogether.

I can now see where several improvements might be made. Insert a spring between the head *G* and the bushing *H*, in order that the teeth would become free upon unlocking the nut *K*. Cut the thread out of the bushing *E* and introduce a disengaging nut. By lengthening the bar at the end *D* and adding gearing with quick action, or self-acting clutch, the bar could be power-driven. Instead of the nut *K* a quick cam action might be better. However, the principle of the thing is shown, and no doubt many improvements might now be suggested.

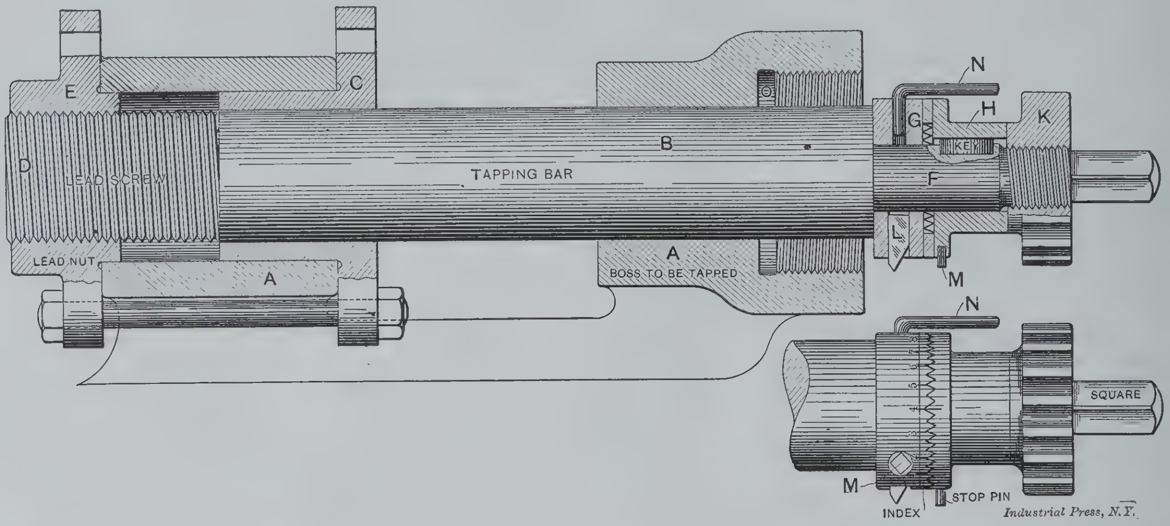


Fig. 1. Tapping Bar for Tapping a Hole Square and in Line with Another.

Another handy rig is shown in Fig. 2. This is an arrangement for feeding the cross slide screw of a planer in accurate intervals. This screw was ¼ inch pitch and the work necessitated the screw being rotated one and one-half time to feed the tool box ⅜ inch, which was the pitch of the ratchet teeth to be cut upon the work. After spacing by use of this tackle a correctly formed tool was fed in by means of the upright slide, a stop being provided to insure the teeth being cut to exactly the same depth as each other.

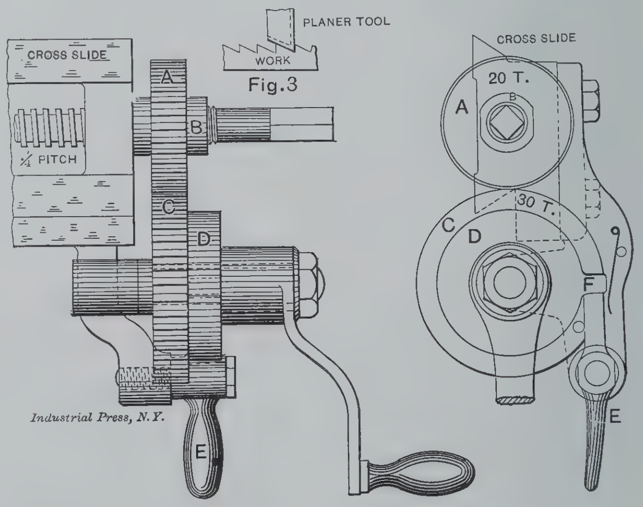

Fig. 2. Device for Feeding Planer Cross-slide for Rack-cutting, etc.

The pinion *A* is locked to the screw by the nut *B*, and meshing into it is a wheel *C*, which wheel has connected to it the stop disk *D*. The lever *E* is pulled forward allowing the stop disk *D* to be rotated by the handle. As soon as the stop *F* on the disk *D* has passed the lever *E*, the lever is allowed to spring back, and thus acts as a stop to prevent the disk being turned more than once round until the lever *E* is again pulled forward. One turn of wheel *C*—which has 30 T. and the piston only 20 teeth—rotates the pinion 1½ times, and hence feeds the tool box 1½ times ¼ inch, or ⅜ inch.

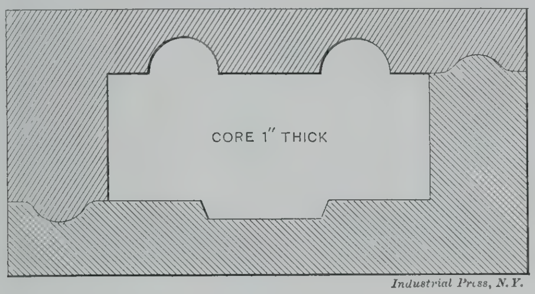
It would be possible to arrange the rig so that wheel in any ratio could be fixed in place of *A* and *C*, in order that any pitch could be cut, but to secure accuracy of division the disk *D* should always make one complete turn.

Birmingham, Eng. FRANCIS W. SHAW.

"TWENTY YEARS AGO"—PATTERNMAKERS' DOGS.

Editor MACHINERY:

In every issue of MACHINERY and other mechanical publications appear articles and illustrations of handy and simple mechanical methods for doing work which are studied and appreciated by the great majority of mechanics, but along comes some fellow who writes that he saw or used the same thing "twenty years ago." Well, suppose he did; if it is a good thing and he saw it "twenty years ago" is that any reason why others should not know of it?

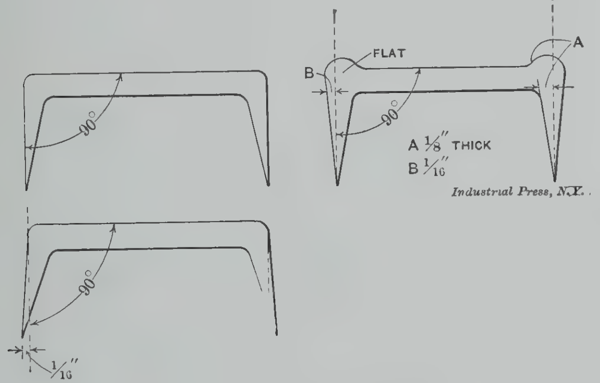


Industrial Press, N.Y.

Fig. 1. Simple Method of Making Core Box.

I send herewith sketch of a simple way for making a core box which may be old to some but new to me, and it may be to others. The core box, Fig. 1, was made in fifteen minutes, all done on a band saw.

The writer once had a number of boards to glue together, edge-to-edge, and to clamp them used the ordinary iron "dogs." I had two dozen clamps, but found only 7 fit to use, so I went to the workman next to my bench to borrow a few, but like myself he had only 5 in 3 dozen in order, and so it was with two other men; these iron "dogs" are used almost as much as any other tool in a patternmaker's kit and how few workmen keep them in working order.



Industrial Press, N.Y.

Fig. 2. Patternmakers' Dogs.

The patternmakers started in to discuss the "dog" question and what was the best shape and design for clamping and strength. Each man had his way for making a clamp, but no two men agreed that any particular "dog" was shaped right. I send sketch of a few "dogs" that each man had, and each thought his was just right. I would like to hear from some of your readers what their ideas are on the dog designs.

PATTERNMAKER.

A SCREW MACHINE CHUCK.

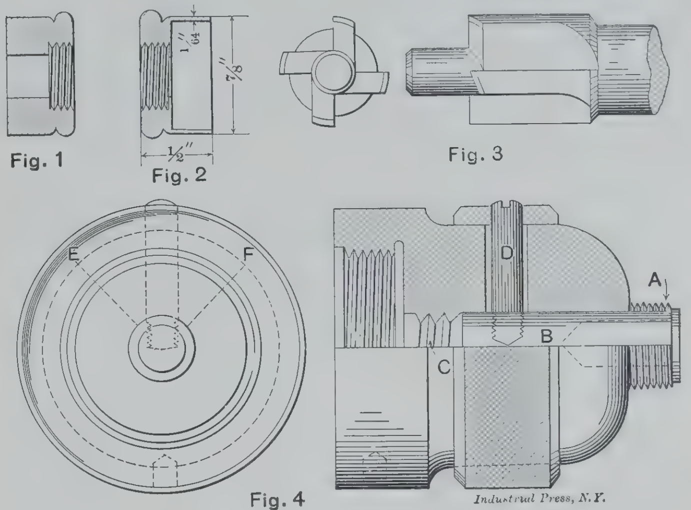
Editor MACHINERY:

A short time ago I had a screw machine job which seemed to present some difficulty but which was easily accomplished by use of the chuck here shown. The main difficulty came in performing the second operation, which left the piece with a wall of metal but 1-64 inch thick. Fig. 1 shows one of the pieces after the first operation has been performed and it is ready for the second operation, for which this device was constructed. Fig. 2 shows one of the pieces as completed by the second operation. This operation was performed by the counterbore, Fig. 3, the piece being held in the chuck shown in Fig. 4.

The end of the chuck was threaded at *A* to receive the tapped end of the work. Through the body of the chuck ran the plug *B*, which had a left-hand thread for fitting the chuck at *C*. A pin *D* connected the plug to a knurled ring on the outside of the chuck.

The pin *D* worked in a slot from *E* to *F* so that the ring could be turned through one-fifth of a revolution.

The method of performing this second operation was as follows:



Industrial Press, N.Y.

Screw Machine Chuck.

The knurled ring was turned until the pin *D* bore against the side of the slot *E*, when the work was screwed on the end of the chuck until it bore hard on the end of the plug *B*. The counterboring was then performed in the usual way. Now to release the work the knurled ring was turned one-fifth of a revolution, or until *D* bore against the side of the slot *F*, thus withdrawing the plug *B* from its bearing against the work which was left free to be easily unscrewed.

Syracuse, N. Y. HORATIO J. TAYLOR.

TROUBLES OF THE DRAFTSMAN.

Editor MACHINERY:

When an improvement and addition is made to a machine already being manufactured, every detail of the job is carefully planned out in the drafting room, even to the tools required for doing the work and the best manner of assembling. After a great deal of thought, many changes, and not a few misgivings on the draftsman's part, it is completed and put into the shop with full instructions for operating it; the work is finished, the assembling is successfully accomplished and the machine operates properly.

The passing machinist often thinks, "What a snap those draftsmen have. They simply tell us to do such and such things and *we* have to do the work. There seems to be plenty of room for each part; the idea is simplicity itself, anybody might have designed it, had he been asked to do so." Now this man probably wishes he were a draftsman; but if he knew the difficulties to overcome and the seemingly insurmountable obstacles that present themselves in the process of design, he might think differently. Suppose we give him an idea of the amount of work involved.

If someone invents an attachment for the machine, it is generally turned over to the chief draftsman in the form of a rough pencil sketch, giving no idea of either size, proportion or detail, and generally with no explanation whatever or, at the most, only a few words. The chief draftsman must then study it carefully until he has formulated in his mind an idea of how it can best be built and also something of the size and proportion of the parts to do the required work. He then takes a drawing of the machine, of one quarter or one-eighth size, and tacks a piece of tracing paper over it. On this he lays out the center lines and a few of the most important parts, designing, as far as possible, the best sizes of gears, pulleys, shafting, etc. If the improvement is to be put on a machine which has already been manufactured for several years there is very likely to be a scarcity of room; and this will sometimes necessitate the discarding of several different schemes, on each of which he will spend considerable time. When he finally "hits upon" a design which he thinks will do he calls up his best available man and explains the situation as completely as possible. This man proceeds to make an assembly drawing to the largest advisable scale, first drawing all parts of the original machine which will come adjacent to the new part, or to which it will be connected. At this point his trouble begins, for he soon finds it necessary to change the original machine here or there, to make room for this or that part. This he doesn't like to do for several reasons. It makes trouble in filling repair orders, the machine to be fitted with the new part may only be half done, or there may be a quantity of these particular pieces in the stock room. As a result it is generally necessary to make a compromise between two or more evils.

Next he may want to make a part which is not easily molded or machined, and then another compromise is required. And so it goes, deciding to make each part "so and so," not because it is just what he wants, but because it is the best that can be done under the circumstances; often taxing his mind at spare minutes for days, or even weeks, trying to think of some good way to overcome certain difficulties. Sometimes he thinks of a good plan only after the drawings are completed, when, if it is of sufficient importance, it may be necessary to redesign the whole machine. And sometimes he may think of it the minute he sees the completed machine in operation. I have seen instances where the new idea was enough better than the old to warrant throwing the first into the scrap heap.

But I am digressing a little. To go back to where the drawings are finally completed and approved by the superintendent, they are then sent to the pattern shop where it will be necessary to watch the patternmakers carefully, else they will surely get you into trouble. It must now be decided, by ascertaining the stages of the work already in the shop (unless this has been predetermined by existing circumstances) with which lot of machines to make the change, and then inform the head of each department as fully as possible of that part of the change which will affect him. He must be careful to tell him which lot will first have the change and all the original parts which will be left off or changed in any way.

The best time to make the change is on a lot for which the shop orders have not been sent out. The instructions can then go with the orders, making it comparatively easy. Generally, however, this cannot be done as the improvement is wanted on the first machine possible, even at the sacrifice to the scrap heap of some parts already made. In this case it is sometimes necessary to start some parts in the shop before the drawings of others are fairly finished. It is also necessary to call in from the shop all discontinued drawings and patterns, to avoid the possibility of mistakes which may arise from using the wrong ones. This cannot be done until all machines without the improvement are completed, complicating matters still more by making it necessary to remember just what has been done and what not done, out of a long list of changes. If a complete list be made of the things to be done for each change then as each is finished it can be checked off.

It is always best when a drawing is in process of construction to consult with the heads of the shop departments. Their ideas as to the way in which a piece can best be made are worth a good deal, and they are then more willing to make the change when it comes and have probably already made their plans for doing the work.

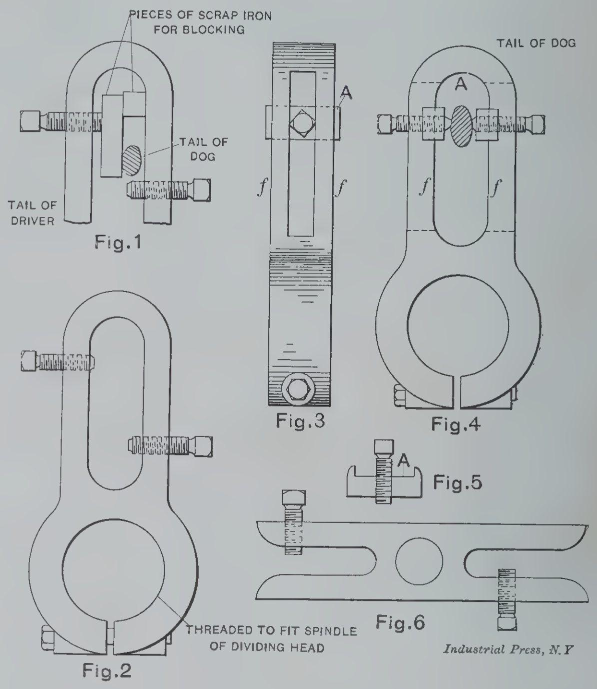
FRED S. ENGLISH.

IMPROVED DRIVER FOR MILLING MACHINES.

Editor MACHINERY:

The milling machine of to-day is, I believe, considered to be the best all-around tool in the modern machine shop and probably is the one that is kept most strictly up-to-date by the manufacturers. I have found, however, that there is one feature on at least two of the best makes that is defective and that is the driver for the dividing head. And this is now constructed it is more a case of luck than design that the set-screw of the driver comes in the proper place to bind the tail of the dog, as is necessary to prevent back-lash when using the dividing head. I have often found it necessary to clamp the tail of the dog in the "toggled-up" shape illustrated in Fig. 1. This of course takes time and makes a very unsatisfactory arrangement.

Having charge of several milling machines, I was free to make such changes and improvements as were found necessary to increase the efficiency of the machines. Fig. 2 shows the style of driver that came with the machines. This driver was quite unsatisfactory for the reason just given and also that the set-screws were not opposite each other. This is often a very desirable feature, as it is mighty handy to be able to loosen one screw and tighten the other slightly on the tail of the dog to shift a piece a little. Figs. 3 and 4 show the improved form of driver that I designed. A pattern was made for the castings and the slots were cored out. These slots were for the sliding nuts *A A* for the set-screws, the idea being to shift the set-screws along the slot to bear on the tail of the dog wherever it was and have both set-screws in alignment. Fig. 5 shows one of the sliding nuts of which there are of course two made for each driver. The inner edges and sides of the slots in the driver (where marked *f*) were machined on a shaper.



Improved Driver for Milling Machines.

The familiar form of driver shown in Fig. 6 was also fitted with sliding blocks or nuts in the same manner. It will be seen that this design makes a driver universal within its limits and that the tails of all dogs used can be properly clamped regardless of their length or position. If a dog is used having a bent tail it can be clamped without trouble between the two set-screws when these are pointed, without causing any twist on the work.

Chicago, Ill. ROBERT A. LACHMAN.

JIGS.

Editor MACHINERY:

The causes for the use of jigs may be summed up under three heads, the order in which they are stated representing fairly well the frequency though not necessarily the importance of the inference of these causes: First, reduction of cost; second, duplication; third, accuracy. We will take first the question of cost.

As no article can, as a rule, be sold in open competition with similar articles unless its cost is somewhat proportionate to the quality of its competitors, commercial considerations demand that the cost be kept as low as possible, while the quality be kept as high as possible. And jigs are one of the chief agents of this in metal work. When a jig is considered, the first thing to be settled is whether it can be made to pay, and if so, how much. The answer to this often involves very many other questions but can generally, if not always, be resolved into computations based upon the number of pieces to be made, and the probable cost of labor per piece when made with and without a jig; and the cost of the jig including maintenance. Also the fact that often a much less valuable machine or one less busy can be used with the jig, may be an important consideration. If no other factor than cost of production is involved, and it is found that the total cost of the jigged work will come very near that of the lot of articles when made without a jig, and no further order is in sight, it is pretty safe to abandon the jig idea; for it is apt to partake very much of the nature of an experiment, and the odds should be decidedly favorable to warrant the risk.

The second reason—the duplication of pieces—has a somewhat different foundation, though cost enters here also, as will be seen later. Suppose the part to be made is subject to wear or breakage, as in agricultural and textile machinery, guns, bicycles, etc. We know the strong disinclination anyone has for buying a wheel the makers of which have gone out of business. It is at once recognized that repair parts cannot be bought from stock dealers, but must be made at excessive cost and delay. So we have before us the importance to manufacturers that the buying public shall have confidence in the interchangeability of parts in order that sales may be made at all upon the open market. It is a fact that where this reason holds good, there is also the reason that costs will be lessened, because production of large numbers of parts is taken for granted. And in considering whether or not a jig shall be made this combination of reasons militates strongly for the jig.

There is also another reason for jigs, based on costs and interchangeability—it is that in fitting and assembling, those parts which are exactly alike require the minimum labor in putting in place.

In the third place, accuracy is often attained only by the use of jigs. There are jobs which could not be finished at all within the limits of accuracy demanded if jigs of some sort were not used.

It will therefore be seen that the determination of whether a jig shall be made may rest upon a number of questions which often demand great care and practical experience to solve in the way best meeting the requirements of the case.

HANDY DEVICE FOR STARTING THE THREAD.

Editor MACHINERY:

I send a drawing of a device for holding up a valve against the pressure of the spring, for convenience when screwing the valve stem in the valve seat. Many water cylinders for steam and power pumps are so constructed that it is difficult to start the thread on the valve seat, owing to the pressure of the spring, as it is impossible to get both hands in the cylinder at the same time. The device will no doubt be handy for men who are repairing or even building machines of this kind.

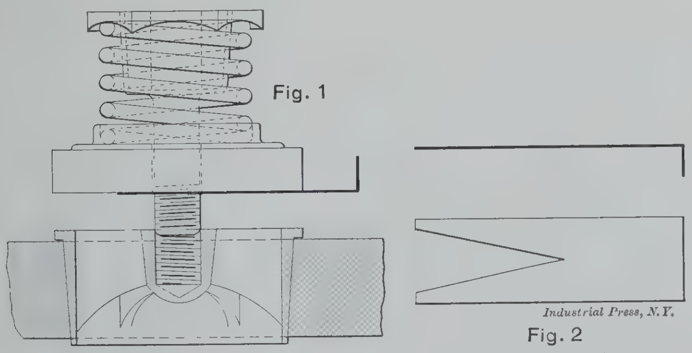

Fig. 1

Fig. 2

Device for Holding Coil Springs in Compression while Starting the Thread.

Take a piece of brass, or of sheet steel, of the shape shown in Fig. 2. Now take the valve in the left hand, press it up and then slide the forked-shaped piece under it in the thread of the valve stem. This will hold up the valve as in Fig. 1. Use one hand to turn the valve and the thread will enter the valve seat. Once the thread is started in good shape the brass fork can be pulled out and the operation continued in the usual way.

It will readily be seen that this device is very convenient in a "tight" squeeze.

Holyoke, Mass.

ADJUSTABLE FACEPLATE FOR THREADING ANGLE FLANGES.

Editor MACHINERY:

We have at times a good many angle flanges to machine for our boiler shop (Struthers, Wells & Co.) and no two angles seem to happen at the same time. The annoyance caused by and the time lost in blocking up some makeshift contrivance led us to make an adjustable faceplate for the lathe which works on a pivot through which a 1¼-inch bolt fastens it at any desired angle.

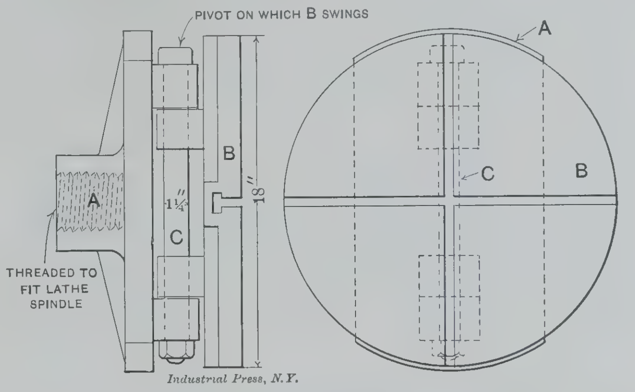

Fig. 1. Adjustable Faceplate for Angle Boring.

The plate *A* with the pivot lugs is cast in one piece, and is threaded to screw onto spindle of lathe. The illustrations, Figs. 1 and 2, show quite plainly its construction and adaptation. By placing the flange to be machined against the faceplate *B* and holding it in place with a pipe center, such pieces can be secured ready to operate on in about three minutes.

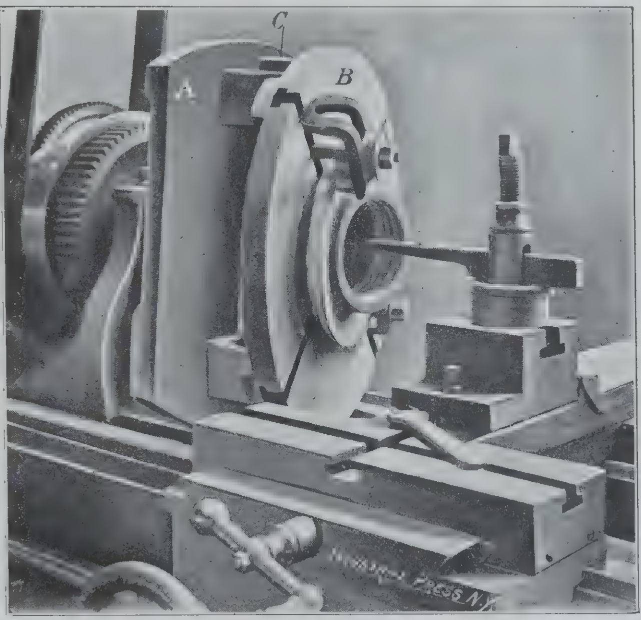

Fig. 2. Adjustable Faceplate for Angle Boring.

Warren, Pa.

A. A. AVERY.

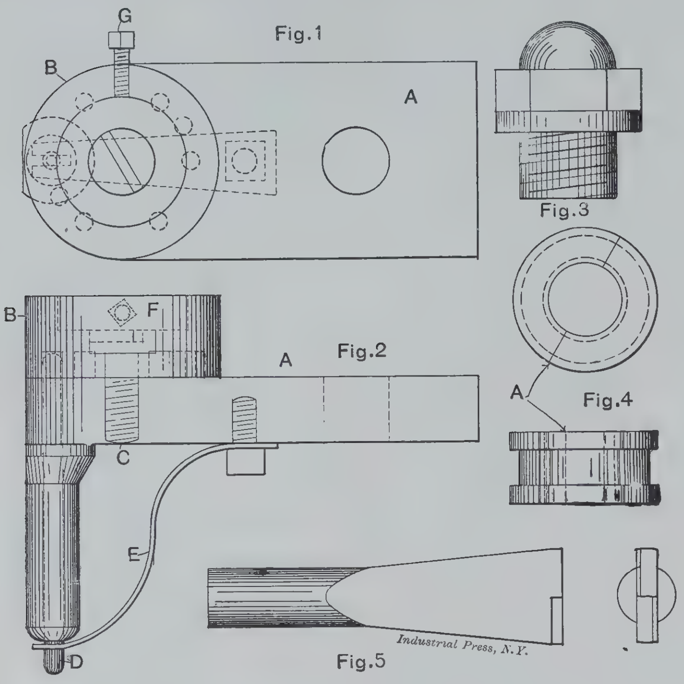
A TURRET ATTACHMENT FOR THE LATHE.

Editor MACHINERY:

A very convenient attachment for holding pieces to be milled is shown in Figs. 1 and 2. This attachment is used on the lathe carriage in place of a tool post. The steel head *B*, which revolves on the central stud *C*, has a number of holes drilled in the bottom to correspond with the desired spacing of the surface to be milled. A spring pin *D* slips into these holes as the head is revolved and holds it in position, while the work is being performed.

Fig. 3 shows a sample of the work for which this attachment is adapted.

The plug here shown is to be milled on six faces. The threaded end is screwed into the steel ring, Fig. 4, and the ring placed in the recess *F* of the turret head. This ring is split at *A* so that it may be firmly clamped to the plug by the set screw *G*, which also fastens it in the turret head.



Turret Attachment for Lathe.

Having clamped the work in the turret, it is fed up to the cutter by means of the cross-feed screw, while the rise and fall attachment of the carriage furnishes the means of vertical adjustment.

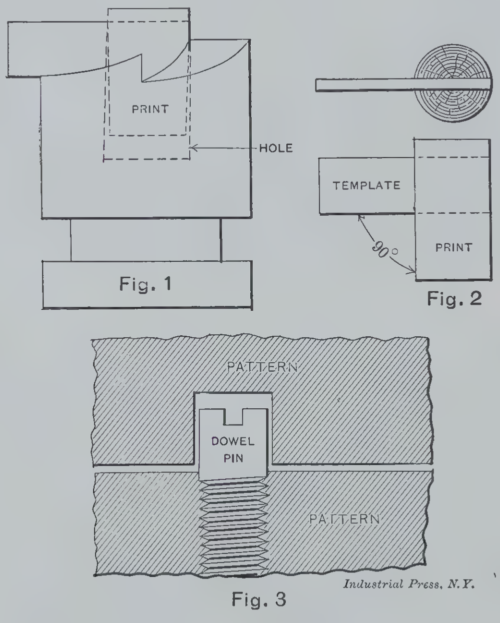
A good style of cutter for this work is shown in Fig. 5. It is held by a clutch on the live spindle of the lathe.

Connersville, Ind. E. M. Burgess.

MAKING A CLUTCH PATTERN—PATTERN DOWEL PIN.

Editor Machinery:

The sketches, Figs. 1 and 2, show a simple template for working the jaws of a clutch pattern. The writer has made several clutches and found this to be a simple and true method to get the jaws correct. I make the block fast to a faceplate with screws, then turn the outside diameter, bore a hole the size of inside diameter and about 1 inch deeper than bottom of jaw, turn a pin or core print to fit the hole, and on this print put a thin piece to act as a template. The print can be put in the hole and revolved round, showing where to trim the teeth, then removed when trimming is being done. A neat, perfect job can be done in this way.



Making a Clutch Pattern, etc.

The writer had a number of small split patterns to make in which it was a difficult job to put dowel pins. After one of the patterns was in the foundry a few days it was returned to have the pins made fast; the dowels were 3-16 inch diameter, ¼ inch long. I saw that wood dowels would not stand the racket, so I made the pins from common wood screws. They not only answer the purpose as dowel pins, but the molder prefers them to wood pins, as they do not swell. I drill a small hole just large enough to turn screw without splitting pattern. I grind the head as shown in Fig. 3, leaving slot.

Chicago, Ill. Patternmaker.

"PISTON HEADS AND PACKING RINGS."

Editor Machinery:

In the July issue Mr. Dunbar writes interestingly on piston heads and packing rings, and in the main, correctly I believe. I fear, however, that he has made one or two statements that may produce a wrong impression, on the younger readers especially, unless supplemented with some explanations that I will venture to give, seeing that no one else has done so to date.

In Figs. 2 and 3 of his article, the writer shows the correct and generally followed method of putting in Dunbar packing rings. He says that it is customary to put them in as shown, to prevent the possibility of the square section ring dropping into the counterbore, should there be a chance of its doing so. Otherwise so far as he is aware there is no reason why they cannot be put in the opposite way if it were desired to do so. Now, in my opinion, it makes considerable difference which way Dunbar packing is put in, and that difference might be sufficient to decide its success or failure. If it is put in opposite to the way shown in Figs. 2 and 3, the steam can blow down through the openings between the ends of the square sections and up through between the ends of the L-sections, provided there is any clearance for the packing rings in the groove and, as Mr. Dunbar says, some clearance of course must always be given. But when put in properly the two rings break joints effectually by being forced against the inner walls of the packing grooves. Of course if the rings are put the other way steam should not blow by the piston since the rings at the opposite end should stop it. I think, however, that most readers will agree that it is not good practice to have the steam blow through one set of rings to be stopped by the other set, at each stroke of the piston. The life of packing under such conditions would be of brief duration.

The foregoing makes it quite evident that with Dunbar packing two rings or sets of rings, are vitally necessary for a tight piston, and I think the same holds true for the ordinary snap ring to a lesser degree. Mr. Dunbar's analysis of the action of packing rings in the grooves throughout a piston stroke, shows in itself that two rings are always required for good results in a steam engine piston. The pressure of the steam keeps a packing ring against the inner wall of its groove during the first half of its stroke at least and its momentum during the second half, if the steam pressure is not sufficient, which, however, it almost always is. The inertia and friction of the ring on the exhaust side of the piston also keeps it tight against the inner wall of its packing groove. So in theory at least the packing rings should have little tendency to side movement in their grooves where there are two, but when there is only one it is of course forced alternately from one side of the groove to the other at every stroke. I believe that two rings—no more—are needed in every steam engine piston. A third ring is of no more use than—(the reader can supply his pet comparison).

It should be noted that the action of the packing rings in a steam engine piston is quite different from that occurring in a pump piston. In a pump piston the rings are alternately forced from one side of the groove to the other irrespective of the number of rings, and this is one reason why they wear out faster in pumps than in engines.

Newark, N. J. F. Emerson.

LONG RANGE CALIPERING.

Editor MACHINERY:

The following problem in "long range calipering" and the way in which it was solved, is but a sample of the jobs which a tool-maker gets out here in the West.

We had a shaft 31 inches in diameter and 47 feet long. A hole, extending through the shaft, was bored 10¼ inches for a distance of 6 feet from each end, after which it widened out to a diameter of 21 inches. The shaft weighed 85,000 pounds, and as this was thought to be excessive a means of measuring the 21-inch portion was desired. I was first called upon to make a caliper that would measure the internal diameter 9 feet from the end of the shaft.

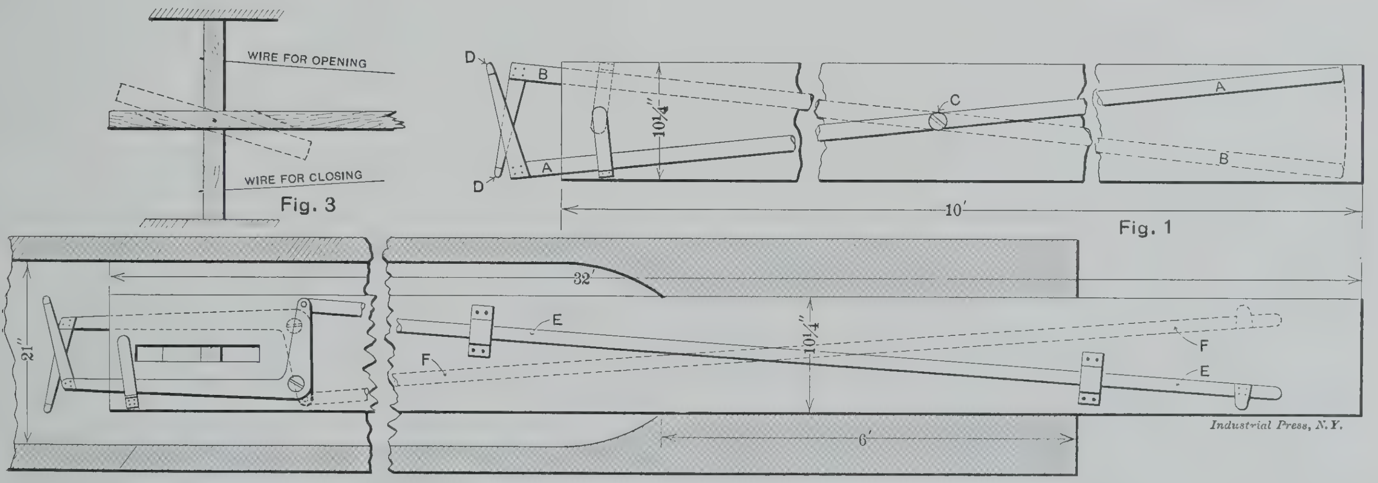
Fig. 1 shows the instrument which I constructed for the purpose. A board 10 feet long was fitted to slide snugly through the 10¼-inch portion of the bore. Upon this board were mounted the wooden caliper legs *A* and *B*, one leg being placed on either side of the board and both pivoting about the pin *C*.

The ends of these legs at *D D* were fitted with metal tips, so arranged that the extreme points were diametrically opposite. At intervals along the length of the legs small strips of glossy rubber were fastened, on the side next to the board, and these relieved any excessive friction between the parts and thus facilitated the operation of the instrument.

To use the caliper, it was pushed through the 6 feet of 10¼-inch bore, at the end, and up to the position where it was desired to make a measurement. The outer ends of the legs were then brought together until the inner points touched the inside of the bore. A mark was made for the position of each leg and the legs brought back to their original position. After the board was removed from the shaft the legs were set, by the mark, to the same position which they occupied when taking the measurement and the distance between the points was measured with an ordinary caliper.

It was, of course, unnecessary to withdraw the board for each measurement as any number of settings could be made, at different distances from the outside, and each set of marks given its respective number so that they could be re-set and measured after the board was withdrawn.

The caliper was used for this job with such success that a modified type, shown in Fig. 2, was constructed for calipering at greater distances into the bore. This caliper was 32 feet long, so that by working from both ends the entire length of the shaft could be measured. As will be seen in the figure, the legs are of the rocker type and are expanded by drawing the rods *E* and *F* outward. It was found that when the caliper was pushed in very far, so that it overhung the support for considerable distance, the measurements were not exact, owing to the sag of the board. To remedy this trouble a supporting stick was hinged near the end of the board, as shown in Fig. 3. This was operated by wires which ran to the outer end of the board. When the caliper was being inserted or withdrawn the stick was closed to the position shown by the dotted lines, and when it had reached the place where the measurement was to be made the upper wire was pulled and the stick brought up vertically until it bore firmly on the top and bottom of the hole. In this position the board was held central with the bore.



Long Range Calipers.

This arrangement was quite accurate, as a test measurement, at a range of 28 feet, showed an error of less than 1-64 inch. Within the tube, the caliper was more sensitive to sound than to touch, the chamber seeming to magnify the sound when the points came in contact with the sides of the wall.

E. J. BUCHET.

Dubuque, Iowa.

WHAT CAUSED THIS BREAK?

Editor MACHINERY:

I inclose a photograph showing an arbor and the result of hardening it.

The lower figure shows the arbor before it was hardened. It was 4¼ inches in diameter at the larger end, 2¼ inches at smaller end, 24 inches long and weighed 57½ pounds. I turned it from a bar of Sanderson's special annealed steel, No. 4½, without forging. On being hardened it broke as shown in the upper figure.

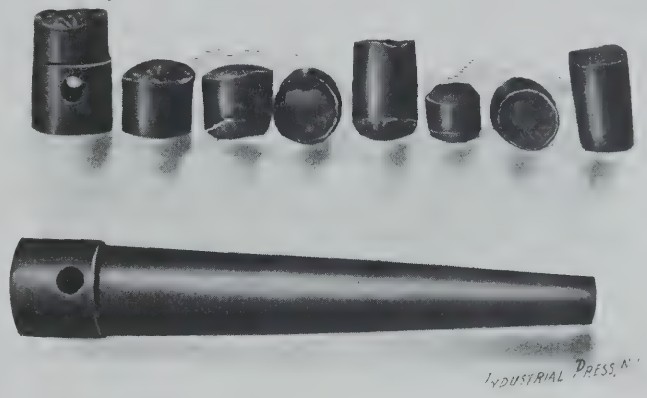


Fig. 1. The Arbor which Broke in Hardening.

Can you tell me what caused the break?

E. J. BUCHET.

Dubuque, Iowa.

We referred the above to our correspondent, Mr. E. R. Markham, of Springfield, Mass., from whom we received the following reply.—[EDITOR.]

Editor MACHINERY:

I have examined photograph sent me of broken mandrel. In order to examine the grain of steel from a photograph it is highly important that a section of the steel be magnified many times when photographed, whereas, the photograph shows the mandrel less than one-eighth actual size. But having had some experience in hardening similar pieces, and having had occasion to look up breaks similar to the one referred to, I will recount some of the causes of steel breaking when hardening.

From the appearance of the fractures it is safe to say that the break was occasioned by internal strains. These strains may have been the result of rolling in the steel mill or of unequal heating when hardening. To anyone who has made a study of steel and the effects of hardening it is truly wonderful that it is possible to produce a metal capable of standing the immense strain a piece of steel undergoes when hardened.

A piece of steel when heated red hot expands very appreciably. When it is immersed in the hardening bath the opposite process takes place, namely, contraction. The more rapidly the piece is cooled the more rapidly it contracts. Now unless the piece of steel is uniformly heated the process of contraction must be unequal, and unequal contraction is what raises the mischief when steel is hardened.

If the strains were due to the processes to which the steel was subjected in the steel mill, then it is necessary to overcome them before hardening, if possible. Now a piece of steel may be annealed in the bar so it is very soft and works nicely. But in order to overcome the strains in the piece to be hardened, it should be annealed after it is cut to length and the outer surface removed. In the case of a mandrel of the form shown in Fig. 1 the piece should be roughed out to shape, that is, turned tapering, leaving it large enough to finish to grinding size after annealing. The annealing heat should surely be as high as the hardening heat, yet not high enough to injure the steel. The piece should be heated uniformly throughout, the small end should be no hotter than the large end, and the outside of the piece should be of the same temperature as the internal portions. This is as necessary when heating for annealing as when hardening. A precaution which has in many cases worked nicely with me consists in heating the piece of steel to a uniform red heat, after roughing to shape, then standing it on end on the anvil and giving it a blow or several blows, on the upper end with a hammer, or sledge, according to the diameter of the piece. Should it be sprung by this operation it should be straightened while red hot. It may then be heated for annealing. This precaution is not necessary with a piece of steel which has been forged, provided it has been hammered to upset any portion after the drawing operation had been finished. But in the case of a piece of steel cut from the bar and machined to shape without forging, my experience convinces me that the above method insures more satisfactory results, especially if the piece of steel be long.

When the bars are rolled in the steel mill the process is one of elongation from start to finish and the process of hammering on the end has a tendency to in a measure counteract the effects of this.

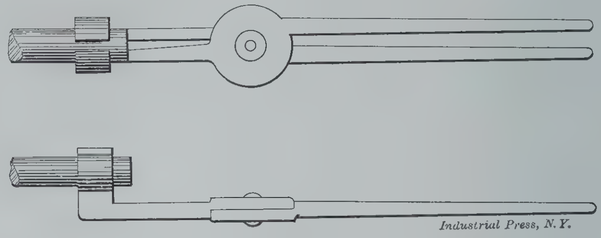
The process of annealing has the effect of overcoming the tendency to crack from the strains. It is an acknowledged fact among authorities on hardening steel that greater care must be exercised in heating round pieces than if the piece were of some other shape. This is because the circular form is the most rigid and offers the greatest resistance to change. For this reason it is necessary to observe extreme care, when heating for hardening, not only that the heat be the lowest possible to produce the desired result, but that it be uniform throughout.

A great many round pieces are cracked as the result of an uneven heat or one that is a trifle higher than necessary, while if the piece had been of another shape it would have come out all right. The fact that the mandrel is larger at one end than the other adds to the liability of its breaking unless the utmost care is used.

When heating for hardening a round piece should be rolled around frequently in order to get uniform results: because if left to lie in one position in the fire until hot it will be almost sure to have a portion along the entire length of one side that will not harden. This will be the case even if the piece is evenly heated. When the mandrel is heated to the proper temperature, and the heat is uniform throughout, it may be quenched in the bath. It must be dipped as near vertically as possible, dipping with the largest end down. The bath should be quite deep, at least 18 inches deeper than the length of the mandrel. The contents of the bath should be agitated from the sides, or a jet of water should come up from a pipe at the bottom to force the steam away from the heated metal in order that the water, or brine, can get at it.

When the red has disappeared from the steel, in the bath, it should be removed and plunged into a bath of oil and allowed to remain until cool. It should then be held over the fire and heated sufficiently to remove the hardening strains, which, in the case of a piece of steel of the shape shown, will be quite uneven, as the hardening will have penetrated much nearer the center at the small than at the large end.

When dipping in the bath it will be found advisable to use a pair of tongs of the form shown in Fig. 2, so that the cooling liquid may get at the center to harden that.



Industrial Press, N.Y.

Fig. 2. Tongs for Dipping the Arbor.

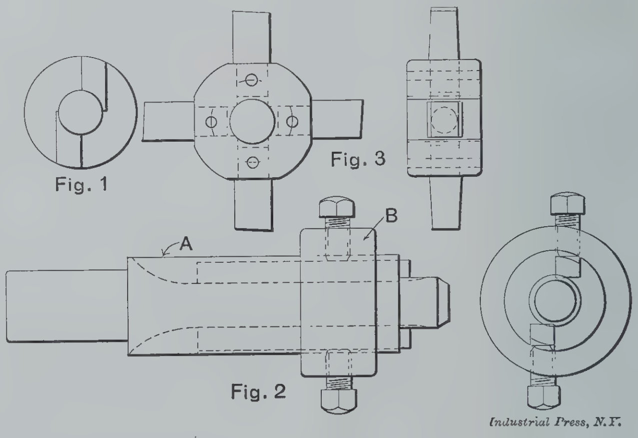
In some shops, where it is found necessary to use steel containing a high percentage of carbon, for cutting tools which must, of necessity, be extremely hard, it is a common error to use this high carbon steel for articles such as the one under consideration, whereas a steel much lower in carbon would answer the purpose as well and be less liable to break in hardening.

NOTES ON COUNTERBORES.

Editor MACHINERY:

The counterbore shown by Corneil Ridderhof in the August number of MACHINERY might be improved if the cutting edges were radial lines instead of tangent to an imaginary circle, the diameter of which is equal to the thickness of the cutting tooth. It will be readily seen, by referring to Fig. 1, that the cutting edges are radial lines and that the cutting teeth are offset enough from the center to form a support directly back of the teat, where the support should be. Counterbores are expensive small tools in almost every shop. Where standard work is done and there is no scale to contend with, the solid counterbore with milled teeth usually does the most and best work.

The writer had occasion to do some facing on rough castings and made a counterbore like the one shown in Fig. 2. The body *A* is slotted with a ¼-inch cutter to a depth slightly below the teat to receive ¼-inch square self-hardening steel blades or cutters. The collar *B* fits the body nicely and contains two screws which are brought to bear against the blades to hold them from end movement. Something over two hundred and fifty holes were swept with this device. The blades are easily removed for grinding, but with the self-hardening steel this was not often necessary, as it was ground but three times in doing this work. This style of counterbore could be changed for different diameters of holes by having bushings to fit the teat. Larger counterbores could be arranged for by placing liners under the blades or by making the blades wide enough to suit the diameter.



Industrial Press, N.Y.

Counterbore and Milling Cutter.

We had some taper slots to mill which were 1 1-16 inches deep, 11-16 inch wide at the top and 9-16 inch at the bottom, and as the job would not permit the use of an expensive cutter, a cheap cutter was made which answered the purpose very nicely. The cutter is shown in Fig. 3. A machinery steel collar 2½ inches in diameter by 1½ inch face was bored ⅞ inch to fit the milling machine arbor. Four holes were drilled into it and reamed ⅝ inch. The cutting teeth were made of ⅛-inch square tool steel, turned far enough back on one end to drive lightly into the holes reamed in collar. Stubs steel pins 3-16 inch in diameter were driven through the collar into these pieces to act as dowels. After the teeth of the cutters were turned they were taken out and the clearance filed. The cutting end was hardened and the teeth were driven into their places. The teeth did not come back to their original position after driving them in the second time, but an oil stone soon fixed the edges so that they all cut uniformly and the work done was very satisfactory. Shop cost of cutter, $1.20.

C. Arbon.

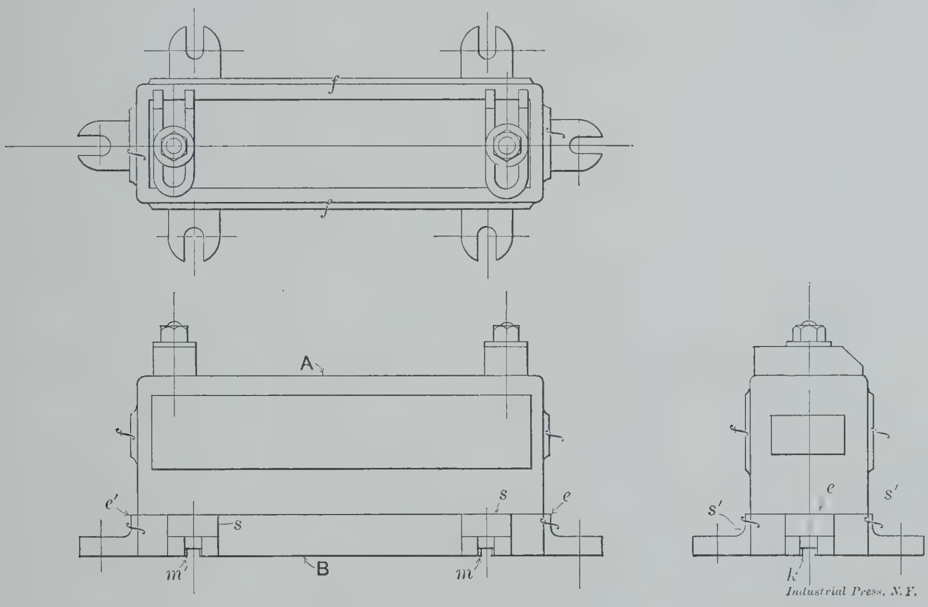
A MILLING FIXTURE.

Editor Machinery:

The accompanying drawing and description show a method of milling pieces in duplicate, where several faces are surfaced, which reduces the setting of the machine and handling of the work to a minimum.

Let *A* represent a piece to be surfaced on spots shown on sides and ends, these surfaces to bear definite relations to one another. It is quite possible to put spotting pieces on top or bottom and finish these first, fasten the work to the platen and finish a side and then by parallels and squaring plates finish the other surfaces from the first. But this means a good many measurements, bolts, straps and settings of the machine, the mass of which may be avoided by the fixture shown.

It consists of a casting *B* to which the work is fastened in any convenient way after being located by the spots e e^1, s s and s^1 s^1, which are finished to the dimensions of the finished work, and serve to show the necessary position of the work in order to clean. The fixture has on its lower side a key slot k corresponding to the slot in the machine platen and spaced equally between the opposite spots s s and s^1 s^1 on the side.



Industrial Press, N.Y.

Fixture for Duplicate Milling.

In setting up the machine, the fixture is located by the key, and the cross-feed screw is used to bring spots s s or s^1 s^1 to the line of cut of a face mill on the spindle nose. As the slot k is located centrally between the sides to be milled, the same setting of the machine answers for both sides, it being necessary only to turn the fixture around. The ends are gotten in the same way and without altering the setting of the machine, for the slots m m^1 near the ends of the fixture are the same distance from surfaces e e^1 as is slot k from surfaces s s and s^1 s^1. Therefore, the operator has simply to see that the key enters the slot fairly.

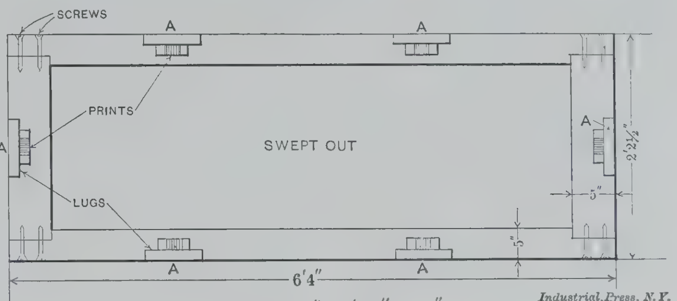
Ears may be provided for receiving the bolts which, when loosened, may simply be moved to suit the new position of the fixture as it is swung around. In practice one side may be milled, then an end, a side, and an end; one rotation completing the piece. On many jobs the key and slots would not be accurate enough, in which case a sole plate upon which the fixture might be located by dowels could be brought into service. The principle, however, would remain the same.

B.

HOW FOREMEN DIFFER.

Editor Machinery:

The construction of a pattern is at times a difficult problem, not so much in making the pattern, but in constructing and finishing to meet the wishes of the foreman, when no instructions are given as to how the job should be done. While working in an eastern shop I was given a pattern to make as shown in sketch. The only instructions given me were, "*Only one casting is wanted.*" I cut the lumber to size, dressed it down to size on planer, and did as little hand planing as possible. The frame I did not touch with smooth plane, just put it together as it came from the planer. The corners were put together as shown, all parts were screwed and no glue used. I did no waxing or puttying, and the pattern was O. K., also the casting.



Industrial Press, N.Y.

SKELETON FRAME 6'4" X 2'2½" X 1¼" THICK

A few months after I quit this shop and went to work in another in the same town. The first job of pattern work was almost the same as the pattern I write about. One casting was wanted. I constructed it the same as the other, and when finished notified the foreman.

He at once gave me a general "*calling down.*" First, the work should be made smooth with smoothing plane; second, the corners should be one-half checked and glued; third, all screw holes and openings waxed or puttied, and fourth, if I knew my business I would do this without being told. When the foreman was done "*calling me down*" I said I would finish the job and quit. He insisted on my remaining at work, but I could stand no such unreasonable abuse as that. A foreman of this type is a disgrace to any shop. When the proprietor or superintendent of a factory finds he has a foreman in his employ who is always finding fault with his workmen, the sooner he gets rid of him the better it will be for his shop, bank account, and workmen.

After leaving this man's employ I made it my business to tell every good mechanic the sort of a boss he was, and I can assure you he had his troubles getting good workmen. A number of men who are to-day placed over good workmen, as foremen, were intended for the police force by nature.

Patternmaker.

A WORD REGARDING CORRESPONDENCE SCHOOLS.

Editor Machinery:

Now and then I have seen much written for and against the efficiency of teaching by correspondence, and the schools established for that purpose in particular. Taking it as a whole it appears that both sides are right and it only reminds me afresh that there could hardly exist an educational institution that would not be criticized on some ground or other. I remember hearing a Cincinnati machine tool builder tell of a young man who was in his employ between terms in college and he asserted that every time this young man came back from college he had to start to learn the trade all over again, having forgotten nearly all he knew.

As the college which this young man attended has a fairly well equipped machine shop, and part of this student's time was spent there, this is somewhat surprising, but the chances are that the fault was more with the student than with the college. One thing I noticed is that many who do not believe in correspondence schools seem to forget that these schools can do the teaching only, the learning being the student's part of the programme and the institution is certainly not responsible for the failure or neglect of the "party of the second part."

That the agents of these correspondence schools often assure stupid men of their ability to become machinists, draftsmen or even mechanical or electrical engineers, in their efforts to secure a commission, I do not deny, for I have seen this done myself; but it is not fair to condemn an institution for the mistakes of a few of its representatives. It is certain that through the work of these agents many a man who never considered himself fit for advancement has been aroused to a realization of what he might be able to do if he only tried and has been assisted onward toward mental and financial betterment.

When it comes to catering to the ignorant for enrollment in correspondence schools the mechanical schools are "not in it." Thinking it might interest some of your readers I give the following extract from the matriculation blank of a college of ophthalmology and otology:

"Sign your name (print it if you cannot write it distinctly) in full. Do not give initials, but write what each initial stands for. Example: Not J. J. Jones, but John Jacob Jones."

To think of such a college attempting to coax into its ranks men who cannot write their own name distinctly is amusing if nothing else. The explanation about not writing J. J. Jones, but John Jacob Jones, would cause many of the kind of men who can scarcely write their own names to write John Jacob Jones no matter what their name might be.

That a school of ophthalmology and otology gets down that low bothers me some, but I certainly hope the mechanical schools will never deem it necessary to swell their ranks (and *rank* they would be) with men who have to print their own name because they cannot write it distinctly. It seems the worse because the instructions quoted are on their printed matter and must come from headquarters so that no poor hardworking agent can be made the scapegoat. Before quitting on this subject, I want to express my disapproval of the practice of correspondence schools of publishing a "key" volume in which all questions asked in the examination papers are answered and which is only too apparently done to save the expense of postage and time required to answer the students' questions, while at the same time it causes him to pick up the book for a solution to the problems rather than to use his brain for that purpose. CORNEIL RIDDERHOF.

Grand Rapids, Mich.

* * *

A ferryboat plying between Long Island City and New York was recently put out of commission for a day or so by a curious accident. A fireman had been ordered to clean a pump in the engine room, that was giving trouble. The cylinder head was removed and the fireman thrust his hand and forearm into the cylinder bore without difficulty, but when he tried to remove it the trouble began. The arm stuck fast and struggle as he might the unhappy man could not loosen it. He finally shouted for help, but when it arrived his arm had swollen so that the combined efforts of the engineer and deckhands could not pull him loose. A surgeon was sent for, not with the idea of amputating the offending arm but to reduce the swelling so that it could be pulled out. His efforts were unavailing and all he could do was to administer a hypodermic injection to reduce the pain. So tightly was the arm wedged that it was not considered safe to break the cylinder with a sledge, and it had to be sawn apart on one side and wedged open. It was six hours before the fireman was released.

ITEMS OF MECHANICAL INTEREST.

LARGE TOOL HOLDERS—ADJUSTABLE JAW WRENCH—SPRING DRIVING BELT A GERMAN SLOTTER—TURRET FOR HEAVY WORK—SLOW-BURNING CONSTRUCTION.

A "horrible example" of power distribution is to be found in a certain shop employing over 1,000 men. The power is furnished from thirteen boilers located at seven different points and fired by ten men, while the engines are of all sorts and descriptions, varying from old hoisting engines to plain slide-valve engines thirty or forty years old. There are better facilities in prospect, however.

A receipt for a pipe joint cement was given by Mr. Light at a recent meeting of the Ohio Gas Light Association, which is claimed to be as effective as red lead putty for either faced or rough flanged pipe joints and which costs only about one-tenth as much. It consists of a mixture of ordinary pine tar and iron oxide (fine borings or turnings well rusted will answer the purpose) mixed to a stiff paste. It does not harden so quickly as red lead putty and is very adhesive under pressure.

EFFICIENCY OF BOILER JOINTS.

The weakest part of a boiler shell is the longitudinal seam. This cannot, of course, be made as strong as the solid plate with any riveted construction, but a good design of joint employing multiple rows of rivets and cover plates, will closely approximate it. The Lukens Iron and Steel Company recently equipped their new power plant with horizontal tubular boilers having quadruple-riveted longitudinal seams. These are calculated to have not less than 94 per cent. of the strength of the solid plate. Samuel Vauclain, superintendent of the Baldwin Locomotive Works, has recently patented a design of boiler joint that has a calculated efficiency of 96 per cent. The weakening of the shell depends on how much of the material is cut away by the rivet holes; the smaller the holes the less it is weakened. This fact may make the use of nickel-steel rivets advisable in boiler construction where a high seam efficiency is necessary. The engineer of tests at the Bethlehem Steel Company has demonstrated that a nickel-steel rivet ¾-inch in diameter is as effective as a 1⅛-inch rivet made of common steel.

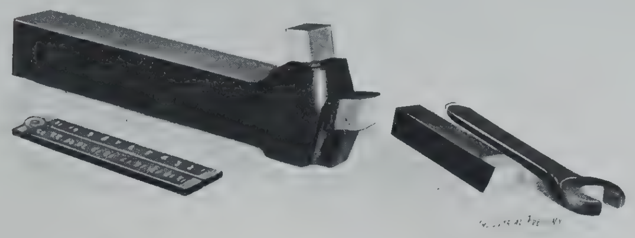
TESTS OF THE STRENGTH OF GLUE.

Bearing on the adhesiveness of glue an item has appeared in a contemporary, whose name we have lost, stating that it may be as much as 715 pounds per square inch. In an experiment performed a force of 1,260 pounds, applied gradually, was found necessary to separate two cylinders of dry ash wood, the ends of which presented a surface equal to 1.76 square inch, and which were glued together end to end and allowed 24 hours to set. Even this weight was sustained for two or three minutes before the joint gave way, and it was found, on examining the separated surfaces, that the glue was very thin and had not entirely covered the surface. The cohesive strength of glue appears, therefore, in this experiment to have been rather more than 715 pounds per square inch, while the cohesive strength of the wood in a lateral direction was found to be only 562 pounds, thus showing that if the joint had been between the sides instead of the ends of the pieces of wood, the wood would have given way before the glue. In this case, however, the glue was newly made and the season very dry, while in some former experiments made in the winter season with glue which had been frequently made, with occasional additions of glue and water, the cohesive force indicated was only 350 pounds to 500 pounds per square inch.

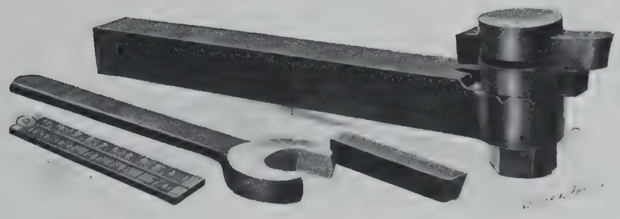
MAMMOTH LATHE AND PLANER TOOL HOLDERS.

While the use of inserted cutters, in lathe and planer tools, is a matter of every-day shop practice, probably few machinists are aware of the size of tools of this type that are practical and profitable.

The Western Mfg. Co., of Springfield, Ohio, sends us the photographs shown on the next page of large lathe and planer tools which they have furnished to many of the leading machine shops. The lathe tool holder is 3 inches square by 20 inches long and weighs 70 pounds. The planer tool holder is 3 inches square by 30 inches long and weighs 125 pounds.



Lathe Tool Holder.

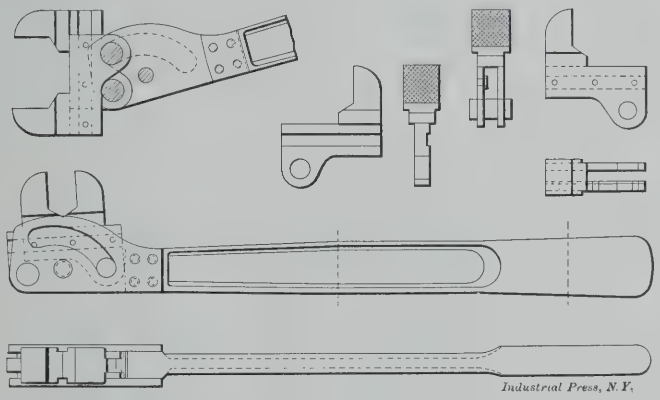


Planer Tool Holder.

Both holders carry self-hardening steel cutters 1½ inch square. These are without doubt the largest tools of the kind ever manufactured.

WRENCH HAVING ADJUSTABLE JAW.

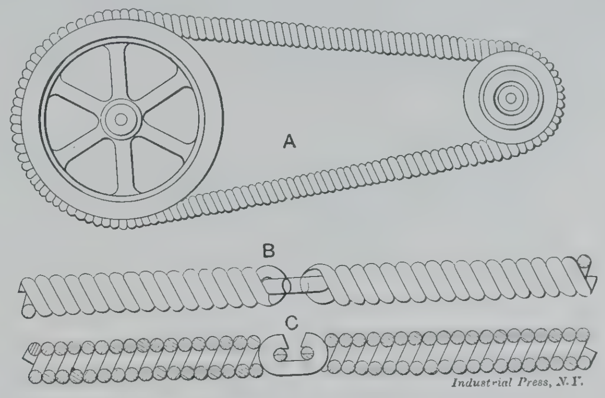
Many inventors have attempted to devise a sliding jaw adjustable wrench to supplant the ubiquitous monkey wrench, but their efforts have generally met with indifferent success. It is true that there are pipe wrenches of this type that are fairly successful, but they belong to a class of tools that apparently must be somewhat cumbersome to perform the work required of them. A sliding jaw wrench for bolts, other than the monkey wrench, that will compete successfully with the latter, is yet to be devised. A German effort in that direction is illustrated in the cut. The principle on which it works is so clearly shown that a long explanation is unnecessary. One advantage it has is that a nut or screw head is firmly gripped in one direction and promptly released when the handle is moved in the opposite way. This is all right within limits, but likely to be somewhat exasperating when one works in a constrained place where only one hand can be used to operate the wrench. Again, the angle at which the jaws stand relative to the handle, varies with the size of the nut. It is unnecessary to point out the nature of this defect to those who appreciate the advantage of the 15-degree angle jaws as found in drop-forged wrenches. There seems to be little likelihood that anything better can be devised for the machinist's use than a set of good case-hardened solid jaw drop-forged wrenches and his old friend and companion, the monkey wrench.



Adjustable Jaw Wrench.

COIL SPRING DRIVING BELT.

The use of steel wire coils for driving belts is something of a novelty—in this country at least. The illustration, Fig. 1, shows a German driving belt for light power that is made of wire closely coiled like a helical spring. In fact it is a spring, being made of tempered steel wire, and its elasticity is what makes it available as a power transmitter in place of leather or rubber belts. It is recommended by the maker, Gustave Pickhardt, Bonn a. Rh. for lathes, steam engine governors, sewing machines, tachometers, revolution counters, etc. Its use for lathes and other machine tools would, of course, be limited to those requiring little power such as bench, precision, watchmakers' and other foot-power lathes, sensitive drills, etc.



Spring Driving Belt.

SLOTTING MACHINE OF GERMAN DESIGN.

A slotting machine containing some interesting features and illustrated in Figs. 1, 2 and 3, is made by the Berliner Werkzeugmaschinenfabrik A.-G. formerly L. Sentker. The ram is screw driven and is not counterbalanced. The driving screw *N*, Fig. 3, has ball thrust bearings and is driven by bevel gears and a short intermediate shaft *M* from a transverse shaft on which are mounted the tight pulleys *A A'* and loose pulleys *B B'*, Fig. 2. The ram, of course, normally works in a vertical position, but it may also be operated in an angular position, as provision is made to shift it around an axis coinciding with that of the horizontal shaft *M*, about 30 degrees each side of the vertical line. A worm and section of wormwheel are provided for shifting it, and four clamping bolts for holding it in any position. The chief feature of interest aside from the driving mechanism is the method of ram reversal. The transverse driving shaft is continued through the column and is geared to the upper end of a vertical screw *Q*, Fig. 3, on which is mounted a nut *R*. This nut has the same length of traverse as the slide and moves in the same direction coincident with it. The points of reversal

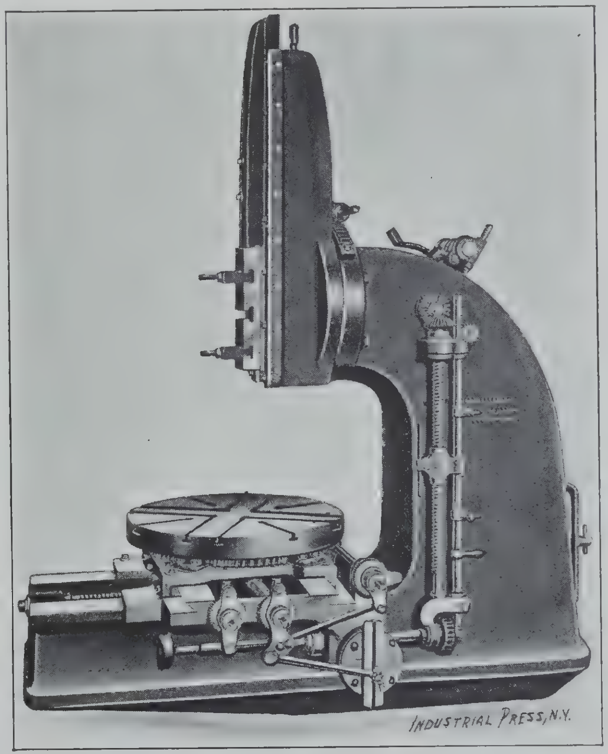


Fig. 1. A German Slotter.

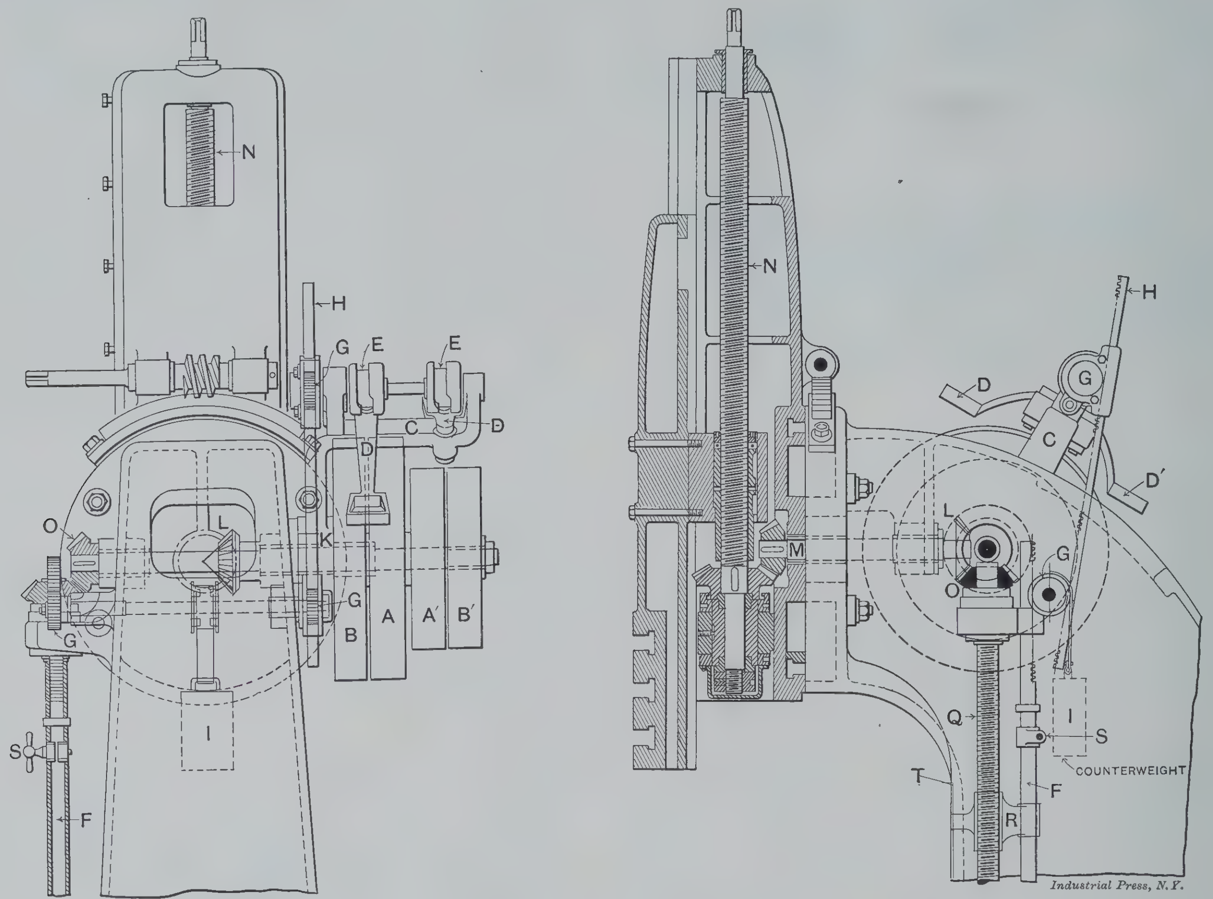
are determined by the positions of the dogs or stops *S* which are clamped to the vertical shifter *F*. A handle is also fastened to the shifter for the convenience of the operator. Some other interesting details may be noted from the illustrations, which were taken from the *Zeitschrift des Vereines deutscher Ingenieure.*



Industrial Press, N.Y.

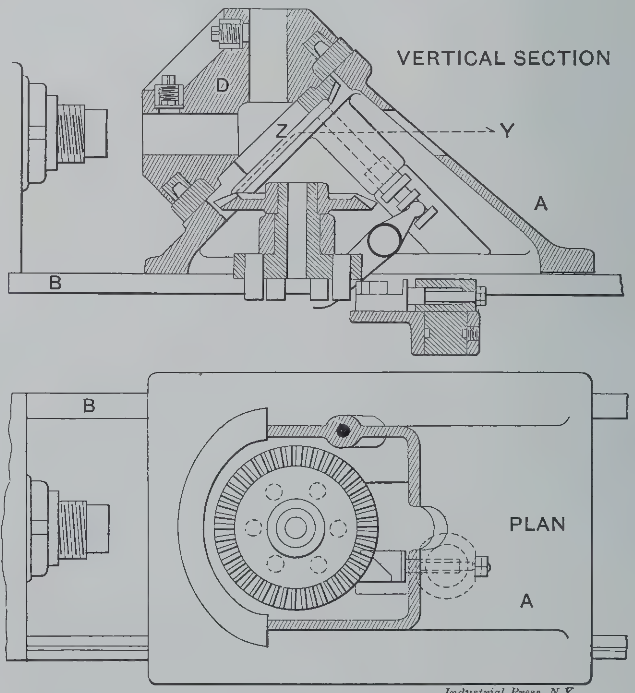
Fig. 2. Detail of Head of German Slotter. Fig. 3.

SLOW-BURNING CONSTRUCTION.

The "slow-burning construction," so frequently employed in the best factory buildings, has a wonderful capacity for resisting the ravages of fire. The heavy timbers which constitute the columns and floor beams, and the thick plank flooring, often stand up under the intense heat of a fire better than the so-called fireproof construction of structural steel, covered with non-conducting material. The heavy wooden timbers char, but do not burn through for a long time, while the steel members of the fireproof buildings warp and twist out of shape. Mr. J. A. Brown, superintendent of building inspection, Pittsburg, gives an example of a fire in a nine-story building of the slow-burning class. He says the building was packed with furniture from bottom to top and the goods in the three upper stories were practically burned up. On the seventh floor was stored a very large quantity of chair materials, packed from floor to ceiling. This material was all consumed, leaving on the floor ashes or charcoal from sixteen to eighteen inches in depth. The wooden beams or girders of the floor above the same, being 10 x 14 in size, were only partially destroyed; some of them burned half way through, none of them entirely. The fire in this story burned fiercely for about four hours.

TURRET CONSTRUCTION HAVING UNLIMITED CAPACITY FOR LONG WORK.

The ordinary turret cannot handle work quite as long as its diameter when all the holes are occupied by tools. A number of designs of turrets have been made to give unlimited capacity to the length of piece being worked regardless of whether all the tool holders in the turret are occupied or not. One form of construction used in the shop of an Eastern manufacturer of brass goods offsets the turret so that the center line of the lathe spindle passes by the side of the turret. The tools are fastened on its side and operate on the work as it passes by. Another design of recent date employs a ring turret that surrounds the lathe bed and rotates on a horizontal axis. The accompanying cuts show a recent German lathe design (Pittler) in which the turret is mounted so that its axis is inclined at an angle of 45 degrees to the spindle axis. The holes in the turret are inclined at the same angle to the base and so they are separated by an angle of 90 degrees, that is, opposite holes. The bevel gear ring by which the turret is turned, allows the work to pass through without interference; therefore, an indefinitely long piece may be turned or threaded. This construction is very similar to that of a tailstock turret made by the W. F. & John Barnes Co. for several years past. In this turret, however, the angle of inclination is 30 degrees and no provision is made for long work to pass through.



Industrial Press, N.Y.

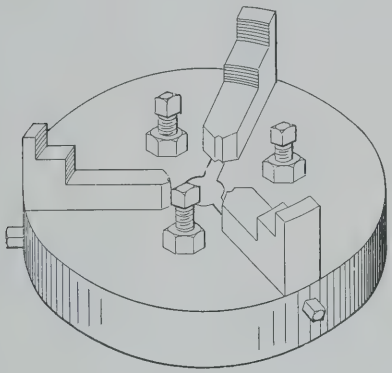
Turret for Long Work.

CONTRIBUTED NOTES AND SHOP KINKS.

TRUING WORK IN A CHUCK.

John Aspenleiter, Cincinnati, Ohio, sends us a kink for truing up work in a chuck when a number of disks, flanges or pieces of that nature are to be bored.

As all machinists know, a great deal of time is often wasted in getting the face of the work to run true in the chuck. To remedy this difficulty, three holes are tapped in the face of the chuck, between the jaws, and a setscrew with check nut provided for each hole. If the screws are set correctly for the first piece and then locked with the check nuts, all that is necessary for the following pieces is to butt them up against the screw heads and they will run all right.



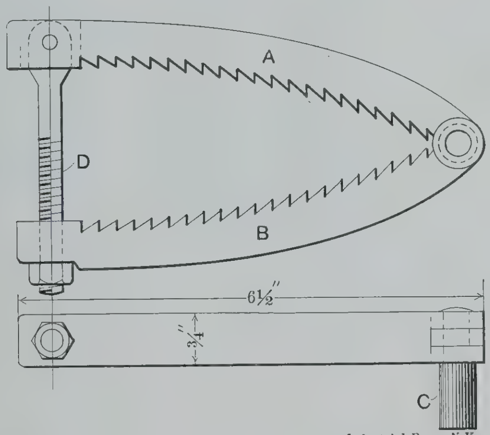
Industrial Press, N.Y.

A "NEVER-SLIP" LATHE DOG.

Warren O. Rogers, Brockton, Mass., writes:

Some years ago, when I was employed as a machinist, among the petty annoyances that would occur was that caused by the slipping of the dog on round work, supported in the lathe centers. I had, however, never seen anything to obviate this difficulty until a few days ago, when I saw a dog that overcame the trouble in a very satisfactory manner. I think this may be of interest to some of the readers of MACHINERY.

As is shown in the sketch, the dog consists of two straps *A* and *B*, which are jointed at one end by a dovetail and pin *C*, while the opposite ends may be drawn together by the nut and screw *D*, thus gripping the work. The pin *C* projects from one side and is used for driving the work. A dog of the dimensions given is suitable to use with work from ¼ inch to 2 inches in diameter.



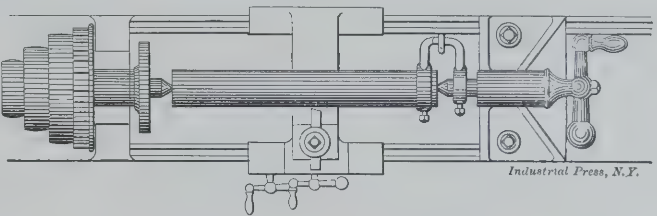
Industrial Press, N.Y.

Lathe Dog.

With this dog, if the work has a tendency to slip, it simply forces itself toward the apex formed by the jaws and thus increases the grip of the dog on the work.

CUTTING KEYWAYS IN A LATHE.

John Aspenleiter, Cincinnati, Ohio, says that in a small shop where there is no shaper, or where the shaper is in use, and it is necessary to cut a small keyway in a shaft, the job can be done in a lathe in a quicker and more satisfactory manner than by chipping and filing. Put the shaft on the centers, as shown in the sketch. Place a lathe dog on the end of the shaft toward the tailstock and another on the tailstock spindle. Clamp the tails of the two dogs together, thus preventing the shaft from turning, yet leaving the live center free. Now put the tool in the tool post with the cutting edge facing the headstock. Gear up the lathe to give the proper cutting speed and use the leadscrew to drive the carriage the same as when chasing a thread. At the end of each cut pull out the tool by the cross feed screw and return the carriage for another cut.



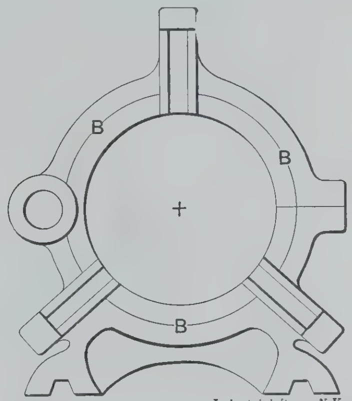
Industrial Press, N.Y.

Lathe Arranged for Cutting Keyway.

If the keyway is very short, the carriage can be fed by hand, but for cutting a keyway of any length it is preferable to use the leadscrew.

CENTERING WORK IN STEADY REST.

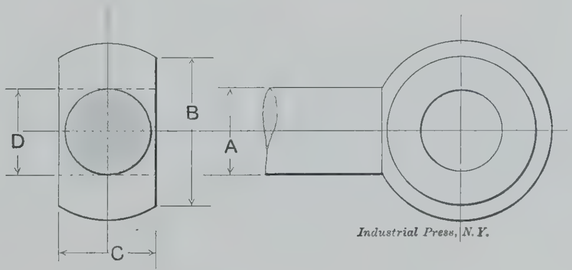
J. W. S. sends a "kink" for ascertaining if work is central when placed in the steady-rest. He first removes the jaws and then with a tracing tool, held in chuck or fastened to the faceplate, he describes the circle *B B* on the body of the rest. The work is then easily centered by measuring to this circle.



Industrial Press, N.Y.

PROPORTIONS OF LINK ENDS.

Robert S. Brown sends a sketch of a steel link end which has proved very satisfactory for use on automatic machinery, engine link motions, etc.; as it gives a finished appearance without costing too much to manufacture. The spherical end may be turned in any lathe which has a swivel tool carriage; or an attachment for turning hand wheel rims, in which the tool point is moved in a circular path, will answer.



Industrial Press, N.Y.

The dimensions are:

$A =$ diameter of link at body.
$B = 1\frac{1}{2} D + \frac{1}{8}$ inch.
$C = A + 1\text{-}16$ inch.
$D = A$.

The flat spot *B* will be seen to give as much bearing as is found between flats on a standard hexagon nut of the nominal size of *D*.

NEW TOOLS OF THE MONTH.

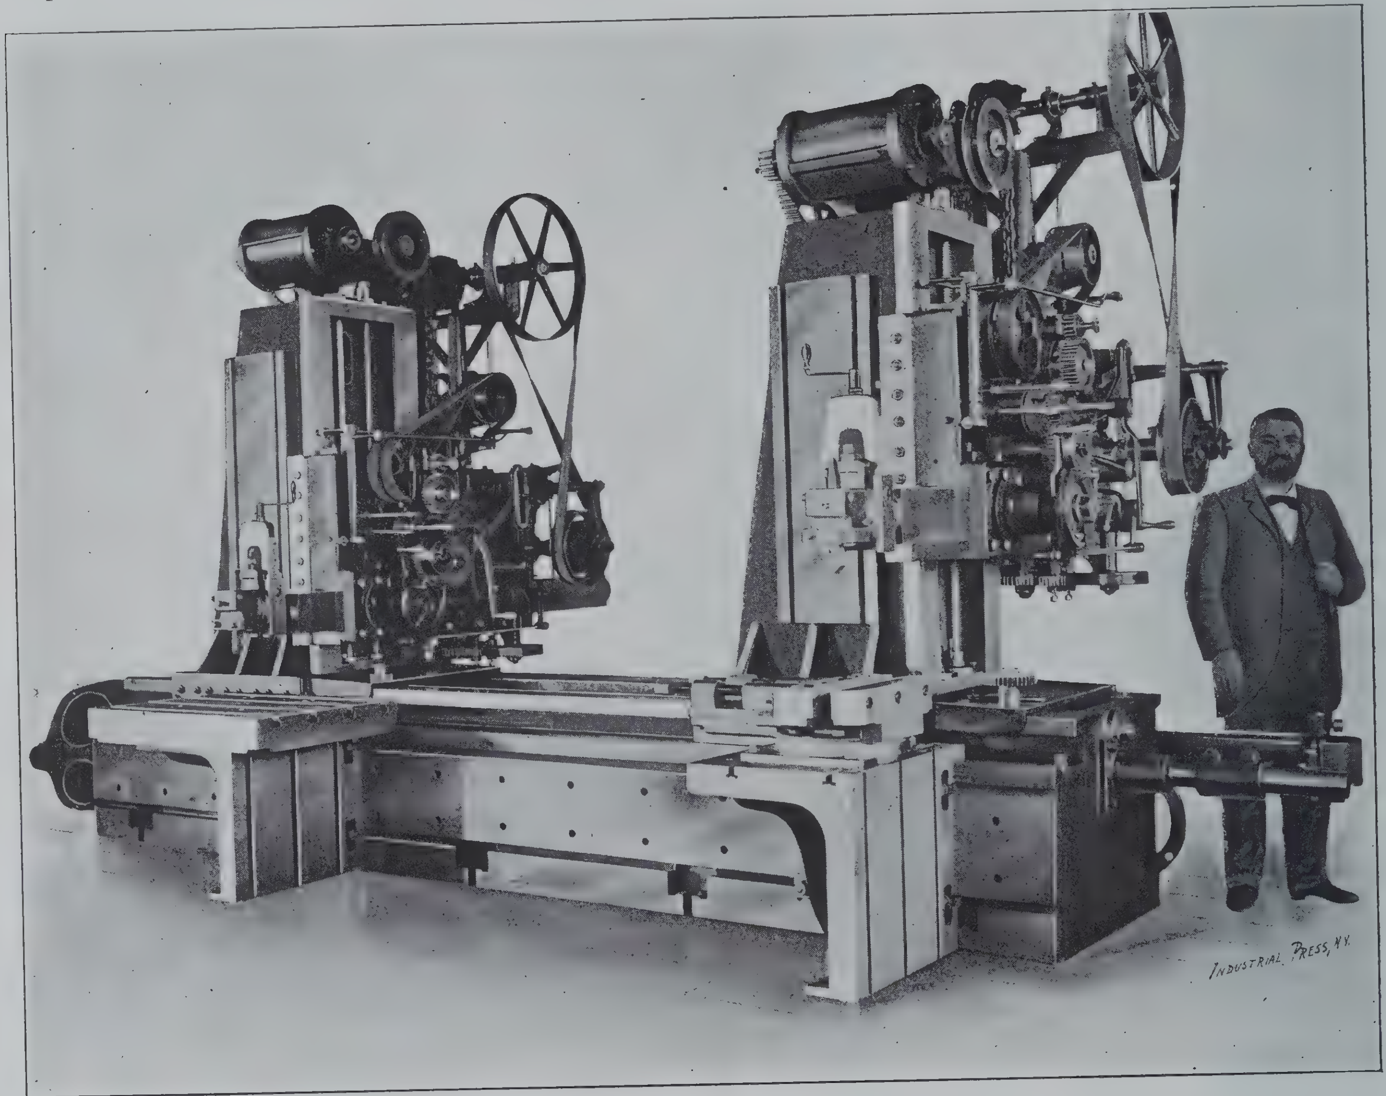
A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

DUPLEX TRAVELING HEAD SHAPER.

The traveling head shaper shown in the engraving has been brought out by the Morton Manufacturing Co., of Muskegon Heights, Mich., and embodies several new and useful features. The shaper is electrically driven and operates on the "draw cut" principle.

This machine has 36-inch stroke, 30-inch vertical feed on the column, and the length of the bed is 14 feet. It is built either single or double-headed and furnished with one or two tables as the case may require. When it is desired, the tables may be constructed to raise and lower for purposes of adjustment.

The machine has automatic feeds in both directions and is also provided with means whereby the aprons and columns may be moved by power, either vertically or horizontally when adjusting them to the work. The movement of the column on the bed is obtained by a screw which remains stationary, the nut revolving. The apron of the shaper is gibbed and fitted to the vertical column, and the vertical adjusting screw is also stationary, being operated with a revolving nut. These revolving nuts are fitted with ball-bearing thrust collars.



Duplex Traveling Head Shaper.

The ram is square and has a bearing on all four sides, wear being taken up with taper gibs. The stroke is adjusted by tappets on a circular disk and a suitable lever is provided whereby it may be reversed at any part of the stroke. The reciprocatory motion of the ram is obtained by two friction clutches, one being operated by an open belt and the other by a cross belt. It has a quick return stroke of three to one.

The countershaft is provided with a friction clutch and is stopped and started instantly at any part of the stroke by means of a lever provided for this purpose, which brings the machine under complete control of the operator.

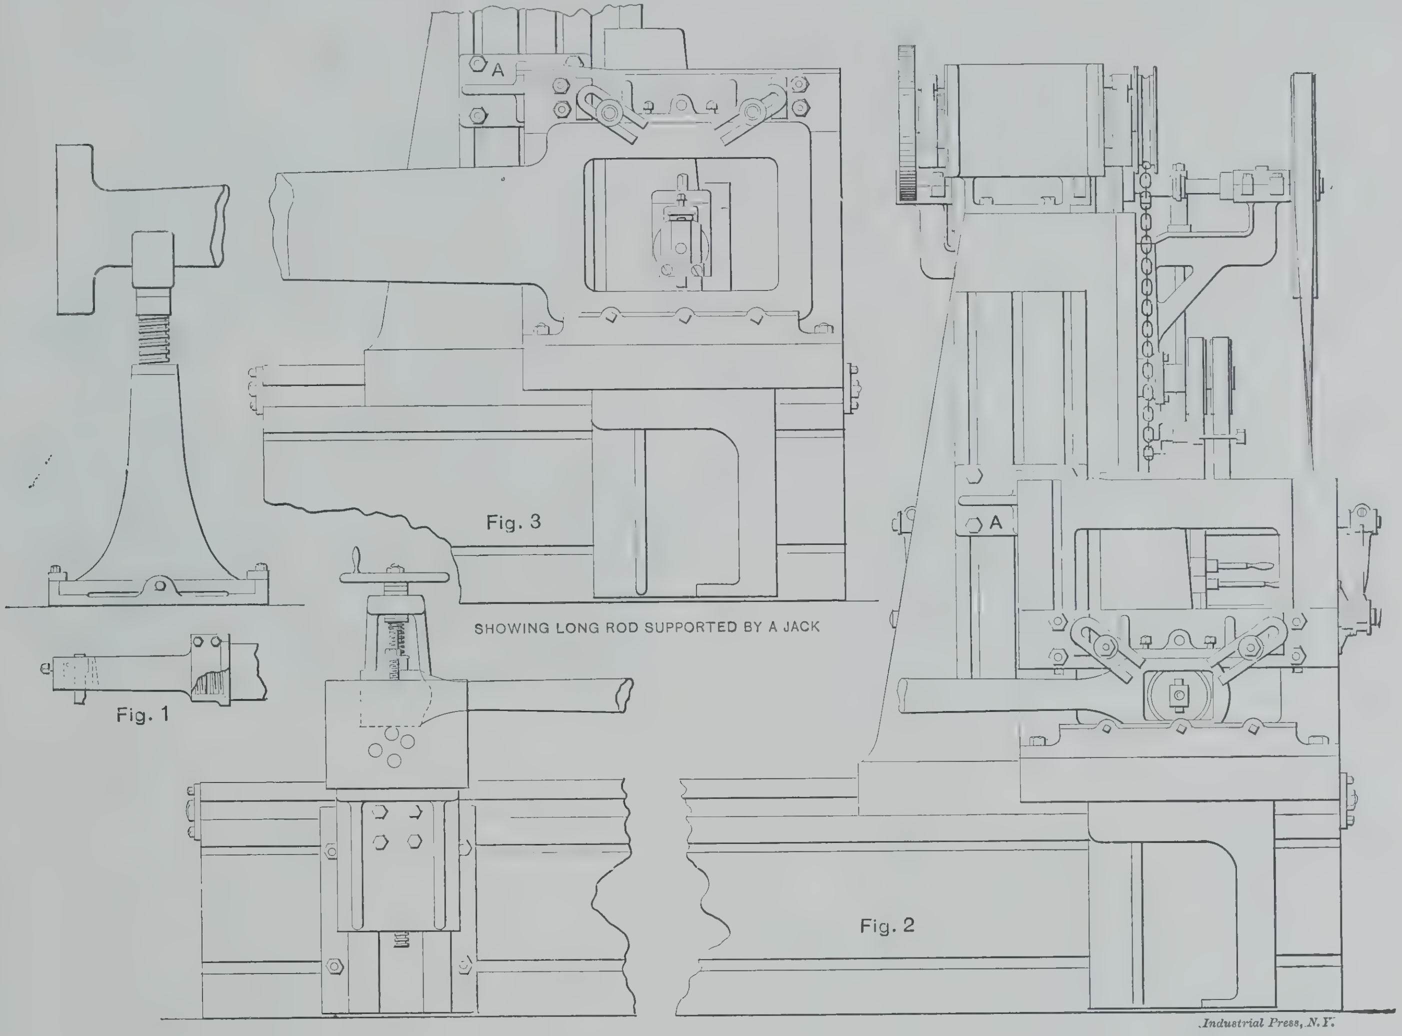
The friction feed is of the automatic relieving type and is positive in its movements.

The aprons are counterbalanced by a special coil spring arrangement inclosed in the cylindrical casing at the top of the column. The rail bearings on all portions of the machine are square and the gibs employed are of the taper type.

One commendable feature of this shaper in which it differs from any other that has ever been produced before, is that of the vertical feed on the column, which enables the machine to take vertical side cuts and makes it well adapted for internal work. The head may be removed and a special head, shown in Fig. 1, secured to the end of the ram so that internal slotting may be accomplished with this tool. Each head is driven independently, so that either one may be brought into action and operated entirely independent of the other. Both heads obtain their feeding power with revolving nuts from the same screw.

A particular advantage with this style of shaper is that one head can be operated on a piece of work 30 inches above the table, while the other head may be operated at any intermediate point.

The illustrations, Figs. 2 and 3 on the next page, show this shaper machining an opening in a solid end connecting rod. It will be noticed that a suitable adjustable chuck is provided for holding the end of the rod to be ma-



Traveling Head Shaper Operating on a Connecting Rod.

chined, and a support *A* is placed between the top of this chuck and the column of the shaper. This allows the machine to be fed vertically or horizontally. When machining the opening, a cut may be taken across the bottom, then the head turned ninety degrees and a cut taken up the side; it can then be changed and a cut taken across the top and another change made and a cut taken down the end. This enables the opening of a connecting rod to be planed out on all four sides, the rod remaining in a stationary position.

As will be seen in Fig. 2, the outer end of the rod is supported in a suitable chuck placed on the second table of the machine. When but one table is furnished an adjustable jack, shown in Fig. 3, is used for this purpose.

It will be seen that with the automatic feeds on the column and the range which the shaper has, a great deal of irregular work may be accomplished which has heretofore been difficult to reach with any tool.

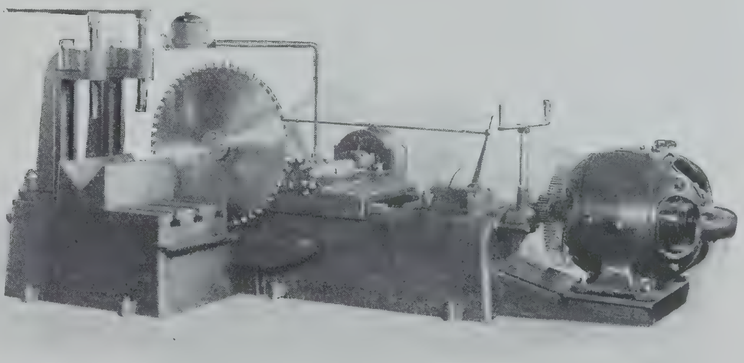
It may also be used in the capacity of a portable shaper, as with the vertical adjustments on the column, it is adapted to be used in connection with a floor plate, in planing off spots on large castings, pillow blocks for medium-sized Corliss engine frames, etc. The plate on the front side of the column is planed so that a suitable bearing may be placed in between the work and the frame of the machine, thereby putting the thrust of the cut directly against the column.

This shaper is very heavily geared and capable of taking a cut of 1¼ inch deep in steel, with 1-16 inch feed.

NEW LINE OF COLD SAWS.

The Q. & C. Co., Chicago, Ill., have recently brought out a line of metal cutting machines embodying several improvements over those formerly built by them. They manufacture two types of these machines—"Bryant" saws, in which the saw blade is driven by a gear or sprocket wheel engaging with the teeth formed on the periphery of the blade, and arbor-driven saws, on which the saw blade is driven by a central mandrel or arbor. Both types are made either as cut-off saws, having a short travel and especially suited for cutting bars and structural shapes; or as universal saws in which the travel of the blade is longer and the machine is fitted with an upper side table on which the work can be cut off for the entire length of the travel of the saw blade, while they are also arranged with V-blocks and lower tables for cutting bars and shapes.

The illustration shows one of the Bryant type of saws operated by an electric motor. They are also manufactured for belt driving. Any machine can, when desired, be mounted on a circular base, which can be completely rotated by rack and pinion, this being a very desirable feature where there is not sufficient room for swinging a long beam. Lateral adjustment of side tables can be furnished, if required, so that work can be adjusted for cutting after being secured.



Bryant Cold Saw made by the Q. & C. Co.

The tables, on all machines, have been so arranged that work can be placed most advantageously for cutting with minimum distance of blade travel, the longer slide tables being of sufficient length to properly support beams when being cut off at any angle up to 45 degrees.

All machines are fitted with friction feed, giving an automatic feed, variable with the machine in motion, from ¼ inch to 1 inch per minute on the Bryant saw and from 3-16 to 13-16 inch per minute on the arbor-driven saws.

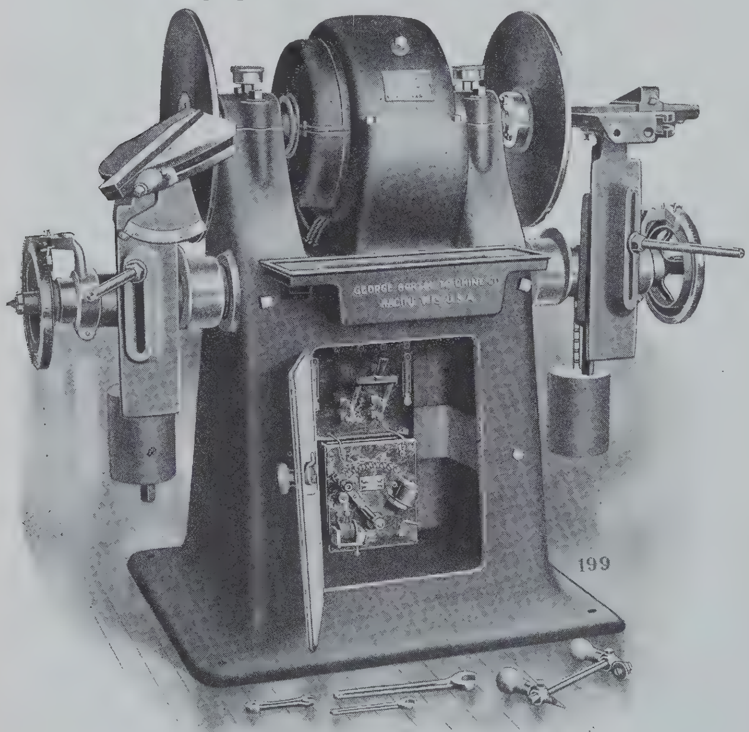
The universal type of machines is fitted with a power return movement.

The "Bryant" saw carriage is in two parts, the sprocket shaft bearing being cast in one piece with the worm gear hood, and movable 2½ inches toward the axis of the blade, allowing for a wear of 5 inches in its diameter. The sprocket is removable, and all sprockets on these saws are interchangeable and readily replaced.

All gears, in both types, are entirely inclosed, thereby avoiding dust and lessening liability to accident.

ELECTRICALLY-DRIVEN DISK GRINDER.

The George Gorton Machine Co., Racine, Wis., have designed their No. 6 B disk grinder for electric driving. The machine has a pedestal cast in one piece, heavily ribbed, internally, and is provided with a dust-proof, automatically ventilated, 5 horse power compound-wound motor. The arbor is of hard tool steel and the armature is mounted upon a conical bearing upon the arbor so that it may readily be removed without driving. The machine is dust-proof throughout and particular attention has been given to the matter of lubrication. The tool is provided with the company's standard feed works upon each table. The handwheels register in thousandths of an inch and are provided with adjustable stop. The left-hand table is adjustable in degrees to the face of the disk and both tables are provided with protractors reading in degrees, which are quickly detached when desired. Each table may be adjusted vertically and is balanced, and is automatically maintained in swinging balance regardless of vertical adjustment.



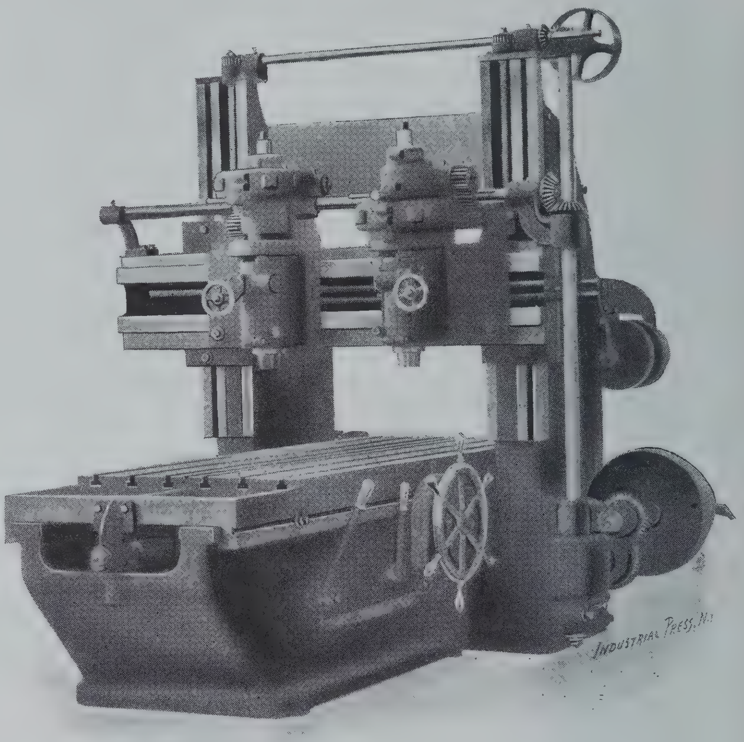
Electrically-driven Disk Grinder.

Each machine has four 18-inch steel disks, accurately finished, a cementing press for the same being provided, with positive means for raising the steel disk from the lower press flange. A water pan is furnished, with a shelf at the rear having a pocket for wrenches, which are also provided. The net weight of the machine is 2,100 pounds.

NEW DOUBLE SPINDLE MILLING MACHINE.

The Beaman & Smith Co., Providence, R. I., have brought out a milling machine having two vertical spindles, illustrated herewith. It consists of a substantial bed on which is mounted a table, and to which uprights supporting the cross rail for the milling heads are firmly attached. The features of the machine are clearly shown in the illustration and it will not be necessary to do more than give the general specifications.

The table is 36 inches wide, 8 feet long, and in addition to the usual feeds by means of a screw, it is provided with quick power movement in either direction. On the cross rail are the heads carrying spindles, which are provided with horizontal adjustment by means of screws.

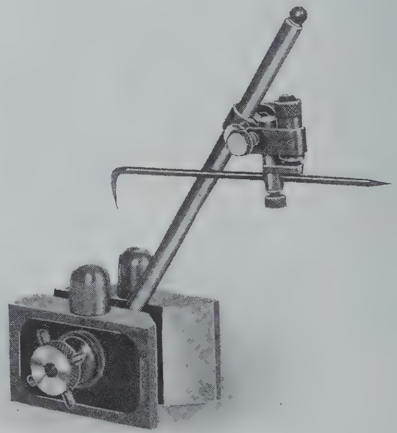


Beaman & Smith Double Spindle Milling Machine.

The spindles are driven by a 3-inch belt on a four-section cone through gearing in the ratios of 4½, 10, 19 and 40 to 1, providing spindle speeds from 6 to 91 revolutions per minute in either direction. They are also provided with independent vertical adjustment of 3 inches.

A NEW SURFACE GAGE.

The Sawyer Tool Mfg. Co., of Fitchburg, Mass., have brought out a new surface gage provided with micrometer adjustment. The sides of the base are ground parallel and true and upon the upper surface are two bosses for use in planer bed slots or similar positions. The base is slotted so that the spindle can be revolved through three-quarters of a circle, thus giving a wide range of adjustment. The clamp upon the spindle holds a block which can be swung either up or down to any desired angle and clamped solidly in position. A knurled thumb screw, on the under side of this block, holds the needle or scriber in position; while a knurled head, on the



Improved Surface Gage.

upper side, gives the needle an up-and-down parallel motion. This motion will be appreciated as a very desirable feature of the gage. The knurled head in front clamps the needle rigidly when the adjustment has been made.

THE BATH AUTOMATIC, UNIVERSAL COMBINATION GRINDER.

Figs. 1 and 2 show a new design of an automatic universal combination grinder, which is being manufactured by the Loop-Lock Machine Co., of Waltham, Mass., successors to the American Watch Tool Co., under the direction of the inventor, Mr. John Bath. The machine is being placed on the market by Messrs. Hill, Clarke & Co , of Boston, New York, and Chicago.

Fig. 1 shows the machine arranged for cylindrical grinding. The wheel is guarded by an adjustable band and provision is made for the use of water.

The knee and frame of the machine are so constructed that all water returns by the trough, shown around the base of machine, to the tank. This attachment is so constructed that it takes away all the water, producing no slop around the machine.

The wheel head is carried by a vertical arm, the top portion of which is threaded, and is moved up and down by a combined hand wheel, nut and dust cap. This is provided with a micrometer adjustment. The head is also gibbed to a vertical slide which provides rigidity in any position.

The swivel plate has two slots which permit of the headstock, footstock or attachments being removed without any interference with the head of the clamping screw which preserves the set alignment of the swivel plate. The two slots are also useful in clamping work for surface grinding.

Fig. 2 shows the knee swung around the column in position for surface work, and also the new automatic longitudinal feed. The feed is driven from a drum above, in the countershaft, to a cone pulley at the side of the knee. When in use for cylindrical work the belt runs on large step of cone, and for surface work on small step, which gives the higher speed required for surface work.

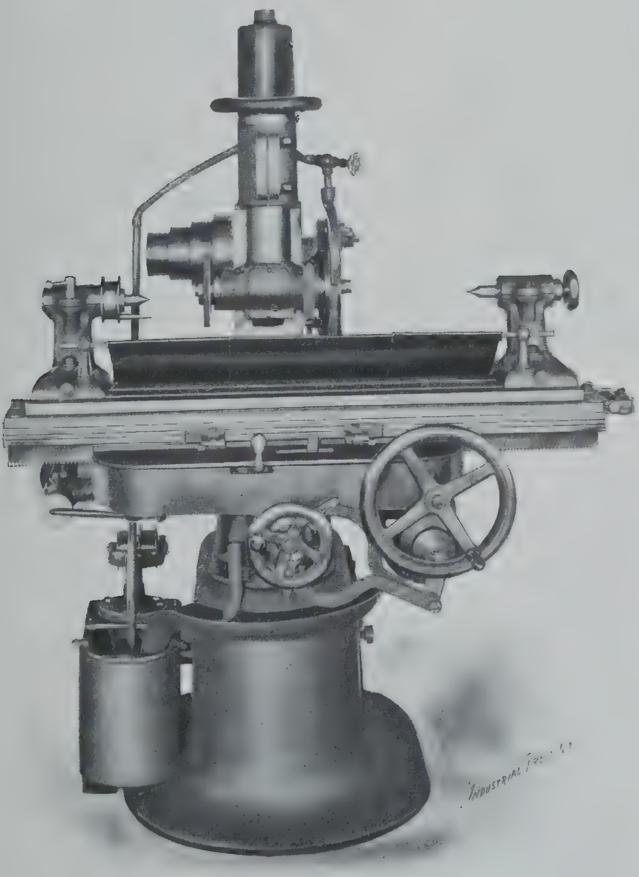


Fig. 1. Bath Grinder arranged for Circular Grinding.

The power cross-feed attachment for surface work is also shown. It is so constructed that either one or two pawls may be engaged at the same time, and adjusted to give a fine or coarse feed. The feed may be quickly disengaged by the knurled knob back of the large hand wheel.

At the front of the bottom slide is an enclosed box apron having a removable top cover, so that all the inside workings of the feed are accessible for inspection or adjustment.

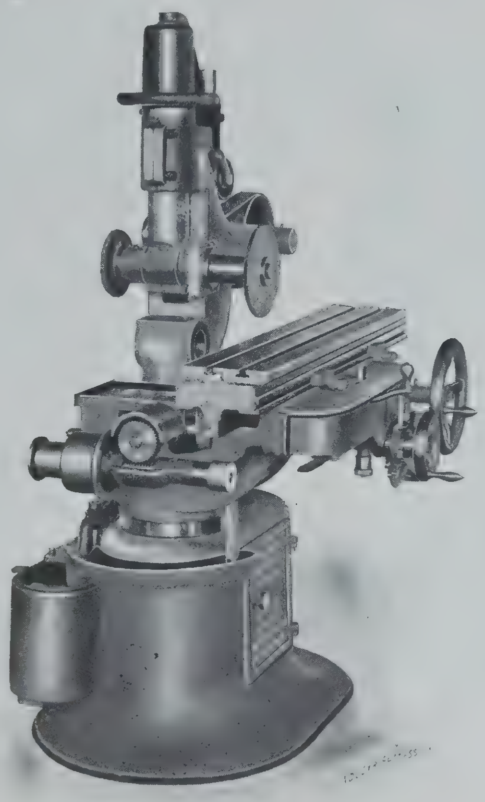

Fig. 2. Bath Grinder arranged for Surface Grinding.

In addition to its use for cylindrical and surface grinding, the machine is provided with numerous attachments that fit it for internal grinding and for grinding all kinds of milling cutters, reamers, twist drills, and lathe tools.

NEW HYDRAULIC PRESSES.

Figs. 1 and 2 on page 116 show two new hydraulic presses designed by Mr. Chas. F. Burroughs, which are being built and sold by the Charles F. Burroughs Company, of Newark, N. J.

These presses were originally intended for jewelers' use, for die sinking and similar purposes, but they are not confined to this field as they may be adapted to almost any purpose where hydraulic machinery is required.

The press consists of but three principal parts, the cylinder, plunger and platen; and the entire press rests upon a substantial base which contains the water used for raising the ram.

The cylinder may be copper lined or not, as the duty may require. A particular feature of the presses is that the cylinder, rods and head are all in one piece.

The smaller press, shown in Fig. 1, is arranged to be operated by the hand pump shown on the side. This pump contains an external and internal piston. The external piston is used to give a large quantity of water at a low pressure, after which it is securely locked down by means of the small handle, shown under the main lever, and at the same time the smaller internal piston is released, thereby enabling the operator to obtain the required high pressure.

Fig. 2 shows a press constructed after the manner of the smaller one, but with the pump arranged to be operated by power. This pump consists of an internal and external piston the same as the hand pump, except that the larger piston is actuated by the springs shown under the pump. These springs are sufficiently powerful to raise the press ram and give low pressure per square inch, after which they remain extended with the large pump piston at its upper stroke. The small internal piston continues to work, giving the required high pressure.

The power pump may be attached to the smaller press if it is desired.

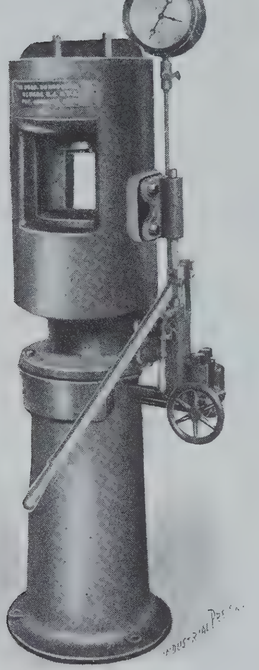

Fig. 1. Hand Hydraulic Press.

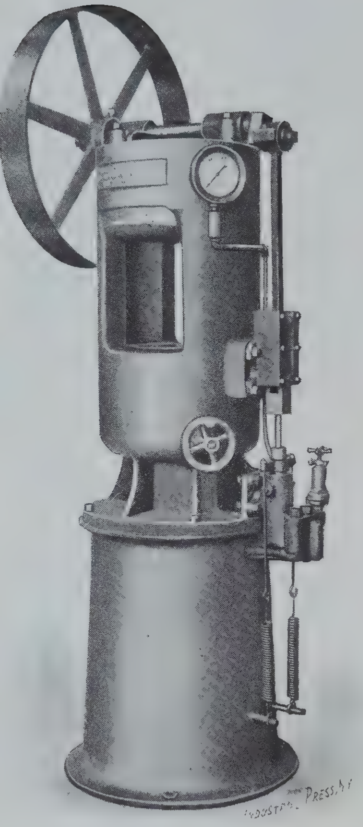

Fig. 2. Power Hydraulic Press.

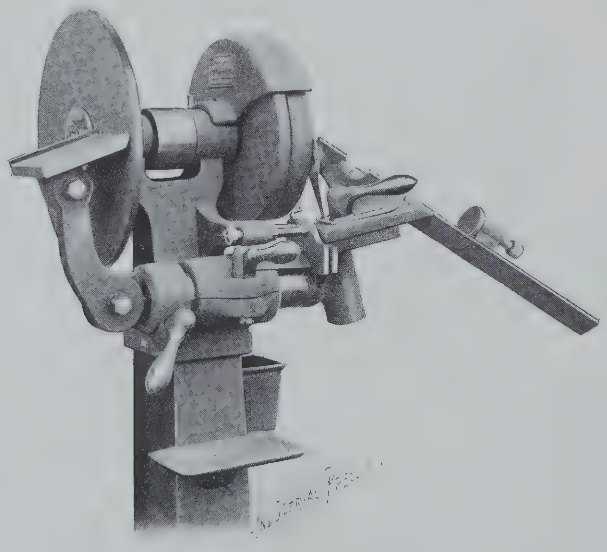
The small press has a capacity of 300 tons and weighs but 1,275 pounds; the larger press has a capacity of 500 tons and weighs 2,300 pounds. The floor space required for the small press is 1½ by 1½ feet and for the larger 2¼ by 2¼ feet.

DISK GRINDING ATTACHMENT FOR TWIST DRILL GRINDER.

L. S. Heald & Son, of Barre, Mass., have brought out an attachment for their twist drill grinder in the shape of a disk grinding attachment which is substituted for the thinning attachment frequently sent out on these machines. This disk grinding attachment consists of a large plate about 12 inches diameter, together with a suitable table which can be tipped to make any angle with the face of the wheel and oscillates on the end of the sleeve, back and forth on the wheel face; or it may be clamped rigidly in any particular position.



Disk Grinding Attachment.

This attachment is designed for grinding and polishing in those shops where the amount of work is not of sufficient quantity to warrant the installation of a regular disk grinding machine.

This fixture is capable of being attached to any of their twist drill grinders now in use.

COLD SAW CUTTING-OFF MACHINES.

A new line of cold saw cutting-off machines is being built by the Espen-Lucas Machine Works, of Philadelphia, after the design of Mr. W. H. Lucas. These machines are being built for cutting bar steel and I beams, and there are three sizes of each pattern. The clamp is swiveled so that it can be quickly adjusted to odd shapes or for cutting on angles. Saw blades 3-16 inch in thickness and 22 inches in diameter are used. The feed is automatic, with automatic safety stops controlling the depth of cut, and is variable from ¼ inch to 1½ inch per minute. The lubrication of the saw is provided for by an oil box in which it constantly revolves.

* * *

ADVERTISING LITERATURE.

The Franklin Machine Works, Philadelphia, Pa. Illustrated catalogue of horizontal floor boring, milling and drilling machines. Also of cold-saw cutting-off machinery and of plain milling machines.

Schumacher & Boye, Cincinnati, O. Special circular descriptive of their 36 and 42-inch triple-geared and back-geared engine lathes. The circular contains a number of fine illustrations of these lathes and a full description of same.

The Standard Tool Co., Athol, Mass. 1902 catalogue of mechanics' fine tools. These include surface gages, steel squares, try-squares, depth gages, bevel protractors, straightedges, calipers, dividers, etc.

The Bradford Machine Tool Co., Cincinnati, O. Circular of their 16-inch engine lathe, containing a full description of this lathe and a cut of same. The lathe is also made in 14, 18, 21, 25, 28 and 32-inch sizes.

The Northern Electrical Mfg. Co., Madison, Wis. Bulletin No. 29 of the "Northern" multipolar motors. The motors and their various parts are fully described and illustrated, and the booklet shows in a very complete manner the variety of "Northern" apparatus.

The New Haven Mfg. Co., New Haven, Conn. Catalogue A of iron-working machine tools, including iron planers, from 20 to 60 inches wide; engine lathes, from 18 to 65 inches' swing, and drilling machines, 28 to 40 inches' swing. The catalogue is handsomely illustrated.

Wyman & Gordon, Worcester, Mass. Pamphlet giving a short account of the life of Sir Henry Bessemer, of Bessemer steel fame, and calling attention to the steel forgings manufactured by the company. These are made by drop hammer, steam hammer and hydraulic press.

The Lunkenheimer Co. Cincinnati, O. Illustrated catalogue and price list of brass and iron valves, injectors, whistles, lubricators and steam specialties. This catalogue contains 208 pages, is fully illustrated and will prove valuable to prospective purchasers of such specialties. The catalogue can be procured gratis by addressing the company.

The Garvin Machine Co., New York. Catalogues Nos. 10, 12 and 14 of the series issued by this company. No. 10 treats of their screw machine tools and attachments; No. 12, of duplex drill lathes, hand lathes, slide rests and spring coilers; and No. 14, of their special machinery. No. 14 also contains a general index of the company's products.

The Hayden & Derby Mfg. Co., 85-89 Liberty St., New York. Illustrated catalogue of the "Metropolitan" automatic injectors, Metropolitan 1898 injectors, and Metropolitan double tube injectors manufactured by this company. Also of the H. D. ejectors and of other jet apparatus. The catalogue contains, besides, much useful information relative to injectors and ejectors, and will be sent to anyone interested.

The Worcester Emery Wheel Co. Worcester, Mass. Circular of the emery and corundum wheels, for fine and rough work, manufactured by this company. Silicate or semi-vitrified wheels, and thin elastic wheels for light grinding or for the grinding of thin, hard stock are also made; and the company also take orders for wheels for special work. A table of grades of emery for various kinds of work and one of the different speeds of emery wheels are given in the circular.

MANUFACTURERS' NOTES.

The Automatic Machine Co., Greenfield, Mass., manufacturers of machine tools, are building a new shop 120 feet square, with a wing 35 x 40 feet. They expect to move in about October 1.

The Baush Machine Tool Co., Springfield, Mass., manufacturers of multiple spindle and radial drills, etc., are adding to their foundry a storeroom and a room for tumbling barrels 30 x 75, 17 feet high.

The Joseph Dixon Crucible Co., Jersey City, N. J., have gotten out an ingenious color chart for so displaying the colors of Dixon's silica-graphite paint as to give an exact idea of each color. The chart also contains instructions for applying the protective paint.

The Whiton Machine Co., New London, Conn., manufacturers of the Whiton revolving centering machine, are building a foundry 66 x 127 feet, and an adition to their machine shop 35 x 80 and 50 x 54 feet, three stories high.

In the advertisement of the Wm. E. Gang Co.'s improved radial drill in our September number, page 33, an error appears in the first paragraph. Instead of reading "The arm is of *one* section, well ribbed," it should have been "The arm is of *box* section, well ribbed."

The Cling-Surface Mfg. Co., Buffalo, N. Y., send us a copy of a letter received by them from the Dominion Motor and Machine Co., of Toronto, expressing their satisfaction with Cling-Surface, and stating that by its use they save from 5 to 10 per cent on their horse power.

The Loop-Lock Machine Co., of Boston, have acquired the plant, business and good-will of the American Watch Tool Co., Waltham, Mass. The manufacture of precision machinery, compound punches and dies, watchmakers' lathes and attachments will be continued by the Loop-Lock company, to whom all checks are now payable. The president of the new corporation is H. N. Fisher; the treasurer, S. A. Barton.

The Hampden Corundum Wheel Co., Springfield, Mass., whose works were destroyed by fire some months ago, now have their new plant in full operation. The buildings are all of brick, of modern construction, and both the office and works are thoroughly equipped throughout. The main building is 80 x 136, four stories and connected with it by bridges are the office and storeroom 50 x 120. The kilns are of the latest design, of two and one-half times the former capacity, and they effect a great saving in fuel over the old ones.

The Bradley Co., Syracuse, N. Y., manufacturers of upright hammers, have commenced work on a new machine shop 80 x 260, one

story high; a forging room 50 x 100, and a building for office, pattern and drafting room 50 x 80, which they expect to have ready for occupancy next August. The new plant will be located on a three-acre plot of ground which they recently purchased near the West Shore Station and within a stone's throw of the center of the city of Syracuse.

THE AMERICAN SCHOOL OF CORRESPONDENCE, Boston, Mass., have made arrangements with the Armour Institute of Technology whereby the Institute will co-operate with the American School in the instruction of their students by correspondence. The American School is located on the Armour Institute premises at Chicago, but remains a separate institution under its own management. The students' examination credits will be counted toward a degree at the Armour Institute, and they will be admitted to classes at the Institute in the subjects in which they have passed by correspondence.

THE STANDARD ROLLER BEARING CO., Philadelphia, Pa., are building shops on a three-acre plot of ground at the corner of 48th Street and Girard Avenue, facing the P. R. R. One building will be 200 feet long and 150 wide, and the other principal building will be 200 feet long and 60 feet wide, three stories high. These buildings, with those already on the property, will give a total floor space of about 80,000 square feet. The new shops will be equipped with the latest and best machinery for the manufacture of ball and roller bearings, and will include a department for the manufacture of balls. The superintendent of the ball department will be Robert H. Grant, formerly of the Grant Ball Company. The plant will be ready for operation about November 1st, when it is expected that about 300 men will be employed.

THE FITCHBURG MACHINE WORKS, Fitchburg, Mass., under the management of Mr. F. B. Manville, formerly of Waterbury, Conn., have taken on a new lease of prosperity and are now running twenty-three hours a day, with orders for several months ahead. The plant is being thoroughly overhauled, new tools are being put in where needed and the works brought up to date. A Gisholt lathe has been ordered, and a universal grinding machine and a large vertical milling machine of the planer type will soon be bought. Manning, Maxwell & Moore handle the entire output of traveling head shapers, horizontal boring mills and countersinking drills for boilermakers. J. J. McCabe and the Marshall & Huschart Machinery Co., in combination, sell the entire output of their 14-inch to 60-inch lathes. The manufacture of planers has been discontinued.

MISCELLANEOUS.

Advertisements in this column, 25 cents a line, ten words to a line.

The money should be sent with the order.

AGENCY WANTED for high-class engineers' and woodworkers' tools by thorough engineer with own workshop. Power in showroom. Good connections in England. Established in 1876. W. ROBERTSON, Engineer, Eccles, near Manchester, England.

FOR SALE CHEAP.—Two colored charts, A. and B., for scientific tool tempering, explaining tempering in oil, water and tallow, and telling what each tool will stand. Also, 40 new steel working methods for forging and welding different kinds of steel and five of the best steel welding compound receipts on earth. All new and up-to-date. Send for free samples. The two charts and the 40 new methods for $1.00. Address W. M. TOY, Sidney, O.

FOR SALE.—The first six volumes of MACHINERY. Address G. H. G., care of MACHINERY, 15 Murray Street, New York City.

INVENTOR'S MODELS built and perfected, special machinery designed and built, small parts duplicated. Let us quote prices. F. J. STOKES MACHINE CO., Philadelphia, Pa.; New York representative, FRANK P. WISNER, 46 Cliff St.

MANHATTAN TYPEWRITER FOR SALE—Same size and keyboard as Remington No. 2. Used about two years and in good running order. Price $25. Address INDUSTRIAL PRESS, 15 Murray St., New York.

MECHANICAL ENGINEER, 24 years old, energetic, ambitious, technical graduate, 5 years' experience in shop and drawing room, good constructor and draftsman, desires to make a change December 1 or earlier, and is looking for a good position with chances of advancement with concern in or near New York City. Address GRADUATE, care of MACHINERY, 9-15 Murray St., New York.

SPECIAL TOOLS, models, fine light machinery and foundry work wanted. MURRAY MFG. CO., Richmond Valley, Staten Island, N. Y.

SWEDISH-AMERICAN FOREMAN.—Wanted, several first-class Swedish-speaking machine shop foremen, well up to date, in modern shop practice. Apply in Swedish, stating age, experience and wages expected. Address AKTIEBOLAGET SEPARATOR, Stockholm, Sweden.

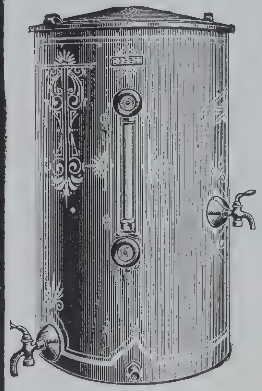
TO EXPORTERS OF MACHINERY TO RUSSIA.—The Toula Manufacturing Company, Limited, at Toula, in Central Russia, beg to inform American makers and engineers, who might be desirous of having their products manufactured in Russia itself, that they are prepared to undertake any orders that might be intrusted to them. The Toula factories include a cast-iron and steel foundry and newly fitted-up works with all the most modern appliances, including a large quantity of American machine tools, for constructing machinery of every description. The arrangement enables the company to undertake, under the most favorable conditions, the manufacture of all descriptions of machinery, machine tools, agricultural machines and specialties of all kinds. Address communications to: LES ATELIERS DE TOULA, SOCIETE ANONYME, 299 Chaussée d'Anvers, Brussels, Belgium.

WANTED.—Mechanical draftsman with experience in machine tools, such as punching and shearing machinery, bending rolls and steam hammers. Give experience, reference and salary expected. Address MECHANICAL, care of MACHINERY, 9-15 Murray St., New York.

WANTED, in the publication department of a large machinery manufacturing concern in New England, a young man to prepare all literary matter, edit a monthly engineering magazine, supervise all illustrative work and conduct the advertising. Much be technically trained, a master of good English, and experienced in the work above outlined. A permanent, growing position for the right man. State experience, submit samples of work and specify salary expected. Address PERMANENT, care of MACHINERY, 9-15 Murray St., New York.

WANTED.—Foreman polisher by a medium heavy machine tool concern employing 250 men; located 150 miles from Chicago. Splendid shop in city of 25,000 people. A man who is a good hard worker; who can take charge and can also keep busy himself. Only a married man of ambition and who is looking for a permanent position need apply. Address Box No. 54, care of MACHINERY, 9-15 Murray St., New York.

"Does All That Was Claimed For It."



We could'nt have a better recommendation for the Warden Filter than that contained in the reason given by a customer for sending a duplicate order—that the filter did all that we claimed for it. That's the way we sell them—on their own merit. If they don't do just what we say we stand ready to take them back, and no expense to you. If you are interested in oil saving let us send one on trial.

HAMILTON, OHIO.

The Burt Mfg. Co., Akron, Ohio.

Gentlemen:—I am instructed by the President of this Company who is also President of the Hamilton Electric Light Company, to order for their use a duplicate of the oil filter which you furnished for this Company a short time ago. Your filter does all that you claim for it, and hence, the duplicate order.

Kindly make this shipment as promptly as possible, and oblige,

Very truly yours,
THE HAMILTON OTTO COKE CO.
Per GEO. WHIPALL, Supt.

Shelby & Co., London, E. C, Eng., Sole Agents for Great Britain.

The Burt Mfg. Co.

"Must Have Another"

The Burt Exhaust Head has nearly as many friends as the filter, because in its own field it is just as good as the filter is, and where we sell one, it is usually a case of "must have another" if the customer has any possible use for another. The Burt is a modern exhaust head built to meet the requirements of a modern steam plant, and never fails to give satisfaction. Sold on the same terms as our filter—if it don't do the work, send it back.

MARINETTE, WIS.

The Burt Mfg. Co., Akron. Ohio.

Gentlemen:—Please send us one 10 in. Burt Exhaust Head, same as shipped us in December. We assume the price will be the same. We are charmed with the efficiency of the one put in by us and must have another.

Please ship at once if possible.

Yours very truly,
N. LUDINGTON CO.

MACHINERY.

November, 1902.

SHOP CONSTRUCTION.—2.

THE GUIDING CONDITIONS—GENERAL FEATURES OF THE BUILDINGS.

OSCAR E. PERRIGO.

Having arranged and planned the buildings for carrying on the work for which our plant is designed, making each of a size large enough for the equipment to be installed and the number of men required to operate it; and having placed the several buildings in convenient adjacency for economically passing the work through them, from the raw material to the finished product, let us now consider the construction of the buildings planned.

Manufacturing buildings are erected for utility rather than ornament, and the latter characteristic is always made secondary to the practical question of best fitting them for the special work to be done in them. To this end one must be guided by several well-known conditions. First, the buildings should be strong enough to bear the weight and withstand the strain of the machinery operated in them, and the materials used in manufacturing, with which they are loaded. This load frequently varies within a wide range as to weight at different times, and is also constantly being shifted from one point to another, so that provision must be made for this condition. Second, the building must be of such construction as to be amply rigid for all purposes, and to a certain extent be elastic enough to remain uninjured under the shocks that it is liable to undergo. Third, there should be ample opportunity for ventilation, yet not unnecessary height, as the expense of heating would be needlessly increased.

Fourth, ample provision should be made for light, for which purpose the windows should be placed at short intervals and extend nearly to the ceiling. At the same time an extravagant use of glass will also increase the cost of heating. Fifth, the floors should be of such strength and material as to bear whatever weight is to be put upon them, either regularly or temporarily. Sixth, Numerous exits should be provided for the use of employees in case of fire. This becomes more imperative as the number of employees increases in proportion to the area of floor surface; as for instance, in factories, particularly where boys and females are employed.

Seventh, the roofs should be so constructed as to bear the weight of snow in winter, as well as the pressure of high winds; and they should be so designed as to give a minimum amount of after-expense from deterioration and from leaking, the latter cause usually costing much more from damage to stock and machinery than for repairs to the roof itself.

For manufacturing buildings in general there is probably no construction more satisfactory in every respect and that answers all the usual conditions better than brick walls and an iron roof. The walls should be of a thickness proper to the size and purposes of the building, and, except when the building is for light work, should be strengthened by buttresses placed between the windows or groups of windows.

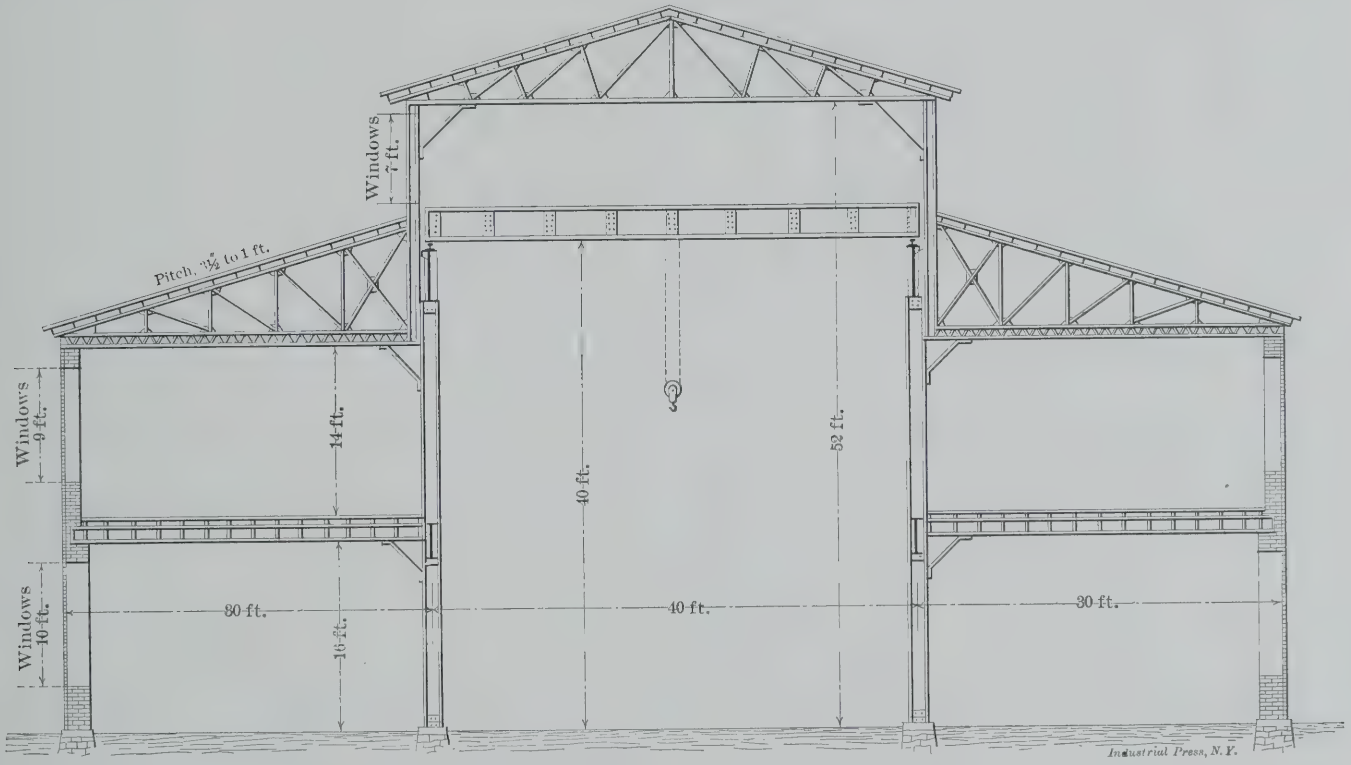

Fig. 1. Cross Section through Machine Shop of Model Plant.

The roof* proper should be supported by trusses at each division or bay, and connected by purlins, all securely braced; by which construction lightness, combined with great strength and ample elasticity is secured. For a covering, wood may be used and covered with roofing tin and always protected by a good coating of mineral paint. The covering may be of corrugated iron, although this has the very serious objection of moisture condensing on its underside and dripping into the interior of the building. This may be wholly prevented by laying on a couple of thicknesses of tar paper, or other paper impervious to water, and as a protection against fire from the underside of the tar paper, first laying two thicknesses of asbestos paper. These four layers of paper are supported by galvanized wire netting, tightly stretched over the purlin supports. This is probably the best form of roof

---

* The roof designs shown are substantially those adopted by the Berlin Construction Co., New Britain, Conn.—EDITOR.

Industrial Press, N.Y.

Fig. 3. Section through Cupola Platform at Right Angles to Fig. 2.

covering yet devised for the roofs of manufacturing buildings, and with brick walls, truss roof and covering as described the building is practically fireproof.

Referring to Fig. 1, the machine shop is seen to be constructed with a central portion 40 feet wide and covered by a traveling crane, giving a clear height of 40 feet beneath it. This crane is supported by wide plate girders resting on the main columns, and runs the entire length of the machine shop. It may be operated by belting and gearing, but preferably by electricity, as the necessary power is much more readily transmitted to any point in the length of the building by conducting wires and a suitable trolley than by means of shafts and belts with their attendant expense and annoyance.

On each side of the central portion of the building are wings 30 feet wide, extending the whole length of the structure, and built in two floors, the upper one, or gallery, being used for light machinery. It extends across the front end, both as a means of conveniently connecting the two galleries and of affording a platform for transferring to and from the ground floor by the traveling crane.

The lower member of the roof truss is of latticed form, to give the required strength for supporting the lines of shafting. The floors of the galleries are supported by girders, upon which floor joists are supported, and to the under side of which the line-shaft hangers are attached.

The side walls are built 20 inches thick for the first story, or 16 feet, and 16 inches thick for the remainder of the height, and are strengthened by buttresses 8 inches projection and 24 inches wide. Each bay, or division, is 18 feet 3 inches centers, and the side wall is pierced for two windows on each floor, each window being 4 feet wide; the lower ones 10 feet, and the upper ones 9 feet high. Above the wing roofs is another series of windows 5 feet high, extending the entire length of the building and separated one from the other only by about 12 inches, thus giving ample light to the central portion of the building. Every alternate sash is pivoted so as to be opened for ventilation.

The roof is constructed as has already been described, with an outward covering of corrugated iron, and has a pitch of 3½ inches to the foot, as have the roofs of all the buildings of the plant. The form of truss is the usual one, as shown in the engravings.

The foundry is built on a plan similar to that of the machine shop, with a central part 35 feet wide and side wings 25 feet wide each. On the cupola side the wing proper is extended 30 feet further, to furnish accommodations for the cupola platform, chipping, core and flask rooms. See Figs. 2 and 3.

The central part of the foundry is covered by a traveling crane supported by plate girders resting on the main columns and having a clear space of 30 feet beneath it, while the side wings are 20 feet in the clear. The operations of the foundry do not require this height, but it is very desirable to have ample space for the steam and gases, incident to "shaking out" the flasks after pouring off. To further facilitate their exit the upper windows 5 feet in height, opening over the roofs of the side wings are all made with pivoted sashes, so as to be readily opened when necessary.

The bays or divisions between columns are 18 feet 6 inches centers. The side walls are 20 inches thick, strengthened by buttresses of 4 inches projection and 18 inches wide, and each bay is provided with two windows 4 feet wide and 12 feet high, affording ample light to the side wings and, by the aid of the ventilator windows, completely lighting the whole interior. The lower member of the roof trusses for the side wings is of latticed form to afford sufficient strength for supporting the cranes, and for trolley hoists at any point needed.

The cupola platform construction is shown in cross-section in Fig. 2 and at right angles with this in Fig. 3. A floor supported by suitable timbers forms the cupola platform proper. This may be constructed entirely of iron, if desired, in order to lessen the liability to damage by fire. The platform should be covered with sheet iron, at least in the immediate vicinity of the cupolas, and should be placed at a proper height to suit the cupolas used. It may be reached by way of an elevator carrying one of the yard tram cars, as will be described hereafter in another article.

The forge shop is built much heavier in proportion to its size than the other buildings, on account of the strains and shocks caused by heavy hammers and drop presses. It is 50 feet wide, 80 feet long and 18 feet high in the clear, and no columns or other obstructions interfere with the free working. The roof girders are strongly built and thoroughly braced, and the lower member made in latticed form for supporting the usual overhead work of the shop. See Fig. 7.

The walls are 20 inches thick and 18 feet high, strengthened by buttresses 8 inches thick for a height of 8 feet and 4 inches the remainder by 20 inches wide. The spaces or bays are 13 feet centers and the wall is pierced for one window to each space. The windows are 4 feet wide and 12 feet high, and located, five on each side, three in the front and one in the rear, making fourteen in all.

The roof ventilator is 12 feet wide and extends the entire length of the building, with openings 4½ feet high, as in Fig. 4.

Along the outer wall are arranged chimneys for six forges. If the system of downward draft is employed these would not be needed, the smoke and gases from all being carried to one chimney conveniently located for that purpose. In consequence of the arrangement necessary for these chimneys, when such construction must be used, the buttresses on this side are placed opposite the chimneys and the windows between. This necessitates the use of a steel I-beam in the wall over the windows for supporting the roof trusses. By reducing the number of chimneys to five, this may be avoided.

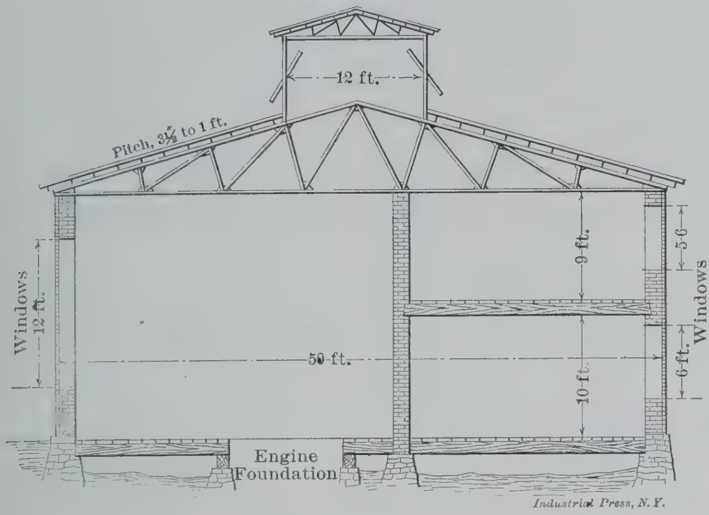

Fig. 4. Cross Section through Power House.

The power house is of construction similar to the other buildings. The walls are 16 inches thick and 20 feet high, with buttresses 4 inches thick and 20 inches wide. 12-inch walls divide the boiler room, engine room, water closets and wash rooms from one another, the last two being built in two floors—the lower one 10 feet and the upper 9 feet high, in the clear. There is a ventilator 12 feet wide, running the whole length of the building, with pivoted windows on each side, 5 feet high, shown in Fig. 4.

When the power required would render it necessary the entire building might be devoted to the boiler and engine rooms, and the wash rooms and water closets be provided for in a side addition. They are placed as shown in order to secure a central location and immediate connection with the machine shop without encroaching on its space. Plenty of light is provided for the wash rooms and water closets by rows of ten windows, 3 feet wide, on each floor, the upper ones being 5½ feet and the lower ones 6 feet high.

The engine room and also the boiler room are lighted by four windows, 4 feet wide and 12 feet high, in the outer wall; while two extra windows are placed in the end of the boiler room for the purpose of giving extra light in the rear of the boilers. In the end of the boiler room is a double door 12 feet wide, one-half of which only need be opened to admit the coal car. Near this door are the track scales for weighing the coal as it is brought in. The tram track is continued the length of the boiler room, in front of the boilers and through the door into the engine room, as a convenient means of bringing in or taking out any small machines such as dynamos or similar apparatus.

The engine room connects with the machine shop by an opening 14 feet wide and 16 feet high, through which engines or large pieces of machinery may be moved, and through which main belts may be run. This space may be closed up, after the power plant is installed, either by doors or by a wooden partition containing suitable doors.

The storehouse for finished machinery, and the carpenter shop adjoining, Fig. 5, are of the same general construction as the other buildings, so far as the walls and roofs are concerned. Both have 16-inch walls, 14 feet high for the carpenter shop and 18 feet for the storehouse, and strengthened by buttresses of 4 inches' projection by 16 inches' width.

The storehouse floor is 3 feet above the level of the machine shop floor. Near the back wall (next to the railway track) the floor is cut out and a specially constructed tram car traverses the space, the top being on a level with the floor. This car track crosses the machine shop floor, and passes over the scales located in it, directly under the traveling crane. By this arrangement machines may be transferred from any point in the shop to this car, standing on the scales, and may be weighed, run into the storehouse and stored away or conveniently run into a car on the railway track, the top of the cars being also on a level with the storehouse floor.

In case the machinery built is of sufficient weight to make such an arrangement desirable, the lower member of the roof trusses should be of latticed form, or, if needed, several of them may be plate girders, in which may run trolley hoists for lifting a machine from the tram car and running it back into the rear of the storehouse or out upon a railway car. The girders may project out over the railway tracks sufficiently to permit of easy handling in loading cars.

Two sliding doors, one of 8 feet and the other of 12 feet in width and both 12 feet high, are provided for shipping convenience. The storehouse is lighted by eleven windows, each 4 feet wide and 10 feet high. Additional windows might be located in the rear wall, over the storage sheds and in the end toward the forge shop if the machinery manufactured was of such small size and such variety as to make a division of the storehouse necessary to properly store and care for it.

The carpenter shop is provided with a sliding door, 6 feet wide in the side, where a branch of the tram tracks enters, and one in each end 10 feet wide. The shop is lighted by thirteen windows, 3½ feet wide and 6 feet high. The roof trusses are placed 15 feet from center to center, the lower members being latticed to afford support for the shafting driving the wood-working machinery. See Fig. 5.

The storage sheds for coal, sand, coke, etc., as well as those for cast iron, steel chips and similar materials, may be built of wood, but a brick construction will be found to be much more satisfactory.

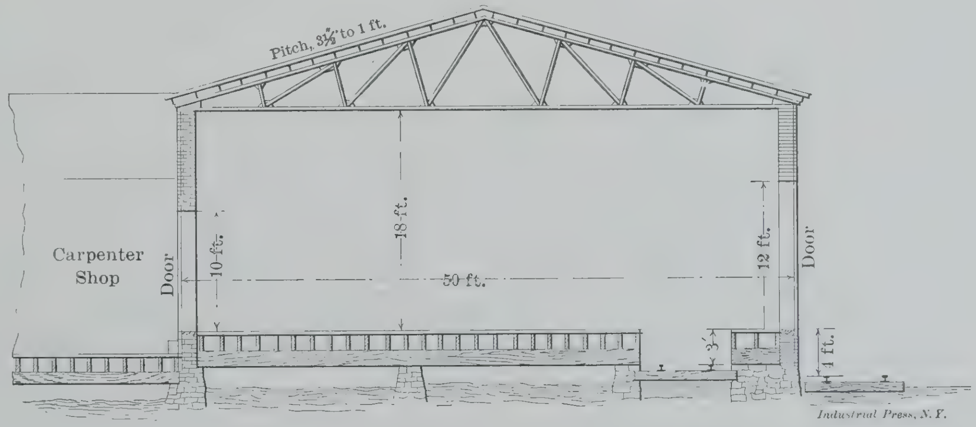

Fig. 5. Cross Section through Store House, Carpenter Shop, Tracks, etc.

The walls should be 12 inches thick and 8 feet high on the side next to the yard. The roof may be what is termed a "gravel roof;" that is, consisting of wooden rafters covered with one-inch rough boards, over which is placed tarred paper, then a coating of well-boiled gas tar, and upon this a layer of gravel stones of from ⅛ inch to ⅜ inch diameter and perfectly free from dirt. This roof should have an inclination of one inch to one foot, although slightly less is often used.

For the coal and sand sheds the openings in the walls may be 3 feet high, beginning just under the roof, and 6 feet wide, on the side next to the railway track. These should be closed by hinged doors of two thicknesses of ⅞-inch boards, the grain of each thickness crossing the other at an angle of 45 degrees.

On the side of these sheds, next to the yard, sliding doors, hung from the top and usually not over 10 feet wide, are most practical. To be substantial they should be made as described above, of two thicknesses of ⅞-inch boards.

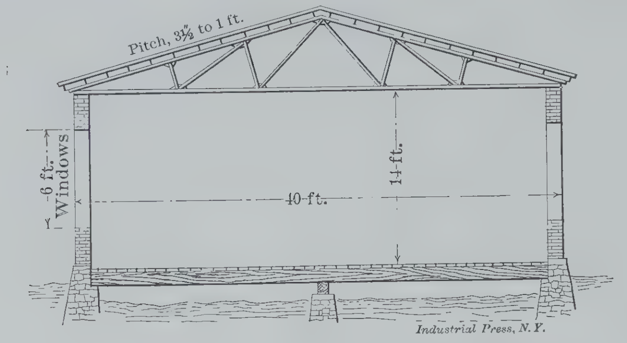

Fig. 6. Cross Section through Carpenter Shop.

Inside of these and about a foot from them planks 12 inches wide and from 2 to 3 inches thick should be set on edge, to sustain the weight of material behind them. These should be fitted in grooves at the ends so as to be easily removable, as occasion may require, and they may have a central support of a scantling set in a hole in the floor and properly supported at the top.

The floors of these sheds may be of 2-inch planks, supported by scantling 4 x 4 inches, laid 18 inches from center to center. But much better than this, and cheaper in course of time, will be brick paving, laid as will be described in a future article on floors.

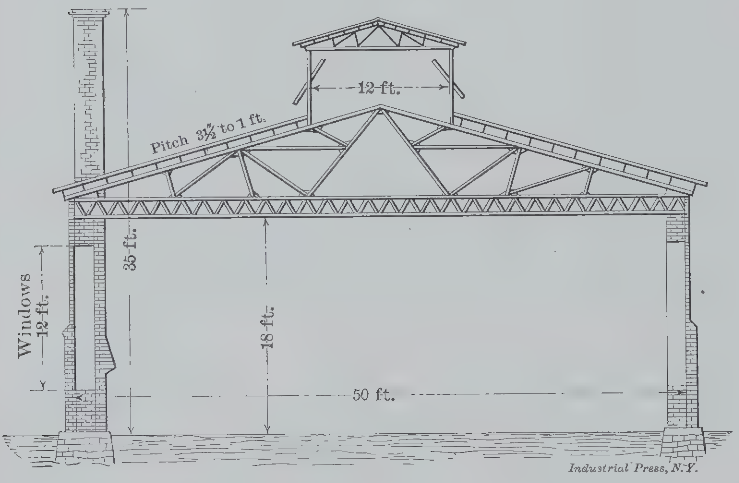

Fig. 7. Cross Section through Forge Shop.

The construction of the shed in the rear of the forge shop should be as described above, except that there will be wood floors for the wash room and water closets.

The questions of foundations and floors have been here omitted and will form the subject of another article of this series, wherein will be considered various forms of floors, both of wood and other materials, and wherein some of the reasons for the failure of many of them now in use will be pointed out.

* * *

The accurate determination of high temperatures involves the use of expensive and delicate instruments, known as pyrometers. For determination of muffle temperatures the following observations made by Violle will give very approximate results: Fireclay just glowing in the dark is at a temperature of about 525 deg. C.; dark red, 700 deg.; cherry red, 900 deg.; bright cherry, 1,000 deg.; orange, 1,150 deg.; white, 1,300 deg. To convert degrees centigrade into degrees Fahrenheit multiply by nine, divide by five and add thirty-two: Thus, 1,000 deg. C. equals 1,832 deg. F.—*Mining Reporter.*

STEEL AND ITS TREATMENT.—3.

ANNEALING.

E. R. Markham.

According to the generally accepted definition of the term the object of annealing steel is to soften it, so that it may be machined at the minimum cost of labor and tools. Steel is annealed by heating red hot, and cooling *slowly*. The greater the amount of time consumed in the cooling operation the softer the steel will be—everything being equal.

The method pursued when annealing steel depends, as a rule, on the facilities which the shop possesses for doing the work. A piece of steel may be softened somewhat by heating red hot and laying to one side to cool in the air. It must not, however, be placed on any substance that will chill it, nor where any current of air can strike it, or it will cool too quickly to become softened; in fact, it will very likely be harder than if worked without attempting to anneal it.

The young hardener should understand that a piece of steel is hardened by heating red hot and cooling *quickly;* the more rapid the process of cooling the harder the steel will be. With annealing the process is just the opposite; the steel is heated red hot and allowed to cool *slowly*, and the slower the cooling operation the softer the steel will be. Now it is evident that if a piece of steel be heated to a red and laid on an anvil or other piece of cold metal, or thrown on the floor, the portion lying on the cold substance will chill, and the process of hardening, instead of annealing, takes place. The same is true if the piece be placed where a current of air can strike it, even if it is warm air; for it will be cooler than the steel, and the heat in the steel will be taken up by the air.

It is the custom in many shops to anneal steel by heating and putting in a box of ashes or lime. Now this may or may not be advisable, according to the condition of the contents of the annealing box. If the room in which the box is kept is damp, the ashes or the lime—especially the lime—will absorb enough moisture to chill a piece of red hot steel, particularly if it be a small or thin piece. When steel is to be annealed by this process heat a piece of iron or scrap steel and bury it in the ashes or lime, leaving it there until the piece to be annealed is properly heated. Then remove and put the piece to be annealed in its place. The ashes or lime being hot and every trace of moisture removed the process of cooling will be slow, and the results satisfactory. A box of lime furnishes an excellent means of annealing steel, if the precaution mentioned is observed.

A very satisfactory method of annealing, which has been used by the writer many times, where there were only one or two pieces to anneal at a time, is as follows: Take an iron box; put two or three inches of ashes in the bottom. On this lay a piece of board a trifle larger than the work. Heat the pieces to the proper degree, lay them on the board, put another piece of board on top of them and fill the box with ashes. The pieces of board will smoulder and keep the steel hot for a long time. The process of cooling will be very slow.

There is a method of annealing practised in some shops which, while it has many advocates, can be recommended by the writer only as a means of annealing a piece of steel that is wanted for immediate use. It is known as cold water annealing. The steel is heated to a red and allowed to cool in the air where no current of air can strike it. It is held in a dark place, and when every trace of red has disappeared it is plunged into water and left until cold. The steel will be softer if plunged into soapy water or oil. This answers in an emergency, but owing to the liability of the ends cooling faster than the center, and the smaller portions cooling more rapidly than the larger ones, it is evident that the steel when chilled must be of an uneven temperature throughout.

The method used in many shops of heating a piece of steel in a furnace using gas, oil or gasolene as fuel, to the proper annealing heat, then shutting off the supply and allowing the work to cool down with the furnace, is attended with varying results. While many mechanics advocate this method and claim excellent results, and while it has been used by the writer to his satisfaction, yet quite a number of cases have come to his notice of late where persons had annealed in this way with results that were far from satisfactory. An investigation showed that in heating the steel the furnace had been forced in order to heat the piece quickly. As the steel was heated by radiation it was necessary that the walls of the furnace or the muffler should be hotter than the piece of steel being heated. When the steel had apparently reached the proper heat the supply of fuel was shut off; but the inside walls of the furnace being much hotter than the work, imparted heat to the steel after the fire was put out, with the result that the steel was overheated and injured, and in some cases entirely unfitted for use.

A steel maker of national reputation says that "many thousands of dollars' worth of steel are ruined annually in this way, and it is in every way about the worst method of annealing that was ever devised." Consequently the writer feels it his duty to condemn in no uncertain words a method he had successfully practised under favorable circumstances, because mechanics are not all so favorably circumstanced and do not use sufficient care in heating steel. Very especial care is necessary when it is nearly to the proper heat, but most men insist on forcing it; and this is detrimental to the edges and corners, which will heat faster than the center, and to the whole piece. For if the furnace is hotter than the steel, then when the fire is extinguished the furnace is closed and there is no means of looking into the oven to determine the amount of heat the steel is receiving.

A method of annealing that gives universal satisfaction—when properly used—and that is employed in many shops, consists in packing the steel in iron boxes, filling the spaces between the pieces of steel with powdered charcoal. In this method it is necessary to place one or two inches of charcoal in the bottom of the box before putting in any steel, and the pieces of steel should not come within one-half inch of each other in the box, or within one inch of the box at any point. When the box is nearly full, fill the balance of the space with charcoal, put on the cover and seal with fire-clay. The steel should be kept from coming in contact with the boxes, because iron—especially cast iron—has a great affinity for carbon and will, when the steel and iron are both red hot, extract this carbon from the steel, leaving the steel somewhat decarbonized at the point of contact.

To determine when the contents of the box are heated to the proper degree several ¼-inch holes should be drilled through the center of the cover and a 3-16-inch wire run down through each of these to the bottom of the box. When the work has been in the fire (according to the judgment of the operator) long enough to heat through, draw one of them by means of a pair of long-handled tongs or with a pair of ordinary length, slipping a piece of gas pipe on each leg to give the required length. If the wire shows hot the entire length the operator may rest assured that the steel is of the same temperature, because the wire was run down between the pieces in the center of the box. If the wire does not show red hot he must wait a while then draw another. When a wire is drawn that shows the proper degree of heat the box should be left long enough to insure the steel being heated uniformly throughout; then the fire may be extinguished. If the walls of the furnace are much hotter than the boxes the door may be left open until they are somewhat cooled. If the furnace shows a disposition to heat the boxes too much with the door open the box may be removed for a few minutes until the furnace is somewhat cooled. Then the box may be returned to the furnace, the door closed and the work allowed to cool slowly.

A way to insure excellent results is to plan to empty one furnace of work to be hardened some little time before the work being annealed is sufficiently heated. Keep the first oven closed to retain the heat as much as possible; but it will pass the stage where it is liable to overheat the articles and will commence to cool down somewhat. When the work has been subjected to the heat for a sufficient length of time the boxes may be removed from the oven they were heated in and placed in the first oven. All danger of overheating from radiation is then done away with. This cannot, of course, be practised where there is but *one* furnace.

While it is generally understood that the object of annealing steel is to make it soft enough to work to advantage, yet from the hardener's standpoint annealing has another and more important office than simply to make steel workable. A piece of steel as it comes from the steel mill or forge shop is very apt to show a difference of grain in its various parts, due to uneven heating and unequal closing of the pores from the process of rolling or hammering. Consequently there exist internal strains in the piece. To overcome the effects of these internal strains, which must manifest themselves when the steel is hardened, the work should be blocked out somewhere near the shape and annealed. If the piece is a milling machine cutter, punch press die or similar tool, having one or more holes through it, the holes should be made, but somewhat smaller than finish size, before annealing to remove strains. If it is a milling machine cutter of irregular contour it should be blocked out as represented in Fig. 1. The finished cutter is shown in Fig. 2. The benefit gained in pursuing this course is that, so far as shape is concerned, it is heated for annealing under—as nearly as possible—the same conditions as when heated for hardening. Consequently the tendency to change shape will be overcome in the annealing.

Long pieces of steel to be hardened will give much better results if roughed out. Remove all scale or outside surface by turning or planing, then thoroughly anneal. Should the piece spring when annealing do not straighten it cold, as it is almost sure to spring when hardened. If it is not sufficiently large to turn out without straightening, it should be heated red hot and then straightened.

The hardener is blamed many times because a costly reamer, broach or similar tool is crooked in hardening when in reality the blame rests with the man who turned it or planed it to size. After it is annealed he tests it in the lathe, and, finding it running out somewhat, he takes it to an iron block or an anvil and commences to hammer it. He finally gets it to running very nicely and feels quite proud of his job. He doesn't like to see a man turn or plane a piece of steel which runs out even if it will finish out, when a few strokes of a hammer will "fix it all right." But by means of the hammering he has set up a system of internal strain much more serious than the one removed by the process of annealing. He now commences to machine the piece; every time he goes below the effects of a hammer mark the piece goes in some direction at this point, and it is necessary to repeat the operation of "hammer persuasion" again, with the result that by the time the article is ready to harden it is in no condition to be hardened. It is either crooked in all directions, or it is only waiting for the fire to relieve it and allow it to go where it will.

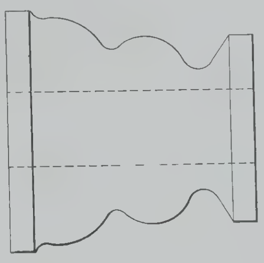

Fig. 1.

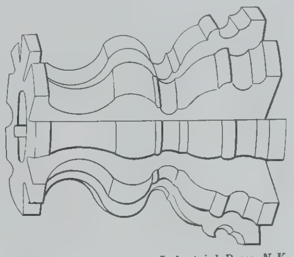

Industrial Press, N.Y.

Fig. 2.

When the hardener gets through with it, it looks like a "cow's horn." And, of course, the hardener is to blame. If he happens to be a man without machine shop experience or does not understand the nature and peculiarities of steel he does not know where to place the blame—and perhaps it would do no good if he did. But he, of course, is not going to shoulder it; so the fault is laid to the steel. Consequently, if the trouble continues, another make of steel is bought, because the men in charge do not know or cannot spend the time to locate the trouble. "It cannot be the fault with the men in the shop," they say. "It *must* be the steel." Or, again, they decide it must be the hardener, because some other concern with whom they are acquainted use this same steel and have no trouble. So the hardener, poor fellow, must bear the brunt.

A successful business man is quoted as saying: "If I were to drive a mule team I would study the nature of mules." To be a successful hardener a man must study the nature of steel; he must know what steel is liable to do under certain conditions, and how to avoid undesirable results, no matter whether it relates to his department or some other department. He should know that it is possible for the toolmaker to so treat steel that results anything but satisfactory *must* follow when it is hardened; that he may make the steel unfit for use by overheating when annealing or by not heating uniformly throughout when annealing. If a satisfactory steel is furnished the hardener should never blame the steel for bad results caused by his ignorance or carelessness. The next time he may be furnished with an undesirable steel, and after a while those over him in authority will tire of complaints about a steel that another concern is satisfied with.

In some shops they pack the article in a box with cast iron dust or chips. Now this method works nicely when annealing forgings or other pieces of *machinery steel* which were hard and showed glassy spots and could not be softened by the ordinary processes of annealing. The cast iron seems to have an affinity for the impurities liable to be present, and the result is very soft, easily-worked pieces. But if this method is applied to *tool steel* the carbon, as we stated before, is extracted to an extent that is highly injurious to the steel. To be sure, tool steel can be annealed very soft if packed as described, but the results are anything but desirable.

Another way to anneal machinery steel is to pack the pieces in the annealing box in expended bone—that is, bone that has been previously used in casehardening. This is also an excellent way of packing cast iron that requires annealing, such as small castings for typewriter parts, etc., which must be very soft in order to machine nicely. But tool steel should never be packed in any form of bone, as bone contains phosphorus, which is the most injurious of any of the impurities tool steel may contain. The steel maker uses every effort possible to reduce the percentage of this impurity to the lowest point; for, while it is a hardening agent, its presence makes tool steel brittle. And it is folly to pay a high price for steel which the manufacturer has spent much care in ridding of undesirable impurities and then to use a method whereby the steel will be charged with these very impurities.

In conclusion, it may not be amiss to emphasize a few facts that have already been mentioned. Do not overheat steel when annealing, or it will be *permanently* injured. Do not subject it to heat for a longer period of time after it becomes uniformly heated throughout than is necessary to accomplish the desired result. For while it is essential, when annealing, to heat to as high a temperature as for hardening and for a period of time that insures its being of the same temperature in the middle of the piece as it is at the surface, yet care must be taken not to overdo it. Steel kept at a red heat for a long time, even if not overheated, will betray the fact when the temper is drawn, if not before. It may to all appearances harden all right, but when the temper is drawn the hardness apparently "runs out." For instance, when the piece is heated to a straw color it can be filed very readily; whereas a piece from the same bar not annealed, or that has been annealed properly, then hardened and drawn to the same temper color, would show all right; that is, a file would just catch it.

Uniform heating when heating for annealing is as desirable as when heating for hardening. If in a large block the corners and edges are hotter than the main part violent strains are set up at these points. It is therefore readily apparent that uniform heating is one of the secrets of successful handling of tool steel.

Lastly, remember that any process of annealing which takes from the steel any of its hardening properties is not fit to use, no matter how soft it may make the steel. It is better to work a piece of steel which is hard than to unfit it for doing its maximum amount of duty when finished. But it is possible to anneal most steels so that they will be workable and yet harden in a satisfactory manner; in fact, in a much more satisfactory manner than if not annealed.

The writer wishes it understood that these articles deal entirely with *carbon steels*, and not with the so-called self-hardening steels. These are very valuable, but are not under consideration at this time.

NEW WORKS OF THE B. F. STURTEVANT CO.

GENERAL FEATURES OF THE PLANT AND THE CONSIDERATIONS WHICH LED TO THEIR ADOPTION.

The new works of the B. F. Sturtevant Co., now nearing completion at Hyde Park, Mass., present an excellent opportunity to study the factors that control in the location and design of a modern manufacturing plant. The present plant at Jamaica Plain, Mass., is too small for the business and has no room for growth. A fire, which nearly destroyed the whole plant a year ago, forced an immediate selection and a site of 20 acres was procured at Hyde Park, Mass., six miles from the present location, the home of several prominent machine works. In deciding upon the new location, the claims of the West were weighed against those of the East, but an abiding faith in the future prosperity of New England and the fact that a large number of skilled mechanics are available in the vicinity of Boston, won out in the end, in spite of the somewhat higher rates for raw material in the East. The lot selected has a frontage of 1,300 feet on the N. Y., N. H. & H. R. R., and one side is bounded by a large brook, which will supply water, and there is ample space for dumping waste material.

In laying plans for the buildings, the head of each department was consulted, his recommendations reduced to writing, and frequent conferences were held. With these data at hand the plans were started with the idea of providing a total floor space slightly more than double that of the present plant. The lay of the land and its available area being somewhat against a group of one story buildings, and a simple calculation showing that the actual cost of the power expended in a single year for lifting the entire product of the works through a distance of 20 feet figured only a very small sum, determined the company upon the erection of multi-storied buildings. The character of their products readily lent itself to such a design, and it was believed that the expense in going from floor to floor would be more than offset by a reduction in the horizontal distances necessary to be traversed.

The arrangement of the buildings was determined by the provision to be made for growth. One arrangement of a series of parallel buildings permitted increase only by multiplication of buildings, but provided an excellent opportunity for the carrying of switch tracks across both ends of each building. The other arrangement provided for a group of buildings parallel to the railroad tracks, with accommodation for switch tracks between buildings, and for their entrance at the ends of the building, with an opportunity for growth by extension in length, and this was the plan adopted.

For the construction of the buildings the latest all-steel and concrete type with large window areas did not appear to meet the requirements of the group. All steel buildings, brick walls and concrete fire-proof floors presented disadvantages in the way of discomfort to workmen, inconvenience in attaching machines on hangers, and excessive expense which did not appear to be offset by advantages to be secured in the way of absolutely fire-proof construction. The type finally selected is composite in its character, consisting of steel interior columns and main steel girders, with heavy brick walls, wood timbered floor and plank roofs. In the case of the one-story foundry, the roof is supported by steel trusses; in the other buildings open timbering with wooden columns in the upper floor is employed. The main floor in the machine shop is of tar concrete with spruce and maple flooring. The upper floors are carried upon wooden beams spanning the spaces between the steel girders, which follow a unit system of 20 feet on centers through the building. All roofs are of 3-inch plank with tar and gravel top.

The question of power was early decided to the extent that the entire plant would be electrically driven from a central power house; that the engines would run condensing; that the exhaust steam derived from engines under test, which is considerable, would be utilized for heating, with supplementary amount of live steam admitted at reduced pressure as might be required. The power house was placed sufficiently far from the ends of the buildings to permit extension of each, and near to the water supply.

The pattern building provides at one end a two-story portion 80 feet square for carpenters and flask makers on the first floor, and for pattern makers upon the second floor. The balance of the building which is devoted to pattern storage is provided with intermediate floors, making four in all, separated from the other portion of the building by double fire walls and automatic fire-closing doors. The close proximity of this building to the foundry facilitates rapid intercourse.

The foundry, 170x350 feet in dimension, is designed with the idea of distributing iron upon a track system, and is to be equipped with narrow gaged railways bedded in concrete, making runways between the moulding floors. Two craneways run lengthwise of the building through the greater part of its length, and the tracks extend beneath the crosswise traveling cranes in the cleaning room at the end of the building. The brass foundry is located in one corner, a wash room in the adjacent corner, a core room between the two; the latter has ample opportunity for growth towards the center of the foundry, while the foundry itself can be extended to practically double its length. Storage for supplies is provided upon one side adjacent to the railroad switch. From the bins thus provided, the iron and fuel charges will be carried directly to the charging floor.

From the foundry the castings will pass to the rear of either the machine shop or the fan shop. The former is of the familiar gallery type, 500 feet long, with wings 40 feet wide, and central runway of the same width for crane of 20 ton capacity. The lighting will be principally by a series of sawtoothed skylights running crosswise of the roof, with glass facing due north. The crane will serve the entire floor and transport heavy castings from the machine tools to the erecting floor. Here the completed engine or generator may be lifted upon a transfer car passing through the testing building, and there picked up by another 20-ton crane which will drop it upon the testing plate and subsequently carry it forward to the steam railway track which passes through the end of the building and provides space for the loading of two cars at a time. The upper floor of this building, together with portions of the adjoining buildings, is devoted to the electrical department and provided with individual small traveling cranes.

The building devoted to the manufacture of fans, heaters, etc., is 80 feet in width, of the same length as the machine shop (500 feet), is three stories in height, of typical mill construction, with conveniences for handling material and arranged so that shipment can be made from numerous points along one side, while supplies are brought in from the court between it and the machine shop.

The smith shop, 40 feet by 80 feet, serves both buildings with equal facility while the wash house and locker room, measuring 40 feet by 100 feet and three stories in height, is so located as to reduce to a minimum the distance to be traversed by the individual workman. The third floor will be used as a lunch room.

The standard first floor height in the main building is 17 feet, that of the second and third stories is 15 feet. The windows are large and numerous.

The office is to serve as headquarters for the entire business. It will contain the correspondence, designing and drafting offices, the superintendent's quarters, the cost department, the advertising bureau, and a printing office which will be located in the basement. It will be three stories in height with a finished attic to provide additional drafting room space.

The equipment of this plant will be largely "Sturtevant" in its character. Beginning with the power plant, the mechanical draft apparatus, the engines and generators and the exhaust head will be of Sturtevant make. The buildings will be heated by the Sturtevant system; the shafting and individual machines driven by motors of the same make; the removal of refuse from the wood working machinery, the dust from the foundry cleaning room, the ventilation of the offices, toilet rooms, and wash house, and the removal of smoke from the smith shop will be accomplished by Sturtevant exhaust fans. Sturtevant blowers will be used for brass and iron foundry, forge shop blast and the like, and Sturtevant steam traps will be employed upon the steam drivers.

INSURANCE CANCELED BY AN OWNER BECAUSE HIS BOILER WAS UNSAFE.

"If you don't play in my yard I won't play in yours" indicates a spirit that is not by any means confined to childhood. But it is a little strange that business men should allow such considerations to influence them in so important a matter as steam boiler inspection and insurance, as related in the following extract from *The Locomotive*, published by the Hartford Steam Boiler Inspection and Insurance Co.:

> We recall a meeting of certain commissioners, held in a town, a little while ago, at which a report was read concerning a stone crusher boiler that was insured by the Hartford company, and which had been recently inspected. The inspector reported that the boiler was in bad shape, and that it would be more economical to buy a new boiler than to make the extensive repairs that would be required to put the old one in good order. The commissioners at once voted to cancel the insurance on the boiler in question. It would appear that when a report of that kind had been received it would be a good time to continue the insurance as long as the insurance company would carry it, or at least until such time as measures could be taken to put things in proper shape; but we cannot pretend to have the combined wisdom of an entire commission, and so we bow as gracefully as possible to the decision. We may add, however, that we never shed any tears of regret when a patron discontinues his insurance on such a boiler as this. We may also add that if the boiler should blow up, the commissioners would stand in an unenviable position, if they do not take immediate proceedings, on their own initiative, to fix the boiler up, or replace it. Ignorance is never a very good excuse, but when one cannot make even that plea he is in a bad way, so far as moral responsibility is concerned.

NOTES OF TRAVEL.

AN ENGLISH SCALE-MAKING FIRM—A SHOP BUILT BY JAMES WATT—RELICS OF THIS NOTED INVENTOR.

Editor MACHINERY:

In a very attractive album issued by W. & T. Avery, Ltd., of Birmingham, England, builders and manufacturers of weighing machines and steam engines on the site of the Soho Foundry of James Watt, the following occupies the only page of reading matter:

A Short History of the Progress of W. & T. AVERY, LTD.

Birmingham is the center of the weighing machine trade of Great Britain, comparatively little being made elsewhere, and here the business now known all over the world as W. & T. Avery, Ltd., was established in the year 1730. Like many other old businesses it was commenced in quite a small way in Digbeth, one of the most ancient streets of the town. From its inception as a workshop for making steel yards, it gradually grew; other forms of scales and apparatus, including Avery's agate bearings, being added to its list of productions, and the premises continually increased until in the year 1854 Messrs. W. & T. Avery built the first shops of their new factory in Mill Lane, which has in turn continually extended from time to time. In 1868 they purchased the Atlas Works, West Bromwich, where their iron founding was done.

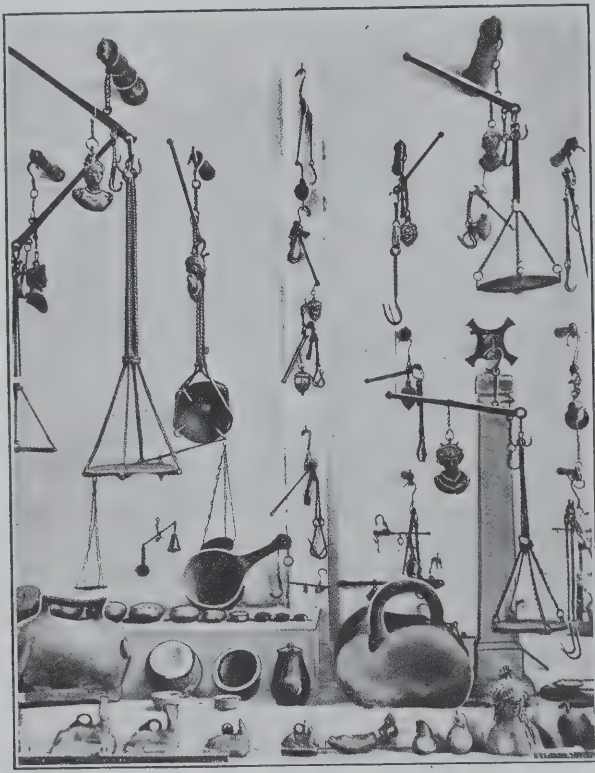

Fig. 1. Weighing Appliances over 2000 years old, found in the Buried City of Pompeii. Highest Weighing Capacity 120 Pounds.

The combined works stood on between 16,000 and 17,000 square yards, most of which were covered by shopping three or four stories high, fitted with machinery of all kinds, driven by five engines of various sizes.

In 1891, Messrs. Avery, finding their business still increasing by leaps and bounds, registered it as a private limited company, and in 1894 as a public company under the title of W. & T. Avery, Ltd.

In 1896, the directors considering the works in Mill Lane at West Bromwich too small for their ever-increasing trade, purchased the Soho foundry made world-renowned by the great James Watt. There they erected extensive buildings upon twenty acres of land, and during the following two years concentrated there their different factories. An extensive plant of special machinery was installed in each department, to insure the most accurate and economical results.

The company employ about 2,000 hands, their production ranging from the finest scientific balance weighing "in vacuo" to the greatest locomotive weighbridge capable of indicating a load up to 180 tons.

The great engineering business of James Watt & Co. is still carried on under the aegis of W. & T. Avery, Ltd.

Messrs. Avery have opened branch works in London, where chemical, assay and other fine balances are made; and in Glasgow where weighbridges are constructed for the Scotch and Irish markets. They have also branches in the principal towns of the United Kingdom.

An inspection of the works under the guidance of the manager convinces one that in the main, the establishment is very much up to date, measured by the gage of an American engineer and manufacturer. The few points in which there is room for modernizing are well known to the manager and he avers that improvements thereon are under consideration. The chief desideratum is quick-acting and powerful hoisting and conveying appliances. The traveling power cranes that are now in use are driven by either one or the other of the power-devouring agencies—the flying rope or the square shaft. Several of the cranes are hand driven.

The old shops of the engineering department, built and used by James Watt, form a striking contrast with the other buildings, well lighted and fully equipped with the appliances of heating and ventilating.

Only a small portion of the engineering department's work is done in these old shops, which are but a small part of the buildings. A few of the tools of this department are very old but are retained on account of being very useful at times. One of a design unknown in modern machine tools, is a wall planer. The guides along which the cutting-tool carrying the head travels can be seen in the view of "the present erecting bay" attached to the wall just beyond the faceplate of the large engine lathe in the right hand foreground of the cut, Fig. 10. The cutting stroke of the tool is parallel to the wall. It can readily be seen that such a tool would be of little service in any locality where there are great temperature changes acting on the wall and its foundations. It is a better machine for England than for the States.

The heavy scales for weighing horses, cattle, wagons, etc., differ from those of the States in having every part made of metal. No wood is used for any part, be it beam, girder, platform, or casing for the recording parts.

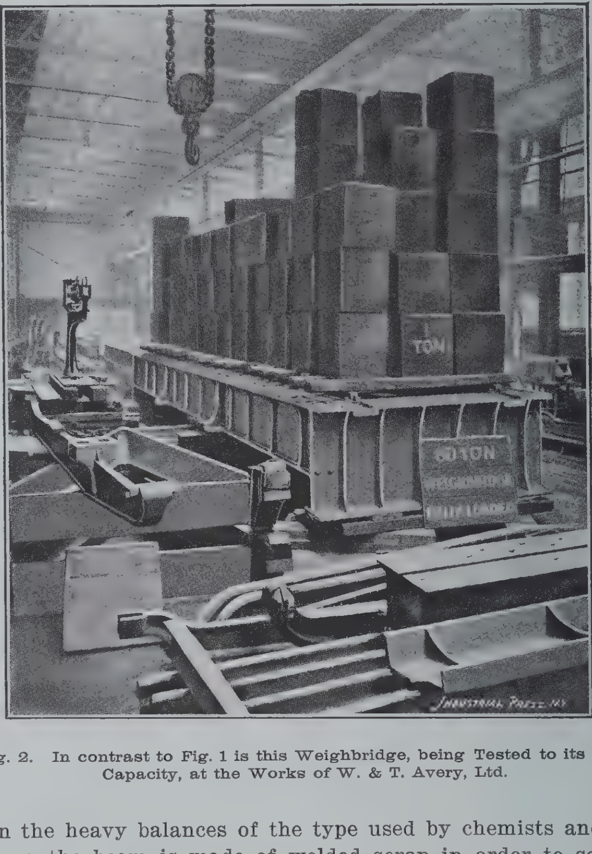

Fig. 2. In contrast to Fig. 1 is this Weighbridge, being Tested to its Full Capacity, at the Works of W. & T. Avery, Ltd.

In the heavy balances of the type used by chemists and assayers, the beam is made of welded scrap in order to secure the greatest toughness. Such balances are used for weighing articles of considerable weight in England, such as bales of cotton, crates, heavy boxes, etc., a use to which this type is not applied in the States.

Continuous weighing and recording machines for grain, coal, ore, etc., are an important part of the product.

The heating of the air for warming the shops is done by a method not common in the States where steam coils are used generally. At Avery's the air is drawn through a large furnace, chiefly of brickwork, located entirely outside of the buildings. The heated air is distributed in each building by metallic pipes with openings and short lengths of pipe on the upper side, so that the air is forced out toward the ceiling or upper region of the space to be heated. This is the reverse of the common practice in the States for heating large shop rooms, which is to carry the air down through branch pipes or outlets from the main, and blow it out toward the floor.

Fig. 7. James Watt & Co. Showing a Pair of Triple Expansion Pumping Engines in course of Erection. Supplied to the Birmingham Canal Navigation in 1899.

Fig. 8. Gas Making. At the rear of this apparatus James Watt erected a gas plant.

A gas reservoir or tank installed by Watt is still in active service. It differs only slightly from those in common use to-day. The chief difference is in the supports of guiding wheels for holding the inverted cup-shaped tank in position and for keeping it from toppling over. Instead of a connected framework for supporting the wheels, each vertical set of wheels is supported by an individual column of its own. The lower part of the column is of heavy masonry, capped by a comparatively short openwork casting. Each column is self-sustaining. A rod or pipe extends up through the middle of the tank also for the purpose of guiding and sustaining it.

A line of pipe led from the tank to Watt's residence, a mile or so away on a neighboring hill. His house is supposed by the Averys to be the first residence ever lighted by gas. The tank is in the rear of the gas-making part of the plant shown in Fig. 8.

James Watt Relics.

In two small rooms of the Tangye Co., of Birmingham, England, is a collection most interesting to the engineer. It consists of a lot of letters, account books, records, models, drawings, etc., that were the property of the Watt & Boulton Co. during its existence. They were purchased by the Tangye Co. at a sale of the goods of the old Watt & Boulton Co. The rooms are kept closed for the most part, and the material is not arranged in any way, but stored in boxes, drawers and cases in the condition in which it was when it first reached the rooms.

During a couple of hours spent in looking through these relics a number of interesting things were found.

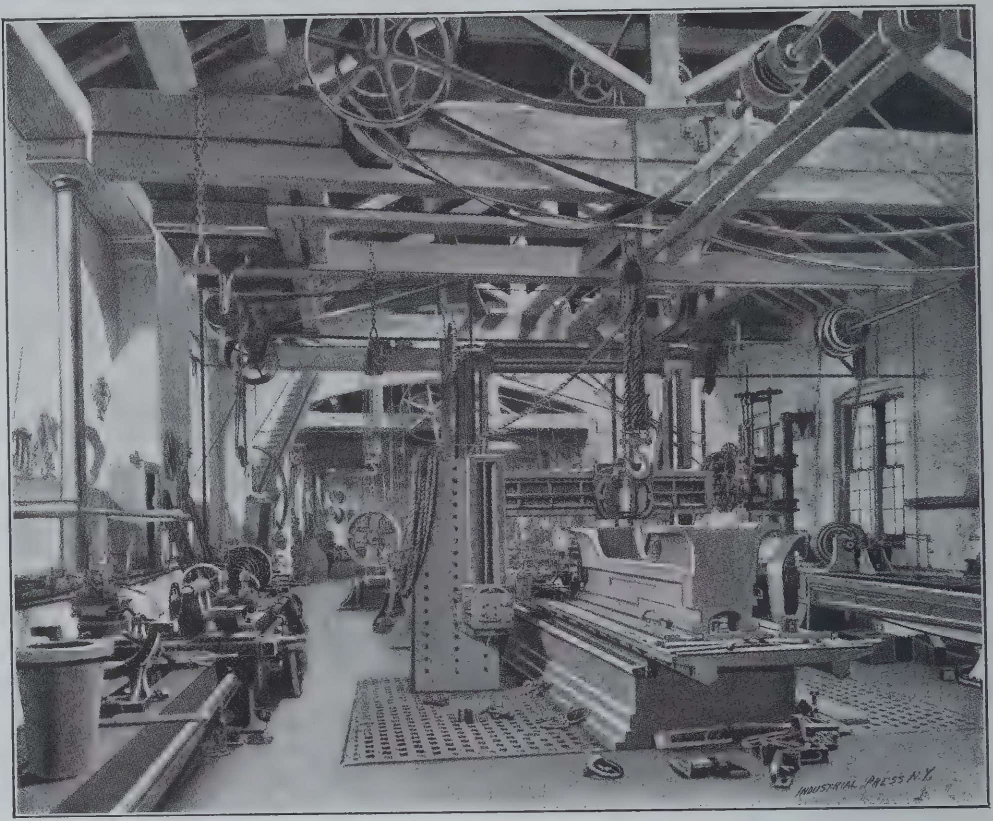

Fig. 9 Engineering Department James Watt & Co. Showing Fitting Shop, 208 ft. x 25 ft., built by James Watt and still in occupation.

The reason for Watt's inventing and adopting the "sun and planet wheels" seems made clear in some of the letters. It appears that Watt invented the (now) common crank mechanism for transforming reciprocating into rotary motion. As has often happened, however, some one else learned of Watt's invention and immediately had it patented. An enormous price was then asked of Watt & Boulton for the grant to use the device on their engines. The price was prohibitory, so Watt invented the sun and planet gears by means of which each double stroke of the piston, acting through a beam and connecting rod to the lower end of which one of the gears is rigidly attached, gives the main shaft of the engine two revolutions instead of one, as is obtained with the ordinary crank, connecting rod and beam. It might be added that the second gear is on the main shaft of the engine. Both gears are of the same diameter. A link or arm, much resembling a crank, but free to rotate about the main shaft, holds the connecting rod gear into mesh with the main shaft gear.

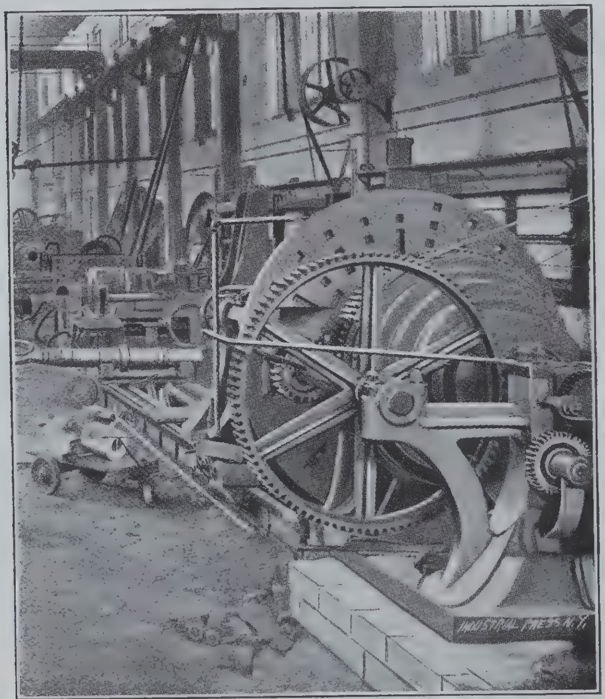

Fig. 10. James Watt & Co. The present Erecting Bay. A Wall Planer shown back of the Lathe was erected by James Watt.

It seems certain that the sun and planet gears were not adopted by Watt & Boulton for mechanical reasons, but for monetary ones with possibly a touch of feeling against the patentee of the crank mechanism.

In a letter by Boulton to Watt he inquires whether his understanding of the use of the flywheel is correct. He then sets forth for Watt's perusal an example of how to determine the size of "fly" required for an engine. He first assumes that a man can do a certain amount of work in lifting coal from a mine by means of a windlass—so many pounds an hour lifted a certain height. Then, that if several men work at the same rate to speed up a "fly," putting a given number of man-minutes work into doing it, it will take an equivalent number of man-seconds work resisting the "fly" to stop it. He gives the final result in the words, "then it will take 32 men one second to stop the fly."

In another letter to Watt, written just after an audience with the King and Queen for the purpose of demonstrating the operation of a letter-copying press invented by Watt, Boulton explains how he found their majesties taking coffee at 5 o'clock, was very graciously received, and kept at full conversation till half past seven. During this time he "made a very good copy of a letter written on a large sheet of paper." The King knew very well about Watt and his works and made many inquiries regarding him, despite the fact that Watt had insisted the King knew nothing of him. Boulton further tells Watt that he gave them both a very fine description of him and his works.

Models of the letter-copying press are in the rooms. They are of the roller-platen type. A felt-covered plate passes under the roll which exerts a pressure. The letter and impression paper are placed on the plate so that the pressure makes the copy. It seems that Watt was the inventor of the letter-copying process and of the ink used for the purpose.

A framed copy of "letters patent" hangs on the wall. The great seal of England is attached by a thong and suspended below. It is a piece of wax 5⅝ inches in diameter and about ¾ of an inch thick and the color of beeswax.

Forrest R. Jones.

Oxford, England.

Thomas Jefferson, the father of the American Patent Office, is said to have given personal attention to every application made for a patent during the years between 1790 and 1793.

WORK IN THE NEW MACHINE SHOP OF WM. CRAMP & SONS CO., PHILADELPHIA.

About two years ago Wm. Cramp & Sons Co., Philadelphia, completed a new machine shop directly across the street from the shipyard on the water front. A recent visit disclosed a very well-equipped shop for the building of marine engines, it being a decided and agreeable contrast to the old machine shops in the shipyard.

The new shop is a large building of brick with a three-gabled roof facing the street. The erecting floor occupies the middle section, and the machine tools are on the sides of the main floor under the galleries. The traveling crane runway over the erecting floor is well up in the roof, giving a clearance of perhaps 60 feet beneath the hooks. The south side of the building has one gallery over the main floor, and the north side has two gallery floors, which, of course, makes this side one story higher than the main section. Stairways are provided at all four corners leading up to the galleries, and four freight elevators, one at each corner. The tool rooms are in the galleries, there being one on each of the gallery floors. Lavatories and closets are provided on all three floors. Beside the traveling cranes over the erecting floor there are traveling cranes beneath both galleries. A bay is built out from the south gallery floor so that large heavy parts may be moved out over the erecting floor where the traveling crane can handle them. This makes the transfer of large parts, between the two floors, that cannot be handled on the freight elevators easy and convenient. The lighting is excellent, and is all that could be desired for machine shop purposes. The Sturtevant system of forced hot air circulation is employed for heating.

The section under the south gallery is given over to heavy machine tools. Here are a heavy 125-inch crankshaft lathe, a large planer for machining engine frames and bed plates, and three large horizontal drilling, milling and boring machines. All the large tools are driven by independent electric motors, but the smaller tools are motor-driven in groups, the lineshaft being divided into, say, three sections in the length of the shop.

At the time of the writer's visit one of the horizontal drilling machines was employed in boring the bolt holes in the flanges of an intermediate shaft for the battleship *New York*. This is a modest chunk of nickel steel, say, 30 feet long and 18 or 20 inches in diameter. The flanges were about 3 feet in diameter, and each one has eight holes for the coupling bolts. The boring was accomplished by first drilling 1½-inch holes and then enlarging them to the required diameter, which was 4¾ inches at the large end, by means of counterbores. The coupling bolts are made with a quick taper and have no heads. The holes were roughly tapered by using three diameters of counterbores through one flange so that the reaming would be somewhat facilitated. The reaming is not done until the shafts are in place on the vessel, where it is done by hand. This means a lot of hard work for three men at the end of a long reamer handle. About ¼ to 5-16-inch stock is allowed to be reamed out.

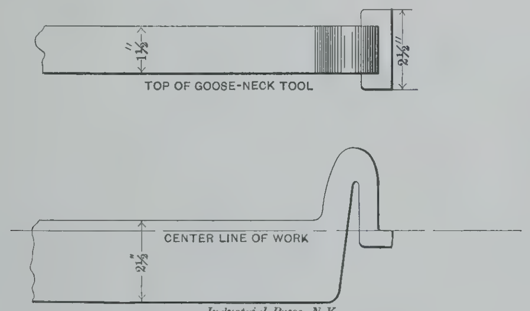

Fig. 1. Tool used in Finishing Nickel Steel Tail Shaft.

A nickel steel tailshaft was being finished in a lathe at the time. The finishing cut was taken with a goose-neck tool like that shown in Fig. 1 while deluged with a mixture of turpentine and lard oil.

Marine propellers are usually fitted to their tailshafts by being bored with a tapered hole through the hub and fitted to the tapered end of the tailshaft. Two keys and a large nut on the end of the shaft secure the two parts together. In some cases the keyways are planed parallel with the axis of the shaft. This, of course, makes the keyways deep at one end and shallow at the other. In the Cramp shops a Morton draw-cut shaper has been rigged to plane the keyways parallel with the taper. The shafts are leveled in front of the shaper and the keyways cut from the top. To make the cut parallel with the taper the shaper is mounted on tapered blocks which tilt it backward to the required degree. It may be asked why the shafts are not inclined to the required pitch. Since the tailshafts are about 50 feet long the end away from the machine would have to be depressed 5 or 6 feet, which would require that a hole be dug in the floor or that the shaper be elevated 3 or 4 feet.

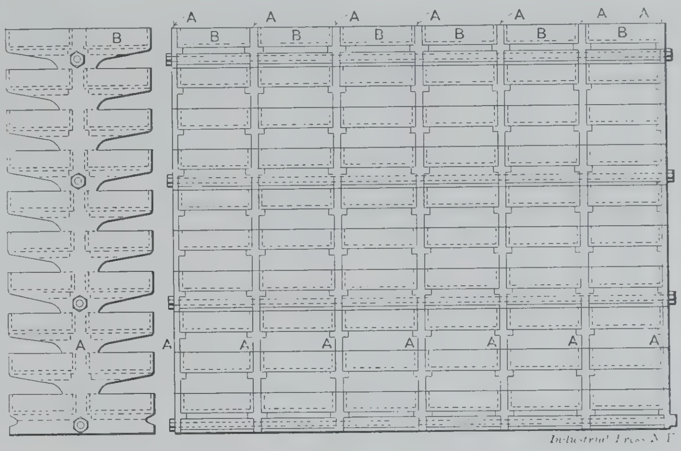

Fig. 2. Tool Room Rack for Trays.

Compressed air is piped to all parts of the shop, and is extensively used for various purposes. On the platen of the large Niles planer was the cast steel bedplate for the engines of a battleship being planed for the feet of the housings. At the same time a workman with a pneumatic hammer was riding back and forth on the platen chipping off the fins and scabs of the casting. Another use of a different character to which compressed air may be put was observed, and that is the cleaning of machines. A compressed air blast is effective in cleaning the dirt and chips from the table of a machine. It leaves the surface practically free from oil and may be used profitably on the frames and other parts that are ordinarily wiped with waste. One bad feature of the practice is that it is likely to cover surrounding objects with grease spattering, unless carefully done.

The tool rooms are provided with racks for trays, on the plan of that shown in end and side views by Fig. 2. They are made of castings like those shown at *A*. These castings are held together by bolts and sections of pipe to act as distance pieces. Ledges cast on the sides support the trays which are made of galvanized sheet iron about 12 inches square and 1½ inches deep. Several racks made on this plan were seen having 13 trays in height on each side and 12 in length, making 312 trays in each rack. The trays are used to hold bolts, screws, rivets, nuts and other small supplies and tools. Being made of iron they do not become oil-soaked as is the case with wood.

* * *

When we speak of the manufacture of iron bolts, nails, rivets, etc., in these days we naturally think that all such work is done, in this country at least, by improved machinery having a large daily productive capacity. Consequently it was with considerable surprise that a shop was recently discovered in Philadelphia, on North 22d Street, working full blast manufacturing carriage bolts and using machinery of the most primitive character, part of which was operated by foot power. The work in progress was forging or upsetting the heads of, say, ⅜-inch bolts. In the machines operated by foot power the hammer was raised after each stroke by a large wooden spring pole attached to the floor overhead. The power-driven machines were of about the same type, the wooden spring pole also being in evidence. The construction of all the machines was of the crudest description and gave evidence of great age. The scene presented seemed quite out of keeping with the present age, it undoubtedly being about as such work was done fifty or sixty years ago.

THE METRIC SYSTEM.

A SUMMARY OF OPINIONS GATHERED BY THE FRANKLIN INSTITUTE, PHILADELPHIA.

While the bill favoring the adoption of the metric system by the various departments of the government was pending before the last session of Congress, a special committee of the Franklin Institute, Philadelphia, had the same subject under consideration. The report of the committee was favorable to the adoption of the system and was as follows:

WHEREAS, It is desirable to obtain an international standard of weights and measures, also to simplify and regulate some of our existing standards; and

WHEREAS, The metric system is commendable not only as a suitable international standard, but also for facility of computation, convenience in memorizing and simplicity of enumeration;

Resolved, That the Franklin Institute approves of any movement which will promote the universal introduction of the metric system with the least confusion and expense.

Resolved, That the National Government should enact such laws as will ensure the adoption of the metric system of weights and measures as the sole standard in its various Departments as rapidly as may be consistent with the public service.

Supplementing the work of the committee the secretary addressed a number of letters to members of the Institute and to others whose opinion on the subject it was thought desirable to obtain. These letters have been published in the last four numbers of the *Journal of the Franklin Institute* and brief extracts from most of them are published herewith, together with quotations from the address of Mr. James Christie, chairman of the committee on the metric system, at the meeting when the subject was discussed; of Mr. George M. Bond, of the Pratt & Whitney Co.; and of Mr. S. M. Vauclain at the same meeting.

In Favor of the System.

In my opinion we need the system and I hope it will become international. We need it because it is the rational system connecting measures of length with those of area, volume, etc. It appears to me that our people have been long enough under the incubus of "long" and "short" tons, "long" and "short" hundredweights, "dry" quarts, "liquid" quarts and the like—units without any rational relation or often with curious fractional relationship to one another.

I may add that I have been in consultation with most of the heads of departments and engineers of the General Electric Co., and find that on the whole they are favorable to the adoption of the metric system, especially on new work, with the idea that it would eventually entirely displace existing measures.—Elihu Thompson (General Electric Co.)

The practical convenience of the workshop must, I believe, give way to the overwhelming theoretical advantages of the metric system. These advantages cannot be successfully disputed, and I have therefore been compelled reluctantly to admit the adoption of the metric system as a wise step for this country to take. Any system is better than none at all, and no system founded on the natural subdivision by 2 would with our present notation be acceptable to the great army of thinkers who plan the work of the world.—Wilfred Lewis.

I have for many years worked with both systems and by practical experience have found the metric system as far superior to our present system (or rather, want of system) as our decimal currency is in advance of the English £, s., d.

When a generation or two hence the history of the present time is written, one of the things that will seem most incredible will be that a nation as far advanced in civilization as the United States is supposed to be, should be weighing its copper by one standard, its silver by another, its diamonds by a third, and its medicines by a fourth, all of them interchangeable only by means of fractions; and measuring its wines by one system, its grain by another and its gas by a third.—Theo. D. Rand.

We consider it of the utmost importance that the inevitable change to the metric system be inaugurated at as early a date as possible. The advantages to be derived from the metric system's adoption are clearly manifest, and opposition to a movement of this kind would seem futile, as, at best, it can only mean a trifling postponement and not, in any way, prevent its ultimate adoption.—The Link-Belt Engineering Co. (J. M. Dodge.)

For more than thirty years we have employed the metric system of linear measurement as being greatly superior for the minute measurements required in the manufacture of watches. In adopting this system we took a centimeter as our unit. This we subdivide into a thousand parts, and have special gages reading to thousandths. In many instances the graduations on our gages we subdivide by the eye. Having this system in use for measurement of watch parts, we also use it in our machine department in the manufacture of machines, and while it is somewhat novel to men when they first come to us, yet they very readily acquire the system, which is extremely simple in computation.—American Waltham Watch Co. (E. A. Marsh.)

We have used the system in our workshop for a number of years, as its units are much more convenient, especially in the fine measurements required in our class of work. We have also published our catalogues of scientific apparatus wholly in the metric system for a number of years, and find that this departure is very much appreciated by the scientific men with whom we deal.—Baush & Lomb Optical Co.

The comparison between the metric system and our system is about equal to dollars and cents as compared with shillings and pence, and I approve any movement which will promote the universal introduction of the metric system, to take effect in the shortest possible time and that will create the least confusion and expense.—Joseph T. Richards, engineer, M. W. (Penn. R. R.)

It would be most satisfactory to have the National Government make the metric system the only legal system throughout the United States, provided sufficient time, say, five or ten years, were given before it became compulsory, so as to permit the different trades to adjust themselves to it.—R. D. Wood & Co.

To argue the superiority of the metric over what we may well blush to admit is still the British and the American system would be a reflection upon the intelligence of the members of the Institute. To my mind the only serious reason for hesitation in pushing the adoption of the metric system is that which, at first sight, appears to be its chief merit, viz., its decimal basis.

The number 10 came to us as a basis of notation through our having each 10 fingers (including thumbs). Its unfitness for the purpose becomes manifest whenever we have occasion to think of the half of a quarter dollar and realize that this half is 12½ cents, bringing us at once into inconvenient fractions. As my good friend, Mr. Benjamin Smith Lyman says, in his paper entitled "Against Adopting the Metric System": "If our early predecessors, in learning to reckon, had but omitted to count their thumbs * * * they would have saved the world a vast deal of labor, and would almost have abolished the use of vulgar fractions."—John C. Trautwine, Jr.

I doubt whether any discussion is needed of the broad subject whether a common system of weights and measures is desirable. That, I think, will be admitted by everyone. Forty years ago the question whether the British system or metric system would ultimately prevail may have been open to discussion. Now the progress of the latter, its adoption by Germany and by Norway and Sweden, its extension in Mexico and South America, its adoption by all scientific men in the researches from which results nearly all human progress have settled that question.

It is not a new thing to change weights and measures. Aside from the recent example set by other nations in the radical adoption of the metric system the English weights and measures have continually undergone change, though the names may have been retained.

The question may be raised, as it always has been, whether the time is opportune for the change. To this the answer seems to be that the difficulties are more apt to increase than to decrease with the lapse of time.—O. H. Tittman (Coast and Geodetic Survey.)

The subject seems to me hardly to require or to permit any extended discussion. It has been familiar to the world, as a question of importance in economics and the industries, in science and in art, for a century, and the system has become general all over Europe and throughout the world, except in the United States, Great Britain and their colonies. In some cases it is used in these countries, and in others generally in their dependencies. The advantages and relative disadvantages of its adoption are perfectly well understood, and have been illustrated by every nation which has accepted it. No nation now enjoying its advantages could be induced to exchange it for our heterogeneous "system" of weights and measures—our no system, rather—and the testimony in its favor from those who have had experience and are best entitled to give trustworthy evidence is practically unanimous. The only voices against either the system itself or its adoption are usually raised where that experience has not been had. It is making progress, slow to be sure, but none the less steady, in our country and in Great Britain. The question is not, after all, on its adoption, but rather regarding the time and the rate of advance toward its installment as a national and officially accepted system.—Robt. H. Thurston.

If called upon to adopt the metric system in any establishment under my control I would make no immediate change in any of the tools, but use them as they are, merely denominating them in the nearest convenient metric unit. For example, call an inch 25 millimeters, and so on with any multiple or subdivision of the inch. It would be urged against this that there is no correspondence between the absolute and nominal dimensions of the tool. This, although very desirable, is not absolutely essential; in fact, in many of our tools, the dimensions are only nominal and not exactly real. It would be desirable, however, to begin to make new gages and tools to replace the old ones as they were worn out. These could be made of actual dimensions to correspond closely with the nominal. The consequence would be that workshops would have for a period two standards, the old and the new; the old applying to all existing products and designs, and the new tools to be applied to new designs and products. The former would gradually disappear and the latter would in time entirely take their place. The manufacturer simply would maintain a double standard—all named in metric units—the one gradually disappearing to be replaced eventually and entirely by the new standard.

The subject of screw threads is frequently quoted and the difficulty and confusion that would result if we were to attempt to change our present system. I may ask, in reply, why change it at all? If it is good, retain it as it is indefinitely.—James Christie.

If we were to go to Germany—any one of us—to start a workshop we would not undertake to start it on an English-speaking basis; we would learn the German language, and we would do our business in German. Now, if we are going to adopt the metric system, all we will have to do will be to learn to think in the metric system. I have known men who have been able to master enough of the German language in three weeks to get along splendidly in Germany. How is this done? Simply by the professor compelling the person to stop thinking in his own language and to think in the language he is going to adopt. When he is compelled to think in that language, it is a very easy matter to teach him to speak in that language; and therefore, instead of making our articles four or three feet long, we would make them a meter long, or a meter and a half long; everything that we would make we would think about in accordance with metric sizes and metric dimensions.—S. M. Vauclain (Baldwin Locomotive Works.)

Opposed to Metric System.

The disadvantage of the French metric system is, that it is an attempt to measure time, space and matter decimally, whereas the decimal system is only specially adapted for computing numbers.

Assuming the advantages of the metric system for purposes of computation, and as the length of the French meter is not a necessary part of the system, would it not be desirable to adopt a metric system for this country with a length for the meter of 40 inches, whereby 25 millimeters would exactly equal 1 inch, with measures of weight and capacity based on this meter as in the French system, so that the system could be used decimally or by whole numbers and fractions as in our monetary system?

Would any advantages claimed for the metric system compensate us for abandoning the standard inch and our fractional and decimal divisions of it, with our engineering literature based thereon?—Wm. Sellers.

The writer was at one time connected with an establishment wherein the metric system was employed in one department and the English system in the rest of the works. It was his experience that foreigners who were used to the metric system, after learning our system, preferred to work with it than with the metric in making drawings; in other words, preferred to work in the department using our present system, rather than in the department where they used the metric.

The writer spent some time abroad a few years ago, and found that for convenience, they used as few decimals as possible upon their drawings, as it was difficult in many places to find room for the figures, just as we try to avoid fractions containing too many figures for convenient insertion.—Southwark Foundry and Machine Co. (Jas. C. Brooks.)

Decimal subdivision may facilitate computation on paper, especially in adding up many digits, but reckoning in the head is much more easily effected with a subdivision by halves or thirds. That is clearly the reason why such fractions are in constant use in the stock market, even with our much vaunted decimal currency established more than a century ago. In a multitude of cases, too, it is easier to make a computation with those easy fractions than to undertake it with the more cumbersome tenths, hundredths and thousandths. Plainly, the mental computations are by far more frequent than ciphering, and would be still more so were we not somewhat tied down to the pencil by the decimal system, as the Chinaman is to his abacus.—Benj. Smith Lyman.

In the absence of convincing argument to the contrary, we would feel, first, that the metric system in itself is not a better system than the English for the purposes of engineering trade; and secondly, even granting its merit, we question whether any such enactments of the National Government would accomplish the desired ends. We believe the American people are too much wedded to the English system to give it up because of any national legislation.—Brown and Sharpe Mfg. Co. (Henry D. Sharpe.)

In answer to question 3, (Have any valid objections against the metric system been urged excepting that the numeration cannot be continuously subdivided by two?), I would say that there are many more valid objections than the one presented in that question. The meter is too large as a unit and a millimeter is too small for uses in the average manufacturing process. The use of the decimal point on drawings and the use of dimensions expressed in decimals is exceedingly inconvenient. The scale of drawings using the metric system is much less convenient than the scales which are derivable from our present units. If it were not the case that some people thought the change desirable, it would be without meaning to have the National Government enter the thin edge of the wedge. There is much productive business in the country bearing no relation to the general government, and those establishments which supplied both the government and general public would be put to the expense of carrying everything in double standard.—F. R. Hutton, Prof. M. E., Columbia University.

The ones particularly affected are the manufacturers, whose standards are all prepared under the duodecimal system; any change to a decimal system would mean to such manufacturers a very great confusion for a number of years, and while I am sure every one would be pleased if all our measures were under the metric system, it becomes a financial question rather than a theoretical one.—New York Shipbuilding Co. (Henry G. Morse.)

In this connection I desire to call the attention of the members of the Institute to an interview I had in 1884 in England with Sir Joseph Whitworth, who, as you are aware, was noted for his improvements in the design of machine tools and the preparation of standard gages, etc. (He at that time was in feeble health, and in point of fact was called from this life a short time afterward.) He raised the question of the futility of asking foreign nations to adopt the standard of England even with improvements as to the simplification of the units of measurement and weight, but he urged that I should use my influence to have the United States in the first place adopt the meter of 40 inches in place of that now represented by a rod of platinum in the archives at Paris, measuring 39.371, approximately. This change would add only ⅝ of an inch to the length of the French meter, and this would appear less in its subdivision, but it would result in an exact correlation between the English unit and its multiple and the metric system. As the comparison now exists, we have the anomaly of assuming 25.3995 millimeters to be equal to 1 inch, while if the change suggested by Whitworth were made, our unit would be 25 millimeters exactly; 100 millimeters (1 decimeter) would be 4 inches exactly; 300 millimeters would equal 1 foot, and 900 millimeters would be 1 yard. The difference of weight that would result from the cubing of these dimensions, or any portion of them, and their contents in the weight of distilled water at a certain temperature, would be insignificant. Already by Act of Congress it has been determined that for postoffice uses, 15 grams French weight shall be taken as equivalent to ½ ounce, although the weight of 15 grams is slightly more than the weight of the ½ ounce of the postoffice measurement.

A tailor in France or Germany or any other country where the French metric system is legalized has a tape-measure divided into centimeters and half centimeters, precisely as a tailor in America has a tape-measure divided into inches, halves and quarters. The finest measurement they have occasion to use is respectively ¼ of an inch in America, and 5 millimeters or approximately 1-5 inch in France or Germany. The division of material bought and sold by weight into halves and quarters, is natural to the human mind. Its division into fifths or tenths is not conceivable. What is possible in money is not practicable in the market. Half of the kilogram, nearly the equivalent of the pound, had to be legalized in France and Germany, and this again is subdivided into quarters, and not into ten parts, in such materials as meat and butter.—Coleman Sellers.

The government is a large buyer of many kinds of manufactured products, and, in order to buy at reasonable rates, must buy what the market supplies; that is, must use what other purchasers require. For example, we have certain standard sizes of pipes and fittings threaded with so many turns per inch; these are well recognized, and we are able to buy pipe of one man and valves or other fittings of another man with reasonable certainty that they will fit one another, and many expensive tools and gages are required to produce this degree of uniformity. Is it intended to forbid the government to buy such pipe and fittings and require it to have made special pipes in millimeter sizes with threads in millimeter pitches? It is hardly conceivable that any one understanding the subject should recommend such a course.

The case is the same with our convenient series of bar sizes, our sheet and wire gages, our bolts, nuts and screws and many other commercial standards in all branches of business. It is true that these conventional sizes are perhaps more or less crude and imperfect; but they are well understood and serve their purpose, and experience has shown how difficult it is to change them when better series have been suggested. It is said that we need not change any actual sizes, but simply call them by new names. For years we have been trying to increase the accuracy of the sizes of things—to have the inch bar or the inch bolt measure 1 inch in diameter and not more or less; but if we must call our 1-inch bar a 25-millimeter bar, which it is not, it seems to me we are retrograding instead of progressing.—C. Sellers, Jr. (Wm. Sellers & Co., Inc.)

Were we to pass upon the simple question of the advisability of having a uniform standard throughout the civilized world, and without regard to the inconvenience and expense incidental to the change, we would decide in the affirmative. We would also be an advocate of adopting the metric system on account of its being more universally used than any one system, rather than to attempt to force the British standards, even though considered as convenient.

In a general way we are in favor of a common system of weights and measures, and the system should be the metric. On the other hand, considering the matter in connection with our own manufacture, or, to make it more definite, we do not believe the time is opportune for adopting this system, as it would lead to considerable expense if it were carried out to a degree that would make it an international benefit. We could readily, and without much expense, express dimensions of tools, fixtures, etc., in metric symbols, but would this be any real advantage unless the pieces so expressed were exact duplicates of similar pieces in use by countries whose standard is the metric system?—Bement Miles & Co. (W. J. Hagman.)

The millimeter is too small for the purposes of the workshop, in that it has to be multiplied many times if decimals are to be avoided and if all the other subdivisions of the meter are to be avoided. If the meter is the unit, then, of course, the decimal point would have to be used.

The Navy Department has, as we all know, adopted the Franklin Institute or Sellers thread for bolts and nuts. That system enters into all construction by the Navy Department and has been used for a great many years. It was on the recommendation of the Franklin Institute that this thread was adopted by the department, and the change to the metric system for the Navy Department in that one item alone would be a serious matter. It would be almost impossible to make the change in even units so as to make the work as interchangeable as it is now required. The railroads, also, have adopted the United States standard thread, and it is now in use on every railroad of the country. These standards are all in English measure, and the pitches are English; so that there would have to be a translation, which means a good deal of trouble and expense.—George M. Bond.

GEAR CUTTER ATTACHMENT FOR CUTTING INTERNAL GEARS.

From time to time we have described some of the interesting tools and devices devised by different members of the Arthur Co., New York, and again have an opportunity to present one to Machinery readers. The present instance is a gear cutting machine attachment designed by Mr. John F. Arthur for cutting internal gears. The firm of which Mr. Arthur is secretary, make a specialty of gear cutting and have designed and built a number of interesting gear-cutting machines for spur and spiral gear cutting. So the device illustrated in the accompanying cuts, is in line with their regular work.

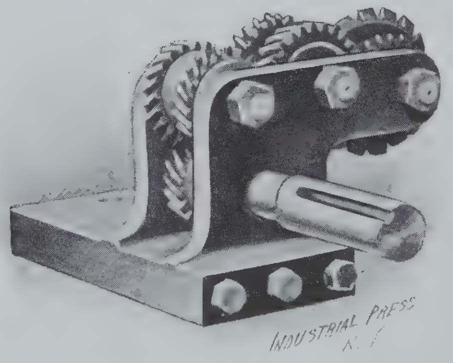

Fig. 1. Internal Gear Cutting Attachment with good Features of Design.

The attachment for cutting internal gears, is shown in Figs. 1, 2 and 3, the first view being made from a photograph and the others from the working drawings, to show the construction. The device consists of a cast iron frame made in two parts which carries four spool gears for transmitting motion from the machine spindle to the cutter. Fig. 1 shows that these gears are right- and left-hand spirals. They are made in this way, of course, to get the smooth driving action characteristic of spiral gearing, and to avoid the end thrust that accompanies single spirals. The gears are alternately steel and bronze; that is, gears *E* and *C*, Fig. 3, are bronze and gears *D* and *A* are steel. The steel gears turn on bronze bolts and the bronze gear *C* turns on a steel bolt. The reason for this is to have both the gears and their bearings in contact with different metals in order to get the best wearing results. This of course does not apply to the bearing of gear *E* as it was necessarily mounted on the driving arbor attached to the machine spindle.

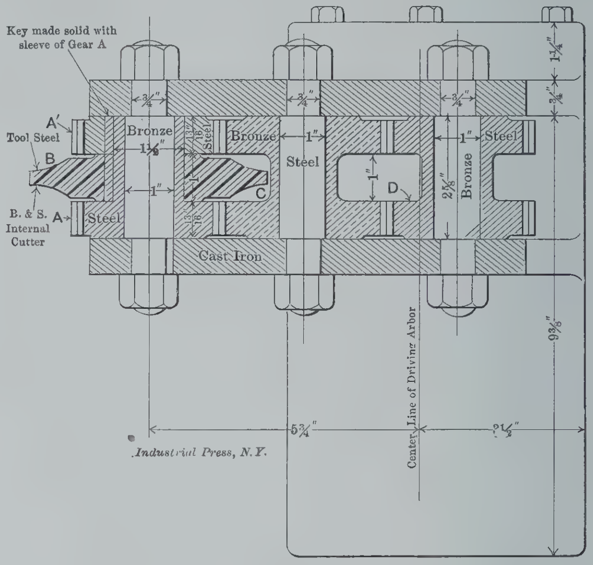

Fig. 2.

Gear *A* is made in two parts designated *A* and *A′* in Fig. 2. A portion of *A* is turned to a sleeve of smaller diameter to form a seat for the cutter *B* and the gear *A′* The end thrust of *A* and *A′*, when driving the cutter in the proper direction, is toward the cutter, thus tending to hold them solidly against the cutter. The advantage of this is obvious since if the spirals were reversed the thrust would be outward which would necessitate a fastening device to hold them to the cutter. Otherwise the thrust would force the gears against the side walls of the frame and cause excessive friction. Another excellent feature of design of this portion of the device, is that the key driving the cutter is integral with the sleeve of *A*, being machined from the solid. We may also call attention to the key, or feather *F*, for transmitting motion from the arbor to the gear *E*. This is made dovetail form and tightly fitted in *E*. The sides of the feather are made radial in the arbor. This type of driving feather has been used for a number of years by the Arthur Co. in their various machine tools. The good features of this form of construction were commented on in the June, 1902, issue in connection with "Some Features of Rolling Mill and Engine Design."

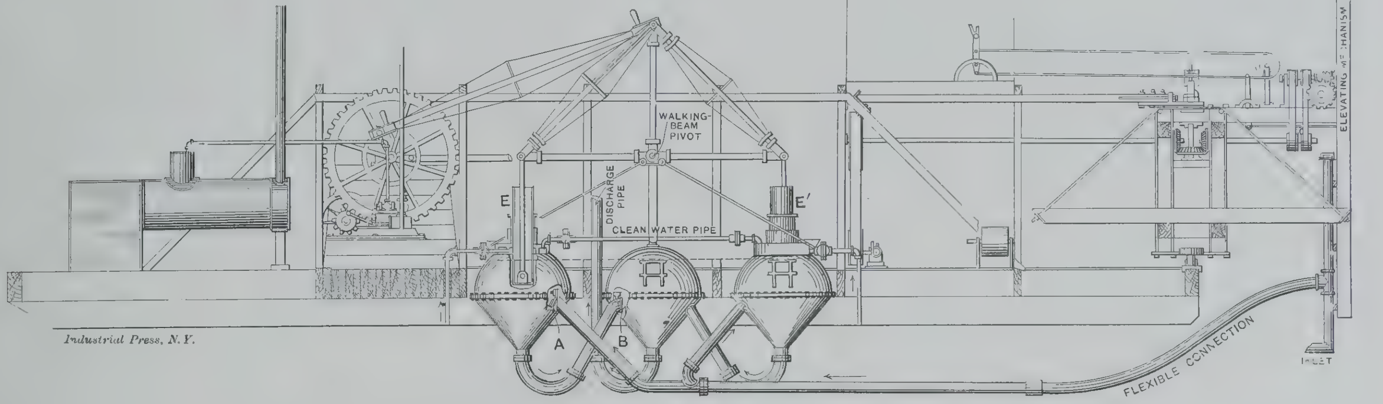
RECLAIMING GOLD FROM THE BEDS OF RIVERS —NOVEL GOLD DREDGING MACHINE.

Prof. Shaler, the noted geologist of Harvard University, declared a year or so ago that he believed the total production of gold throughout the world would eventually be greater than that of silver. He pointed out that while silver is obtained in large quantities, it is only gained by expensive mining operations, so that the price per ounce must always cover a relatively large labor cost. In the case of gold, however, there are possibilities of obtaining great quantities at a comparatively low labor cost by river and ocean dredging. There are great deposits of gold-bearing sands at the mouths of all great rivers draining gold-producing area such as, for instance, the Sacramento in California and the Yukon in Alaska. These gold-bearing deposits could be handled in immense quantities if the proper dredging machinery was provided, and at very low expense. Professor Shaler predicted that dredging machines would be so perfected that the lifting and separating of the precious metal from the ocean deposits would cost so little in proportion to the amount of gold recovered that it would become a most profitable and productive industry, since it is one that would only be limited by the number of machines at work, the supply of gold-bearing sands being practically inexhaustible.



The Bewsher Dredging Machine for Operating in the Gold Bearing Deposits in the Mouths of Rivers.

The production of gold by the present methods on land is an enormously wasteful occupation, considering all the miners and prospectors engaged in it and the total return. It has been estimated by competent authority that every dollar's worth of gold in circulation at the present time has cost a day's labor or more in the aggregate. Some men have won great prizes, but many have gained nothing and perhaps lost their lives in the search. The gold-dredging machine when perfected after the conception of Professor Shaler would make a fixed daily production almost an absolute certainty.

A novel machine for gold-dredging is illustrated herewith, known as the Bewsher dredging pump, which will be found somewhat interesting on account of certain mechanical features. One of these is that the pumps are in effect mechanical pulsometers. That is, they can handle muddy, gritty water or even water carrying large pebbles without damage to the working parts, the same as the steam pulsometer, but at a much higher efficiency in the matter of steam consumption. This machine is designed for river dredging, where the gold bearing deposits may be discharged on land and there passed through sluice boxes. For ocean work it would, of course, be necessary to have all the apparatus on board and to have the dredge a much stronger and more seaworthy vessel.

The pumps *E E′* are attached to opposite ends of a walking-beam which is operated by a 20 H. P. steam engine. As a plunger rises the water from the ocean or river bottom flows through the 8-inch inlet pipe into the large receiving chambers and at such velocity that the mud and pebbles are lifted bodily, carrying the gold nuggets and fine gold with it. Twelve cubic yards are handled per minute, which means a velocity (17 feet per second) sufficient to carry 25 per cent of granular matter in suspension or three cubic yards per minute. To prevent the grit getting on the plungers and cutting the wearing surfaces a spray of clean water is constantly injected around the plungers just beneath the stuffing-boxes. Clack valves are provided with leather hinges to act as checks. These hang in a perpendicular position, which reduces to a minimum the possibility of sand and pebbles preventing their seating properly. The advantage of sucking the deposits from the bed instead of lifting them mechanically, as with a bucket dredge, is that it causes only a local disturbance at the mouth of the inlet pipe. A bucket dredge, on the other hand, disturbs a large area of the bottom and constantly tends to cause the gold to sink lower and lower, where it finally becomes out of reach. Gold has a specific gravity of about 19.3, so it always seeks the lowest levels, tending all the while to lodge in cavities and crevices where it cannot be recovered except by a powerful suction. The general appearance of the machine shown is crude, and the design, aside from the central idea, is not attractive, but it appears, nevertheless, to have possibilities that may make Professor Shaler's prophecy come true before long.

RAPID WORK WITH STEAM SHOVELS.

Probably the most interesting steam shovels in the world are to be found on the "Mesabi Range," one of the five districts which go to make the Lake Superior mining region. Here they render possible in its present scale of magnitude the so-called "open-pit" mining, the shoveling of iron ore directly from its natural resting place in the earth to the railroad cars which are to carry it to market. An "open-pit" mine is nothing more nor less than an immense hole in the ground, perhaps half a mile square. Into this railroad sidings are run, as they might be into a vast stone quarry, and in some of these mines, where fully a million tons of ore are taken out each year, there are in operation simultaneously anywhere from half a dozen to a dozen of the large shovels.

Remarkable records of rapid loading are made by these shovels. As a rule five trips of the dipper are required to fill an ordinary freight car, but so rapidly is the long arm raised and lowered that it is accounted slow work if more than five minutes be consumed in loading a car, and not infrequently cars are fully loaded and pushed out of the way of the shovel at the rate of one every two minutes. From eight to a dozen men are required to operate a shovel of fair capacity, and by steady work they can place fully 7,000 tons of ore aboard the cars in a single working day. In order to make such a record as this, however, it is necessary that the men have an opportunity to work on the side of a pit or mine, where it will not often be necessary to resort to blasting to loosen the ore, so that it may slide down to the shovel, and it is further essential that a locomotive be constantly at hand to shift the cars as rapidly as they are filled, thus preventing delay.—*Philadelphia Record.*

* * *

The following wonderfully intelligent note recently appeared in a New York daily:

That it pays to use a smoke-consuming plant has been demonstrated at the New York Post Office. The building was formerly provided with a 6 horse power steam plant that used 24 tons of hard coal a day. This plant was removed and a 12 horse power smoke-consuming plant put in its place, which uses only 18 tons of soft coal a day. Thus double the power is obtained from one-fourth less coal, and, while money is saved, no nuisance is created. This seems to show that a smoke-consuming apparatus will soon pay for itself.

LESTER G. FRENCH, Editor.
FRED E. ROGERS and GEO. H. HALL, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

NOVEMBER, 1902.

NET CIRCULATION FOR OCTOBER, 1902,—24,183 COPIES.

The entire Engineering Edition is printed on coated paper, and a data sheet is furnished with every copy—price $2.00 a year. The Shop Edition is printed on super-calendered paper—price $1.00 a year.

THE LIGHT UNDER THE BUSHEL.

A somewhat remarkable example of the policy of secretiveness which some manufacturers are wont to adopt occurred at a recent meeting of the American Electrochemical Society, at Niagara Falls. Of the score or more electrochemical industries in that city only five permitted the delegates to the convention to visit their works. Of these five were, the Carborundum Co., well known to our readers, and the Atmospheric Products Co., to whose remarkable work we referred in our July number.

While we are well aware that there are cases where it is advisable to withhold information about processes and to keep one's methods secret, we believe that more often it is a mistaken idea. Does anyone suppose that the five industrial establishments at Niagara where visitors were admitted will suffer from their open-door policy or lose money or business that might have been retained had "No Admittance" signs been posted there? Or is it probable that those who declined admission will have acquired benefits thereby that will not be shared by their more liberal neighbors? On the contrary, the latter secured some valuable free advertising that will almost certainly bring results at some future time.

We recently visited an establishment, with a view of writing a description of its general practice. A simple method of chucking a piece in the lathe was alluded to by the proprietor with the request that a description of it be left unpublished, as it was, in a sense, a proprietary idea, originated in the development of the business. Of course the request was granted, but in visiting a rival concern in another city a little later, precisely the same process was found to be in use there. This is what might have been expected, for every live, enterprising concern generally has methods which compare favorably with those of competitors, accomplishing substantially the same results and in about the same time; otherwise it would not be able to compete. As a matter of fact it is not possible to keep much information of this character a secret where workmen are employed who are liable to change positions, who talk with workmen in other factories and who travel to a greater or less extent. In these days it is seldom that a firm has a process that is not known or used somewhere else, at least in an equivalent form. People who have advanced to corresponding levels in civilization generally have and do about the same things, whatever their color or place of birth, and many instances could be quoted to show that a similar law holds in the development of industries.

And how is it with the individual workman? Years ago a machinist acquired his information and skill through his own personal experience. It was his stock in trade and he was very reticent about giving away to others what had cost him so many years of hard work to learn. But education has changed all this, and to show how such is the case we are able to quote a very apt sentence from one who is a foremost leader in the practical education of practical men:

In a recent address, President Pritchett, of the Massachusetts Institute of Technology, says: "One of the great advantages of education is the preparation which enables a man to learn from other people, without having to wait to learn, bit by bit, from his own hard experience." The experience of those who have gone before is to be found in books; of those who are working to-day, in the technical papers; and one can acquire many times as much information from these sources as he could obtain without them. He can also gain information by traveling and by observation. There is so vast a store of common knowledge to be had from these sources that, except in very rare instances, a man will gain nothing whatsoever by trying to withhold the little mite he has himself found out. If a man has really become proficient in any line of work let him publish his ideas, tell other people about them, explain his methods, and do as much as he can to teach others the same work. If his methods are found to be good ones his fame will widen, he will be consulted as an authority and will be in demand as a workman. If he does not do this, he may feel reasonably sure that some other person will, and that this other person will be the one who will eventually pull ahead, other things being equal.

* * *

THE ENGINEERING AND SHOP EDITIONS.

The many expressions of approval that have come to us regarding the engineering edition of MACHINERY indicate that the paper in its new form will meet the needs of a much larger number of readers than ever before. The reason for this is obvious. There is a demand for a publication dealing with the design, construction and operation of machinery, which covers its field in a complete manner. We have long realized that it was not possible to publish a technical periodical at a dollar a year that was as complete as it should be to enable one to keep in touch with mechanical thought and progress, and the two-dollar or Engineering Edition is the result.

Several subscribers to the dollar or Shop Edition have asked us whether, if they change to the Engineering Edition, they will still have all the matter contained in the Shop Edition. In reply, the Engineering Edition contains all the reading matter and advertisements appearing in the Shop Edition, and there are, besides, from 16 to 24 pages of general and current engineering matter. A data sheet containing four 6 x 9 pages of notes, tables, charts, etc., for notebook use also accompanies every number of the Engineering Edition.

In addition to articles upon machine design and general engineering subjects, the extra pages contained in the Engineering Edition have several features that make the paper of great value to a person wishing to keep in touch with mechanical progress without having to take the time necessary to look through a large number of different publications. Among these are: A summary of the leading technical and mechanical events of the month; a digest or summary of the most valuable articles appearing in the other technical papers; and a summary of the most valuable papers presented before the various engineering societies.

As stated above, the price of the Engineering Edition is $2.00 a year, or double that of the regular edition that has heretofore been published, and it will be found more than twice as valuable to the busy technical reader. The Shop Edition corresponding to the regular edition heretofore published is issued at $1.00 a year. Most of the matter of a technical nature upon machine design that has sometimes appeared will now be transferred to the Engineering Edition, giving more room in the Shop Edition for articles upon shop methods.

THE POSSIBILITIES OF LIQUID FUEL.

The great coal strike and resulting coal famine have turned attention to the possibilities of liquid fuel and although many extravagant claims have been made for it, petroleum can unquestionably be used profitably in many sections of the country. News items in the daily and weekly papers from all parts of the country indicate that the scarcity of coal has caused many power users to at least investigate the question of liquid fuel and in numerous instances to install oil-burning apparatus.

The use of petroleum has not increased in the East to so great an extent as might have been expected, largely because there have been no facilities for bringing the Texas oil to Northern cities. Government regulations are such that the coastwise carrying trade must be by American-built ships, and it has been necessary to refit or to build American vessels for this purpose. Shipyards are busy upon such contracts and within the course of a few months it is estimated that 25 tank steamers will be running between Texas ports and Philadelphia, Baltimore and New York.

On the Pacific coast liquid fuel is meeting with success. The California oil fields have yielded so abundant a supply during the past two or three years that the power situation has been materially changed. The high price of coal in California made steam power almost a luxury, compared with some other sections of the country, and as the State has great water resources it has led the country in plants operated by water, with electric transmission. It is stated by the *Engineering News*, however, that at the present time California steam plants using fuel oil at 70 cents per barrel are producing power at a total cost for fuel and labor of only $34.60 per indicated horse power per year of 313 days of 24 hours each. Wherever oil can be readily transported it is exerting a marked influence from one end to the other of the Pacific coast. As far north as the Columbia and Yukon Rivers oil is being considered in place of cordwood, now used, the only obstacle to its adoption being where steamers go within the domain of the Dominion Government, whose laws do not permit the use of oil for passenger boats.

The first steamship to sail from San Francisco using California oil was the Enterprise, and since that time there is said to have been over 50 vessels equipped for service on the Pacific, many of which visit Japanese ports. It not only requires less weight of oil than coal for a given trip, but much less time for taking on a supply of fuel. This was strikingly shown in the case of the steamer Nevadan, which made a trip from New York to Honolulu and return. Part of the way she used coal and it required two days to fill her bunkers. The balance of the trip was made with oil as fuel and 4,500 barrels were stored in her tanks in five hours.

The most interesting event in the use of fuel oil for marine work is the tests lately made on the steamer Mariposa, which sailed between San Francisco and one of the Society Islands. A Government engineer was on board to render a report to his department. While the Bureau of Steam Engineering is not ready to give detailed information with regard to these tests, a few general facts are known. The vessel has a displacement of 3,160 tons and covered a distance of 3,438 miles. The average daily run was 354 knots; the oil consumed daily, 278 barrels—or 3,720 pounds per hour. This was equivalent to 1½ pound of oil per horse power hour or 50 per cent. less than the weight of coal required for similar service. Only 12 out of the 18 furnaces were used and the engine and boiler room force was reduced from 36 to 20 men.

Turning to railroads the Southern Pacific have about 400 of their locomotives equipped with oil burners; the Atchison have one-third of their locomotives refitted and several roads are using oil to a less extent, as for example the Boston & Maine for its Hoosac Tunnel service, and the Kansas City Southern Railway.

The advantages claimed for liquid fuel are somewhat as follows: It is easily and cheaply handled, clean, and produces a very efficient fire; furnace doors need not be opened in firing; no ashes to cart away; fire can be easily regulated; increase in steaming of the boiler and reduction in the boiler room force. As opposed to this are the claims that the fire is too intense, injuring the boiler shell, and that the flues become coated with a deposit owing to the fact that perfect combustion is not always secured. In locomotives this coating is removed by the sand blast, sand being thrown into the firebox and carried through the tubes by the powerful draft. In stationary and marine work this method is not available, as a matter of course.

The relative values of coal and oil for fuel depend almost entirely upon the locality. Where the oil can be easily transported and coal cannot, oil has the advantage. Prof. Wm. B. Phillips, of the University of Texas, estimates that from 2½ to 4 barrels of Texas oil are equivalent to one ton of coal, according to the quality of the coal. A pound of the oil will give up from 17,000 to 20,000 B. T. U. as against 13,500 for coal. In Kent's "Steam Boiler Economy" several data are published upon the efficiency of fuel. A test by the Twin City Rapid Transit Co., of Minneapolis and St. Paul, showed that with coal at $3.85 per ton of 2,000 pounds, of a quality that would evaporate 7½ pounds of water per pound of coal; and with Lima oil costing 2¼ cents per gallon, and weighing 6-6/10 pounds per gallon, the two fuels were equally economical. A member of the Engineers' Club of Philadelphia in 1892 stated that 1 pound of anthracite coal evaporated 9.70 pounds water; 1 pound bituminous coal, 10.14; and 1 pound fuel oil, 36 degrees gravity, 16.48. The calorific energy of petroleum was estimated to be 60 per cent. greater than that of bituminous coal, although theoretically petroleum would exceed coal only by about 45 per cent. Other tests could be quoted and instances multiplied to indicate the prominence of petroleum fuel for various kinds of service, but a mere collection of statistics would be of no particular interest. It is evident that people are now more familiar with the advantages and disadvantages of petroleum than before the coal strike, and more will use it than ever before and its use will continue to increase until the demand for it is equal to the supply, which unfortunately will probably become less rather than more in future years.

* * *

LOCOMOTIVE MANUFACTURE IN THE UNITED STATES.

The census bulletin on the manufacture of locomotives in the United States compiled by Edward H. Sanborn, records 2,831 steam, 55 compressed air, 155 electric and 5 gas locomotives built during the census year 1900. There were 28 establishments whose sole or chief product was locomotives. These works turned out 2,774 locomotives, employed 19,039 wage earners and paid them $10,899,614 wages. The value of the locomotives built was $27,121,063. In addition there were 272 locomotives built in 26 railroad shops, making a total of 3,046, having a total value of $30,397,456. The average value of the locomotives built in 1890 was $8,199, while that of the 2,774 built in the locomotive shops in 1900 was $9,777, or an increase of 19.2 per cent. This increase is due in part to changes in size and construction.

It is pointed out that in 1890 a freight car having a carrying capacity of 60,000 pounds, was thought adequate for all ordinary purposes, but in 1900 the limit has been increased to 100,000 pounds, while cars of even greater capacity are being constructed. The increase in size has been made possible by the substitution of steel for wood. The general application of air brakes to freight cars enables freight trains to travel at higher speeds than was possible a few years ago. The increased size of the cars and the higher speeds have made necessary the greater size of locomotives. The important features of this development are larger boilers with thicker shells; larger fireboxes and increased grate area; higher steam pressure; the substitution of steel castings for cast iron or wrought forgings; compounding, etc.

In 1890 the average weight of locomotives built in one plant was 92,000 pounds for the engine alone, exclusive of the tender. In 1900 the average weight of locomotives built in the same establishment, was 129,000 exclusive of the tender. The average weight including the tender was 158,534 pounds, or 79.3 tons. The largest locomotive built weighed about 133 tons, or 190 tons with the tender, and it is not safe to say that this limit will not be exceeded. In 1870 the average steam pressure was 130 pounds; in 1890 it was 160 pounds; and pressures have been increased 25 pounds or even more in the last ten years. Locomotives carrying 225 pounds are frequently built. The average thickness of boiler plate in 1890 was ½ or 9-16 inch for the shells, but now it is quite common to use plates ⅞ inch thick.

Considerable valuable information is given in the bulletin relative to compound locomotives. It says that the principle of compounding is not new, patents for compound locomotives having been issued in the United States as early as 1846. The Shepard Iron Works, Buffalo, N. Y., built a compound engine in 1867.

NOTES AND COMMENT.

REVIEW OF CURRENT EVENTS, TECHNICAL AND MECHANICAL.

The Massachusetts Institute of Technology, Boston, the largest technical school in the country, has opened this fall with 1,600 students, an increase of nearly 200 over last year. The freshman class numbers over 500. This unusual growth has taken place, moreover, in the face of the establishment of courses in engineering by many of the academic or classical colleges, especially throughout the central West. It is very evident that there is a decided tendency towards technical training.

In the October number of Machinery reference was made to the Kaiser Wilhelm II., which was launched August 12, as "the largest steamer in the world." This claim was, however, but short lived, for at nearly the same time that the Kaiser Wilhelm II. was launched by the North German Lloyd the White Star Line launched, at Belfast, the Cedric, to which the above title now belongs. Though 6½ feet less in length than the Kaiser Wilhelm II., the extra breadth and draft of the Cedric give her a displacement 12,000 tons in excess. The Cedric is practically a sister ship to the Celtic, but exceeds that vessel in displacement by about 1,000 tons. She is 700 feet in length, 75 feet in beam, 49 feet in molded depth, and at her maximum draft of 36½ feet (to which, by the way, she cannot be loaded until the new 40-foot channels are dredged) she will displace about 38,500 tons.

A remarkable plan has been proposed for handling trains on the West Va. Central R. R. In passing through Tucker County it is impossible to maintain more than a single track because of the wildness of the country. In one place the road passes down through a deep gorge and afterwards up a heavy grade connecting Hendricks and Elkins, West Va. The location and grades of this track are very disadvantageous for handling freight in both directions, and it is proposed to use the gorge route only for west-bound trains and to overcome the obstacles in the way of locating an east-bound track elsewhere, by providing an elevator or an immense moving platform for raising a whole train loaded with coal or merchandise to the height of 1,000 feet, up the side of a precipitous slope of the great "backbone mountains." If this is done, electric power will be used, of which there is an abundance in the vicinity.

The late Henry A. Rowland, physicist and mathematician of the Johns Hopkins University, Baltimore, Md., is perhaps best known by his establishment of the mechanical equivalent of heat at 778 B. T. U., now so generally used in calculations. The extent of his scientific work, however, was very remarkable, and he made noteworthy achievements in various directions. Among these was a system of telegraphy called the Rowland Octoplex system, which secures a simultaneous sending of eight telegrams on one wire—that is, four telegrams in one direction and four in the opposite direction. Twenty thousand words an hour can easily be sent, and if emergency requires this may be increased to nearly thirty thousand. The transmitters used resemble typewriters. A complete installation has four keyboard transmitters and four receiving instruments, which print the messages in Roman type. A telegraph line thus equipped has been established between Berlin and Hamburg, Germany, and a second one is now under consideration.

The occasional interviews with Nicola Tesla published in the daily papers represent his schemes as being so visionary that it is often wondered whether he is actually engaged in any substantial work for the advancement of electrical science. His achievements in the development of alternating currents have been so remarkable that it seems incredible that he should be giving his attention to plans considered wholly impracticable by eminent electricians. It will be new to most readers to know that he is actively engaged in laboratory work on a large scale. He has completed a new laboratory at Wardenclyffe, L. I., about 65 miles from New York. This is a large building, and Westinghouse, Church, Kerr & Co. are to supply the power plant equipment. A large steel tower of peculiar construction has been erected in the vicinity, underneath which is a deep pit. The use of this structure can only be conjectured, as Mr. Tesla always prefers to observe great secrecy with regard to his experimental work. It is supposed, however, that the tower is intended for experiments with wireless telegraphy and wireless power transmission, and that the pit is for the purpose of obtaining a more perfect ground connection.

The *Iron Age* says that the rivets through the keel of the seven-masted schooner Thomas W. Lawson, which was launched from the Fore River shipyards a short time ago, were nearly 5 inches in length by 1¼ inch in diameter. It was not possible to upset these properly with an ordinary yoke, one arm of which served as the anvil to resist the blows of the pneumatic hammer carried by the other arm. To have made the anvil heavy enough to accomplish the purpose would have produced a tool extremely awkward and difficult to handle in the cramped quarters underneath the keel. The difficulty was overcome by doing away entirely with the anvil and substituting a second pneumatic hammer. The two hammers, one on the end of each arm of the yoke, worked perfectly and there was no further trouble in making the rivets fill the holes completely. The strokes of the hammers were so exceedingly rapid that it made no difference whether they worked synchronously or not.

The same scheme was tried at the William R. Trigg Co.'s shipbuilding plant at Richmond, Va., with very satisfactory results as we were informed by Mr. William Burlingham some months ago, who has applications filed for patents on the system.

OCEAN TRIAL OF THE SUBMARINE BOAT "FULTON."

The submarine boat Fulton recently made a trial trip from New York to Washington, on the outside, under its own motive power. This is the longest trip ever made by this type of boat on our side of the Atlantic. The intention was for a longer trip, which would no doubt have succeeded but for the rupture of a pipe, due to the accumulation of sulphuric acid fumes around the storage batteries, which terminated the trip until repairs could be made. No serious damage was done to either the boat or the machinery. This trip was the second of a series of trials that are being carried on to demonstrate the value of this type of boat. The first occurred on November 5, 1901, when she was submerged for a period of 15 hours, during a storm, without any inconvenience to the crew.

Six boats of this class are being built by the U. S. Government at a cost of $170,000 each. The Fulton is 63 feet 6 inches long and has a diameter at the largest part of 11 feet 9 inches. For running on the surface a gasoline engine, capable of developing 160 H. P. is used. This is calculated to produce a speed of 7 to 10 knots per hour. Under water the boat is run by electricity furnished by storage batteries. One charge will last six hours and develop 70 H. P. The armament consists of five Whitehead torpedoes which are 11 feet 8 inches long and carry sufficient explosive powder to destroy the largest vessel ever built. Running out behind the boat are two rudders which, when bent down or up, cause the boat to sink or rise. She can dive out of sight in about 15 seconds and may be sunk to a depth of 100 feet.

If these boats do the work for which they are intended, experts say that every naval power must have them and there will be as great a revolution in ships as when sails were superseded by steam power.

ANOTHER INTERURBAN ELECTRIC RAILWAY.

The October 9th number of the *Engineering News* contains an extended account of the recently completed Aurora, Elgin and Chicago third-rail electric line. This is one of several similar lines that have been built or are now being constructed in this country. Now that the alternating system of electrical distribution has become so well adapted to such lines the development of interurban electric railways, even between quite distant points, may be expected to be rapid. The railroad in question has a main line 33 miles long, one branch 16½ miles, and a branch 6 miles long. Twenty-one and one-half miles are double track, and the whole system conforms very closely to ordinary steam railway practice in location and construction. The railway is built entirely on its own right of way, and its construction has involved some heavy cuts and embankments, bridges, etc. The line will be operated by trains instead of single cars, using the multiple unit system, in which each car has its own motive power, but all the motors are controlled from the forward car. The cars are 47 feet 3 inches long, weigh 74,000 pounds and have 125 horse power motors. The wheels are 36 inches diameter.

The power station for the entire line is at Batavia, Ill., and has three 2,200-horse power Cooper-Corliss engines with General Electric generators. An alternating current of 26,000 volts is employed for this distribution. It passes over high-tension cables to substations, located ten miles apart on the line of the railway. In the stations are stationary transformers which reduce the current to 420-volt alternating, from whence it enters rotary transformers that deliver a 600-volt direct current to the third rail, which is used in preference to trolley wires.

THE COMING AUTOMOBILE SHOW.

The automobile show to be held in Madison Square Garden, New York, January 17-24, 1903, promises to be the most successful event of the kind that has yet been held in America. Over one hundred concerns will be represented by machines of their construction, but it should not be assumed that there are that many automobile companies manufacturing automobiles alone. Many of the machines to be exhibited are the work of firms building machines as a side issue. At the automobile show held in New York last November, 92 companies were represented and 150 machines shown.

As an indication of the unsettled condition of the automobile business it may be mentioned that, of the firms taking part in the exhibit of last year, only a few more than one-half will be represented this year, the remainder being new concerns that have sprung into existence in place of those having gone out of business. While the progress of the automobile industry may follow the upward trend of the now defunct bicycle boom, it must necessarily be slower and on more conservative lines. The sudden and tremendous popularity of the bicycle is only equaled by the suddenness of the loss of public interest in it. Only six years ago the greatest of bicycle shows was held in Madison Square Garden, and now we learn that the greatest bicycle concern of all, and the pioneer at that, the Columbia Bicycle Co., has closed its bicycle plant at Hartford, Conn. The growth of the motor-driven vehicle in popular favor, is slower, and it is fair to believe that it will be much more permanent. The ultimate test of the permanency of the automobile will be how well it serves utilitarian purposes, and that it will do this well, there is little doubt. The motor-driven vehicle is destined to become the principal factor in moving freight in city streets, to the exclusion of the horse-drawn dray and truck. As a vehicle of pleasure it has been an instrument of education, demonstrating the possibilities of motor-driven vehicles. It does not matter if these experiments have been carried out to satisfy the whims of wealthy patrons, the results redound to the benefit of everyday commercial interests by making practical machines possible.

* * *

An immense oil "gusher" has been struck at Cotella on the South Alaskan coast. The spouting oil rose nearly 200 feet before it could be capped. It is said that the oil is of good quality and is worth $4 a barrel at the well. About 10 miles of coast line in the Cotella region have been located for oil borings.

CONVENTION OF THE NATIONAL MACHINE TOOL BUILDERS' ASSOCIATION.

The annual meeting of the National Machine Tool Builders' Association was held at the Hollenden, Cleveland, Ohio, on October 14 and 15, twenty-eight members being present. The subject of prices was not discussed, most of the time being devoted to perfecting and extending the organization, which was originally formed by the manufacturers of lathes, and later extended to include makers of drills, planers and milling machines; and it is now the intention to invite all machine tool builders to join. A number of trade problems were discussed and a committee appointed to recommend a uniform practice in relation to furnishing attachments and accessories to machine tools. A paper on the introduction of the metric system in this country was read by Mr. F. A. Halsey, covering the results of a month's research on the advantages and disadvantages of the metric system of measurement as applied to the machine tool trade of this country, and showing that the change would result in great confusion and expense which it would be difficult to estimate, and which would extend over many years, without any corresponding advantage.

Mr. Fred. Geier, of the Cincinnati Milling Machine Co., also submitted a statement carefully prepared by Mr. E. M. Chase, the superintendent of that company, showing that the actual loss in changing small tools such as drills, reamers, gages, etc., now used in their work would amount to over $50,000; and this sum includes no allowance for loss of time while the workmen are becoming accustomed to the new measurement.

The change not being simply the alteration of English dimensions into metric, but a complete change to the metric basis, Mr. Geier states that in his opinion the best way to make the change would be to start an entirely new establishment with new tools, drafting room and pattern shop. Keep everything separate from the old establishment until the new is running in good order and then drop out all of the old except that needed to keep up the repairs. This may seem to be an expensive method but when the number of things to be altered is considered it appears in a different light.

In Germany the metric system has been in operation, theoretically, for 29 years, yet the two systems of measurement are still in use, as is also the case in 33 other countries where the system has been started.

The difficulties of the change will be felt most by those establishments manufacturing duplicate work in large quantities by the use of special tools, jigs, etc. Here the change will amount virtually to shutting down and starting again under the new conditions. This would entail a great loss of time for making new tools, new drawings, jigs, etc., and changing over all of the large tools to the new system. In the manufacture of large machinery this matter would, of course, be less serious.

Another objection to the adoption of the metric system is that even after all these years no standards have been adopted by the metric countries for screws, gears, bolts, etc., and an attempt to apply our present standards to metric measurements would lead to cumbersome and impractical dimensions.

Coming to the point of just what must be altered or renewed in changing the system, the case was cited of a factory employing 300 men, engaged in the manufacture of milling machines. The following is a list of the tools that would have to be substituted for those at present in use in the above mentioned factory in order to change from the English to the metric standard:

4,000 twist drills of various sizes, 525 counterbores, 1,008 reamers, 905 mandrels, 1,460 gages, 107 chasing tools, 1,300 taps and hobs, 198 boring bars, 2,000 cutters, 255 screw machine forming tools, 1,008 jigs, 315 special cutters and gang mills.

The estimate value of which, as above mentioned, would be as previously stated, $50,000.

After an informal discussion, a committee consisting of Fred. A. Geier, P. E. Montanus and Fred. Eberhardt, was appointed to draw up a set of resolutions. This committee presented the following resolutions, which were adopted:

Whereas the members of the National Machine Tool Builders' Association, in convention assembled, having carefully considered the provisions of house bill H.R. 2054, do hereby emphatically protest against the enactment of said bill because:

First, The experience of Germany in which the old measures are still in large use has shown that the change cannot be completed even after a generation of confusion.

Second, The sale of many million dollars' worth of machine tools, has been made abroad, by members of this Association, especially to France and Germany, without requirement or request, by the purchasers, for changes in general construction, to conform to metric measurements, the only changes being in adjusting and measuring screws; the great majority of machines needing no changes whatever.

Third, The adoption of the metric system would entail an enormous first cost of new equipment to conform to the new standards, a constant increased cost in the maintenance of a double standard for repairs and renewals, and a consequent increased cost of the product to the consumer.

The formation of the Association has already resulted in an extended acquaintance among its members, and a better understanding of the various problems which confront the machine tool manufacturer; and with the increase in membership it is confidently expected that its field of usefulness will be enlarged.

The following firms were represented at the meeting:

C. H. Alvord, Hendey Machine Co., Torrington, Conn.
B. F. Barnes, B. F. Barnes Co., Rockford, Ill.
F. W. Boye, Schumacher & Boye, Cincinnati, O.
W. H. Carpenter, Rahn, Mayer & Carpenter Co., Cincinnati, O.
W. P. Davis, W. P. Davis Machine Co., Rochester, N. Y.
J. B. Doan, American Tool Works Co., Cincinnati, O.
Enoch Earle, P. Blaisdell & Co., Worcester, Mass.
Fred L. Eberhardt, Gould & Eberhardt, Newark, N. J.
Joseph Flather, Flather & Co., Inc., Nashua, N. H.
Philip Fosdick, Fosdick Machine Tool Co., Cincinnati, O.
Fred. Geier, Cincinnati Milling Machine Co., Cincinnati, O.
W. A. Greaves, Greaves, Klusman & Co., Cincinnati, O.
C. F. Hilker, Hamilton Machine Tool Co., Hamilton, O.
H. C. Hoefinghoff, Bickford Drill & Tool Co., Cincinnati, O.
Fred Holz, Cincinnati Milling Machine Co., Cincinnati, O.
R. K. LeBlond, R. K. LeBlond Machine Tool Co., Cincinnati, O.
William Lodge, Lodge & Shipley Machine Tool Co., Cincinnati, O.
P. G. March, Cincinnati Shaper Co., Cincinnati, O.
C. F. Mayer, Rahn, Mayer & Carpenter Co., Cincinnati, O.
P. E. Montanus, Springfield Machine Tool Co., Springfield, O.
J. G. Oliver, Bardons & Oliver, Cleveland, O.
A. B. Pattison, Aurora Tool Works, Aurora, Ind.
B. B. Quillen, Cincinnati Planer Co., Cincinnati, O.
S. C. Schauer, Cincinnati Machine Tool Co., Cincinnati, O.
G. F. Stewart, Bradford Machine Tool Co., Cincinnati, O.
Murray Shipley, Lodge & Shipley Machine Tool Co., Cincinnati, O.
C. E. Thwing, Draper Machine Tool Co., Worcester, Mass.
A. W. Whitcomb, Whitcomb Mfg. Co., Worcester, Mass.

Several other firms, not members, were represented at the social gatherings, among whom may be noted:

E. R. Fellows, Fellows Gear Shaper Co., and D. L. Ballard, of the Jones & Lamson Machine Co., both of Springfield, Vt.; J. G. Oliver, of Bardons & Oliver; Albert M. May, of the Reliance Machine Tool Co.; A. W. Foote, of Foote, Burt & Co.; Mr. Henn, of the National Acme Mfg. Co., all of Cleveland; R. McCarty, of the Bignall & Keeler Mfg. Co., Edwardsville, Ill.; H. E. Morton, of the Morton Mfg. Co., Muskegon Heights, Mich.; T. G. Meachem, of the New Process Raw Hide Co., Syracuse; C. J. O'Hara, of the Wormer Machinery Co., Detroit, and Mr. Hunt, representative of Manning, Maxwell & Moore.

The following officers were elected for the coming year: President, Joseph Flather; First Vice-President, William Lodge; Second Vice-President, W. P. Davis; Treasurer, Enoch Earle, and Secretary, P. E. Montanus.

Meetings in future will be held semi-annually—the next to be in Worcester, Mass.

* * *

A decided virtue of nickel steel, according to government report, is the facility with which a low carbon steel will harden, it being the practice after a piece is forged and rough-machined, to heat it and dip in oil, which hardens it very much. Afterward the forging is subjected to an annealing process which removes any strains set up in the metal by the sudden cooling which it receives. Nickel steel, after the first cost of production, is not much more expensive to forge than any carbon steel that runs over 40 per cent carbon, and about the same care is necessary in heating and forging as is required by a high carbon steel.

THE STEAM TURBINE.

THE GENERAL PRINCIPLES AND LEADING TYPES OF STEAM TURBINES.

In the September number of MACHINERY editorial reference was made to the recent developments in the steam turbine field, with the promise that an explanation would be given in a later issue of the distinguishing features of the leading steam turbines.

There are now three types of steam turbines manufactured in the United States which have been developed sufficiently to be counted as probable rivals of the reciprocating steam engine. These are the De Laval turbine, made by the De Laval Steam Turbine Co., Trenton, N. J., the Westinghouse-Parsons turbine, made by the Westinghouse Machine Co., Pittsburg, Pa., and the Curtis turbine which is built for stationary purposes by the General Electric Co., Schenectady, N. Y. All of these use steam expansively, and therefore economically, and it will be of interest to outline briefly the principle by which this is accomplished in each wheel. In what follows attention will be paid more to their thermodynamic than to their mechanical or constructive features.

General Principles.

To begin with, it will help matters to make a general statement of what must be accomplished in the successful steam turbine; for, while these points are well understood by students in engineering, it is equally certain that they are not understood at all by the great majority of inventors who have made attempts in the line of steam turbine development. An examination of the patent records shows that while there have been numerous patents granted on steam turbines during the past ten years or so, only a very few of the patent specifications embody the elements of success, and most of them are entirely worthless, and display on the part of inventors an ignorance of what a steam turbine should be and do.

The fundamental principle in any economical steam motor is that the expansive force of the steam must be utilized. The direct-acting steam pump, although serving a very useful purpose, is one of the most wasteful steam users in existence. Steam is admitted to the cylinder at boiler pressure and pushes the piston from one end to the other of the stroke under the same pressure, and the cylinder is in communication with the boiler during the whole time. Steam, however, is capable of much better use than this, because it has a great amount of latent or stored energy which is capable of making the steam in a cylinder expand and push forward the piston after the admission valve has been closed and all communication with the boiler is cut off. This is what is done in the steam engine and in consequence no steam engine, in good working order, requires as much steam or as much coal to operate it as does a direct-acting pump of corresponding power.

Inventors seem to take a great deal of satisfaction in seeing their machinery run. If it is a rotary engine and *it runs* they delude themselves and the public by assuming they have scored a success, without realizing, apparently, that it is quite as important to know *how* it runs from an economic standpoint. If the invention is a steam turbine this is equally true. It is not difficult to make a wheel with blades and to direct a steam jet from the end of a steam pipe against the blades. The wheel will buzz around but it will require so much steam to make it buzz that it will be of no practical use.

In the construction of a successful steam turbine, it is necessary first of all to devise a method for using steam expansively, as in the steam engine; and second, to so proportion the wheel that it will get as much of the available energy out of the steam as possible and convert it into useful work, following in this respect the methods that have been applied in water turbine design. In addition, the fact must be considered that the steam turbine has to rotate at extremely high speeds, thus introducing constructive problems peculiar to itself. As stated at the beginning, it is the steam end of the turbine with which we are chiefly concerned in the present article.

Straight and Diverging Nozzles.

The success of the De Laval steam turbine is largely due to the form of steam nozzle used, by which the jet is directed against the wheel, and it will be shown later that the principles used in proportioning the De Laval nozzle hold with as much force in proportioning the parts of other types of turbines, even where no nozzles are employed.

A great many experiments have been conducted on the flow of steam through straight nozzles or short lengths of pipe, like that in Fig. 1, and it is found that when discharging into the atmosphere at ordinary pressures the velocity of discharge is not far from 1,450 feet per second. When flowing from a boiler pressure of 200 pounds the velocity is about 1,500 feet per second and when flowing from a pressure of 25 pounds, about 1,400 feet, showing that a difference in pressure does not make a great difference in the velocity, owing mainly to the fact that the density of the steam and the weight to be moved increase with the steam pressure.

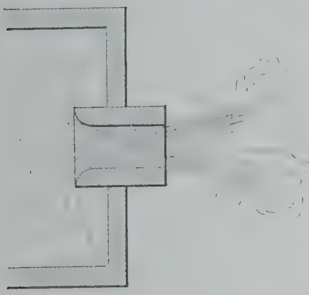

Fig. 1. Straight Nozzle.

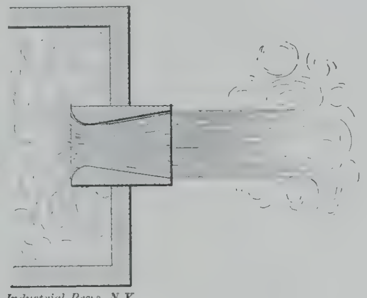
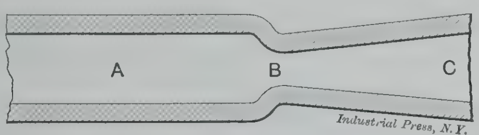


Industrial Press, N.Y.

Fig. 2. Expanding Nozzle.

Another important fact determined by test is that the pressure in the nozzle does not vary greatly from 60 per cent. of the boiler pressure, this percentage being nearly constant under ordinary conditions, without regard to whether the boiler pressure is high or low. When the steam issues from the nozzle, therefore, and drops to atmospheric pressure, it must fall in pounds an amount equal to 40 per cent. of the boiler pressure. In making this drop the steam is free to expand in all directions and its energy becomes dissipated. The jet enlarges after issuing, becomes broken up and scattered and is inefficient for turbine propulsion. The success of the jet turbine must therefore depend upon securing a more efficient jet, one in which the expansion of the steam is made to give it a higher velocity, instead of to increase the size of the jet after it leaves the nozzle.

This is accomplished by using a diverging nozzle, larger at the outlet than at the inlet, similar to the steam nozzle that has been employed for many years in some types of steam injectors. In such a nozzle, as shown in Fig. 2, the steam expands to atmospheric pressure within the nozzle itself and when the steam discharges it takes the form of a solid cylindrical jet, equal in diameter to the outlet diameter of the nozzle. The walls of the nozzle confine the steam so it can expand only in one direction, lengthwise, or the direction in which the steam is flowing. Thus the expansive force of the steam is all utilized in giving the steam velocity, and none of it is wasted in dissipating the jet, as with the straight nozzle. The velocity with a diverging nozzle, when expanding to atmospheric pressure, is about 3,100 feet per second for a boiler pressure of 200 pounds, or more than twice the velocity with a straight nozzle. At 100 pounds pressure the velocity is about 2,800 feet, a gain of nearly 90 per cent. over the 1,450 feet quoted above for the straight nozzle. The gain in *energy*, however, is much greater, since the energies of the two jets are as the squares of the velocities, or in this case approximately as 7,800,000 is to 2,100,000.



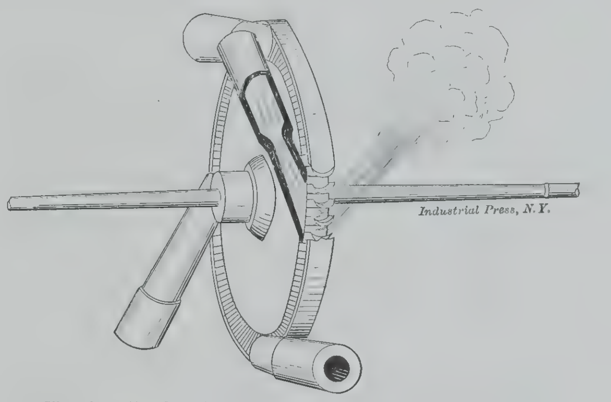
Industrial Press, N.Y.

Fig. 3. Expanding Nozzle.

In Fig. 3 is shown a longitudinal section of a diverging nozzle. Steam enters through the pipe, *A*. At *B* is the contracted entrance to the nozzle, and at *C*, the outlet. At *A* the steam is at boiler pressure; at *B* the pressure is 6-10 boiler pressure, as in the case of the straight nozzle, and the velocity at this point is approximately 1,450 feet per second for a boiler pressure of 100 pounds. From *B* to *C* the steam expands from 6-10 boiler pressure to atmospheric pressure. During the expansion part of the steam is condensed and the specific volume—that is, the space occupied by unit weight—is much greater at *C* than at *B*, and still greater than at *A*. In proportioning the nozzle, therefore, the cross sectional area at *C* must be enough greater at *C* than at *B* to allow for the greater specific volume of the steam at the lower pressure; but inasmuch as the steam is moving faster at *C* than at *B*, the areas must be modified accordingly. They may be calculated by compound proportion, making them directly proportional to the specific volumes of the steam at inlet and outlet and inversely as the velocities. Space does not now permit, however, a mathematical discussion of the subject, and readers who care to pursue the subject further are referred to Kneass's Theory and Practice of the Injector, and Peabody's Thermodynamics, both published by John Wiley & Sons, New York.

The De Laval Turbine.

The first turbine to use the expanding nozzle was the De Laval. It consists of a single disk with buckets or vanes on its periphery, against which the steam jets impinge, as indicated in Fig. 4. The steam enters a ring-shaped chamber surrounding the casing of the turbine and cast in one piece with it, and from this it enters the several nozzles that convey the steam to the turbine buckets. The speed regulation is by means of a throttling governor. The power of the turbine depends upon the number of nozzles in action at a time. Each nozzle may be connected with or disconnected from the steam chamber by a hand-operated valve, and the wheel runs with almost as good economy when one nozzle is operating as when there are several, in marked contrast to the action of the reciprocating steam engine under light loads. The expansion of the steam in the nozzles is practically adiabatic, there being no loss in temperature except through radiation, and the expansion in the nozzles is complete. The economy of the wheel, therefore, hinges mainly upon the degree of success in utilizing the energy of the jets. Theoretically the wheel should have a peripheral speed of about 50 per cent. of the speed of the steam jet. Practically this would be impossible without bursting, and the highest speed at which it is thought advisable to run the wheel is 1,350 feet per second, which speed requires a special steel and special construction of the wheel. It is possible, however, to obtain results comparing favorably with steam engine performance even under these conditions. A 300 H. P. turbine was tested recently at the Trenton factory by Dean and Main, consulting engineers, with the following results:



Industrial Press, N.Y.

Fig. 4. Wheel and Nozzles of the De Laval Steam Turbine.

Number of Nozzles Open.	Loads, Brake H.P.	Relative Loads per cent.	Steam per B. H. P. per hour lb.	Quality of Steam.
8	352	100	13.94	Superheated
7	298	85	14.35	"
5	196	56	15.53	"
8	333	100	15.17	Saturated
7	285	86	15.56	"
5	195	59	16.54	"
3	119	36	16.40	"

The very high speed at which the De Laval wheel must run in order to utilize a considerable proportion of the energy in the jet makes it necessary to provide for speed reduction and this is accomplished by spiral gears. While these and other features of construction are of the greatest interest, they cannot be dwelt upon here.

The Westinghouse-Parsons Turbine.

There are three conceivable ways in which steam might be used expansively in a steam turbine. First, by expanding in a diverging nozzle, and allowing the jet to impinge against the wheel buckets; second, by expanding the steam within the spaces between the vanes and between the blades of the wheel as the steam passed through the turbine; and third, by a combination of the two methods.

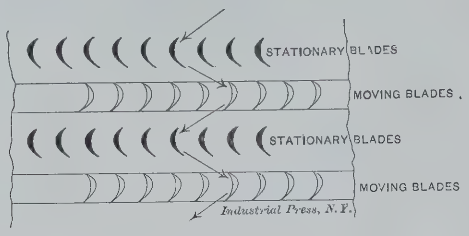


Fig. 5. Blade Arrangement of Parsons Turbine.

The Parsons turbine is in the second group. This turbine has alternating rings of revolving and stationary blades through which the steam passes in much the same way that water passes through the well-known flooded or pressure type of water turbine, as opposed to the impulse type of which the Pelton water wheel and the De Laval steam wheel are examples. The arrangement of the blades and the passage of the steam are indicated roughly in Fig. 5, and the general plan of the turbine in Fig. 6. In the Parsons wheel the whole turbine casing may be said to correspond to the expanding nozzle of the De Laval wheel. Steam enters at one end, at boiler pressure, and expands as it passes among the blades, increasing in speed at the same time, just as in a diverging nozzle. Referring to Fig. 6, steam enters chamber *B* through steam pipe *A* and passes to the right through the first group between the blades to chamber *C*. At this point so much space is required for the steam blades that it is necessary to jump to a larger diameter and the steam flows through a second set to *D*, and finally through a third set to *E*. The disks *a*, *b*, and *c* are for the purpose of equalizing the end thrust of the turbine, due to the pressure upon the blades. Steam is admitted to the turbine in puffs, by means of a reciprocating valve under the control of a governor. The Parsons turbine runs slower than the De Laval turbine, since the steam travels at a much lower rate of speed through all except the last few rings of blades. A Westinghouse-Parsons turbine of somewhat novel design is described in the engineering review of this number.

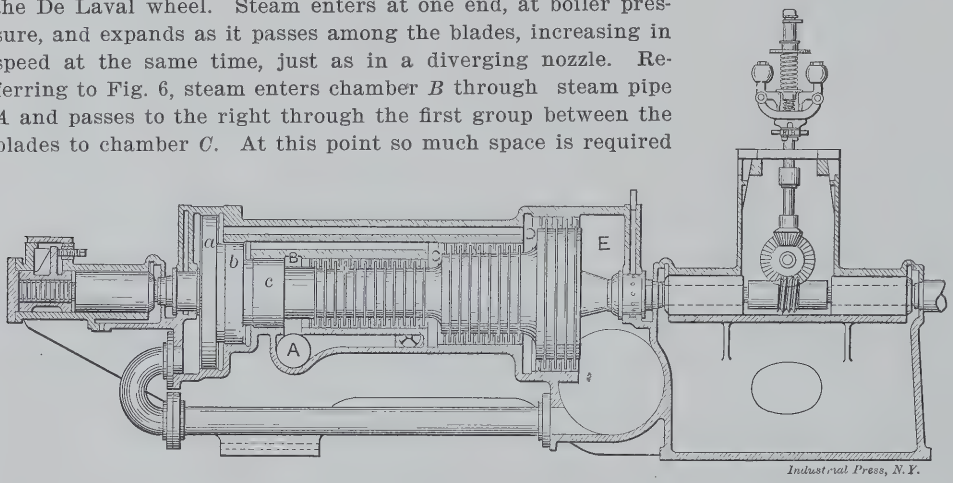

Fig. 6. Section through Parsons Turbine.

The Curtis Turbine.

This, the latest candidate for favor, is a combination of the De Laval and Parsons plans. A steam nozzle is employed to expand the steam, but the expansion is not complete in the nozzle, Mr. Curtis preferring to have a certain amount of expansion occur in passing through the wheel to overcome any retardation that might take place through the friction between the blades and the steam.

As already explained, the best results with a jet turbine are obtained by having the peripheral velocity of the wheel about half the velocity of the steam jet. When, as must always be the case, a turbine wheel runs at a peripheral speed less than one-half the velocity of the steam jet, the steam will have a residual velocity as it leaves the wheel; and the slower the wheel runs the greater will be the residual velocity, and hence the waste energy. In the Curtis turbine a modified form of the De Laval nozzle is used, the wheel is run at comparatively low speed, and the residual velocity of the exhaust steam is used to run a second wheel on the same shaft, thus making a compound turbine.

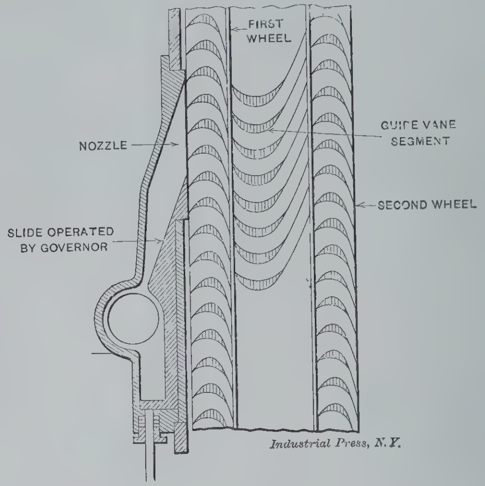

Fig. 7. Section through Nozzle and Vanes of Curtis Wheel, showing Governing Arrangement.

In its simplest form the Curtis turbine consists of two rings of curved buckets mounted upon disks revolving with the shaft. Between the two revolving rings is a group of curved blades in the form of a short segment fixed to the interior of the turbine case. The nozzle is of rectangular cross section, so designed that one side of it can slide under the action of the governor without altering the ratio between the inlet and outlet area of the nozzle, as illustrated in Fig. 7. By this means the quantity of steam delivered is adjusted to suit the load, whereas regulation in the De Laval turbine is accomplished partly by throttling and partly by using one or more nozzles, as required. For marine work the Curtis wheel has two sets of concentric rings of blades. One set is used with a nozzle on one side of the wheel for forward rotation and the other set with a nozzle on the opposite side of the wheel for backward rotation. A number of patents have been taken out by Mr. Curtis embracing features calculated to produce good economy, but the foregoing will give a general idea of the wheel. In the yacht *Revolution*, driven by a Curtis wheel, compounding is carried far enough to reduce the speed of rotation to about 650 revolutions a minute.

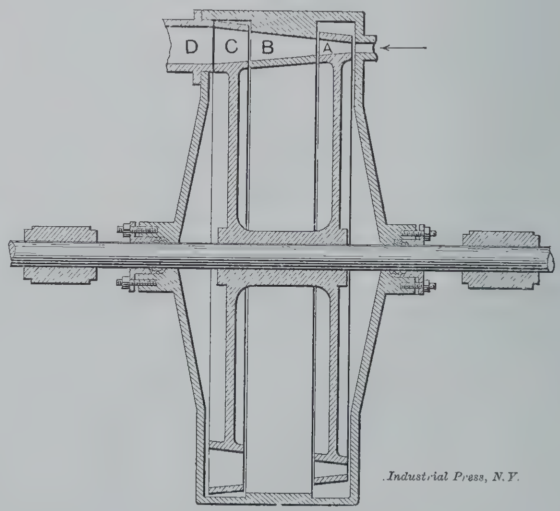

Fig. 8. Section through Curtis Compound Steam Turbine.

Referring to Fig. 8, the method by which compounding is effected and the expansion of the steam occurs is clearly illustrated. Steam enters in the direction of the arrow, passes through the nozzle and the constantly increasing space between the blades. *A* and *C* are the wheel blades, rotating together on the same shaft, *B* represents the intermediate stationary blades and *D* is the exhaust passage.

A DEVELOPMENT OF MACHINE SHOP FORMULAS.

METHODS FOR FINDING THE COST AND PROPORTIONS OF MACHINES BUILT IN A SERIES OF SIZES.

Stanley H. Moore.

The problem of cost reduction forces itself, with increasing vividness, upon the mind of every person who has to do with the manufacture of machinery. To the "small shop" people, and to those whose product is unsystematized and whose ideas of methods to pursue are, as yet, vague, this article may prove of some assistance.

There are three important means by which the shop product may be systematized: By the use of formulas; by the use of tables; and by the use of charts. As the two latter may be considered as the tabulated, or graphic results of the former we will deal only with the formulas. In determining sizes, weights and costs, these formulas are generally most efficient time-savers. For convenience, formulas in this article will be divided into two classes: The class used to produce the first of a type of machine we will call fundamental; and the class used to produce several sizes of this type of machine, empirical. Upon seeking fundamental formulas in text books and in mechanical engineers' pocket books we are confronted by a diversity of opinions and tabulated results that are, at least to the novice, a bit confusing. These formulas, it is always to be remembered, have their application in the special case under consideration, and are to be used only as guide posts in our journey of design. It is evident to most designers, I think, that some sort of a tentative method must, sooner or later, be resorted to in the type design, for in nearly all machines the governing conditions soon become so numerous or indefinite as to render a subdivision of the problem a necessity.

A certain amount of judgment is absolutely essential in the use of most fundamental formulas, and discrimination is always necessary. To illustrate, suppose that we have to determine the diameter of a particular shaft and we find in our various authorities some such formulas as these:

$$D = C' \sqrt[4]{\frac{H\,P}{N}} \quad \text{(No. 1)} \qquad D = C_1' \sqrt[3]{\frac{H\,P}{N}} \quad \text{(No 2)}$$

The above formulas have their origin in the simpler one of

$$D = C \sqrt[4]{F\,L} \quad \text{(No. 3)} \qquad D = C_1 \sqrt[3]{F\,L} \quad \text{(No. 4)}$$

where $D =$ the shaft diameter, $C =$ the constant for the material, $F =$ the force tending to rotate the shaft, and $L =$ the length in inches from the point of application of F to the center of the shaft. Formula No. 3 is based on the fact that under this condition the torsional deflection of the shaft shall not exceed a predetermined angle per foot in length; and formula No. 4 under the condition that the moment FL produces a torsional stress not more than a predetermined amount per square inch. It is evident that if a complete table of values for C under varying conditions is not given, these formulas are rendered but little better than none.

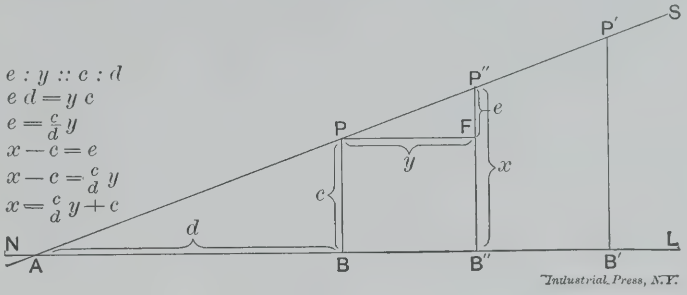
Graphically these two fundamental formulas could be represented by biquadratic, and cubic parabolas respectively; while our empirical formulas would rest on no such basis and would hold true for but a certain series within certain limits. This constitutes the vital difference between our fundamental and our empirical formulas.

Suppose that we have built two or three sizes of a certain type of engine and that they are successful; we desire to put on the market an entire line. Our sizes of this type of engine will run from 10-inch cylinder diameter in the smallest to 30-inch cylinder diameter in the largest. We have built a 12-inch and a 24-inch engine and perhaps an 18-inch. These engines were, as was imperative, tentatively designed. In seeking the derivation of the empirical formula for the length of the crosshead shoe we find that on our 12-inch we have given it an area of 52½ square inches, and on our 24-inch its area is 190⅛ square inches. In each case the length of the shoe was nearly twice its width, so we decide to make it so in our line of engines; solving for the width, we have in the 24-inch.

$$2\,x^2 = 190.125$$
$$x = \sqrt{95.0625}$$
$$x = 9.75$$

making our shoe length for the 24-inch engine 19½ inches, and for the 12-inch engine 10½-inches.

To any scale in Fig. 1, perpendicular to the line *NL*, lay off these shoe lengths *PB* and *P′B′*—10½ inches and 19½ inches, respectively—making the distance *BB′* equal to 12 inches, the difference between our sizes 12 inches and 24 inches. Through points *PP′* draw line *SA* intersecting *NL* at *A*. At *B″*—for our 18-inch size—erect a perpendicular *B″P″*. Draw *PF* intersecting *B″P″* at *F*. Using the notation given in the figure and from its geometry we get the simple equations shown in Fig. 1.



$$e : y :: c : d$$
$$e\,d = y\,c$$
$$e = \frac{c}{d}\,y$$
$$x - c = e$$
$$x - c = \frac{c}{d}\,y$$
$$x = \frac{c}{d}\,y + c$$

Fig. 1.

In this last formula many will recognize an old acquaintance—the equation for a straight line—which in one of Prof. Perry's books proves such an efficient servant. Let us now analyze this equation. From the figure it is seen that $x =$ the desired dimension and that $\frac{c}{d} =$ the rate of increase in the slope of the line. If now we measure the distances and substitute their values for c and d we may determine the ratio $\frac{c}{d}$ which we will call f.

Then $f = \frac{c}{d} = \frac{10\frac{1}{2}}{14} = \frac{3}{4}$: again $x = f\,y + c$, or $x = \frac{3}{4}\,y + 10\frac{1}{2}$.

In interpreting our empirical formula $x = fy + c$, we have

$y =$ a common unit to which all other sizes are to be referred,
$x =$ desired dimension,
$f =$ a factor of y,
$c =$ a constant increment to be added in each case.

The unit value of y as generally selected is a bolt or cylinder diameter, or the capacity of the machine. Obviously in our line of engines we select the cylinder diameter D as our value of y, and our unit formula then becomes $\frac{3}{4}D + c$. The value of c is now determined by direct substitution in the following manner: x being the shoe length, we substitute for it 19½ inches its length on the 24-inch crosshead; then

$$\tfrac{3}{4}\,(24) + c = 19\tfrac{1}{2}$$
$$c = 19\tfrac{1}{2} - 18$$
$$c = 1\tfrac{1}{2}.$$

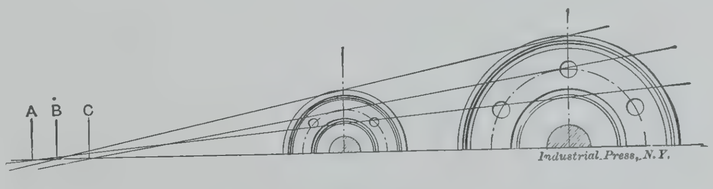


Fig. 2.

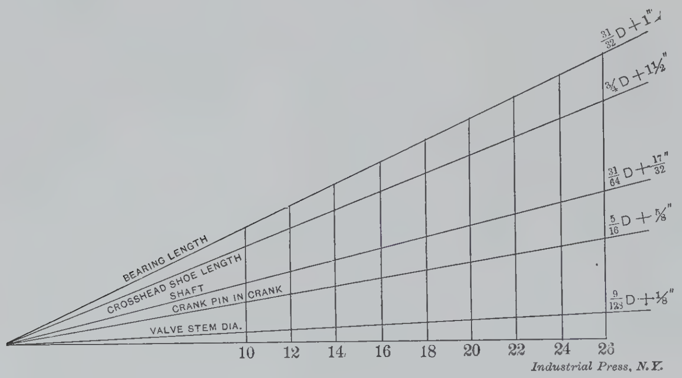
Note, that while we have assigned to y and c other values we have not altered the relations; our formula for this particular crosshead dimension now becomes $\frac{3}{4}D + 1\frac{1}{2}$ inches.

For convenience in charting these sizes some point is determined upon as a pole about which these lines (represented by our formulas) are drawn as vectors, the ordinate length for a particular size giving the desired dimension. If now in the determination of other formulas it be found, as is likely to be the case, that these lines do not all pass through a common point it becomes necessary to select one. In well designed machines the intersections of these lines with the base line will come close together and an average of these intersections is selected as a pole. Figs. 2 and 3 will serve to illustrate the purport of this paragraph.

Experienced designers are well aware that the final test of any dimension in a design is that of satisfying all fundamental calculable conditions; nevertheless, the instances where our empirical formulas prove incorrect are very few indeed.

With the design for our line of engines thus systematized, let us consider what are to be the advantages that will naturally result from it. In the first place, the weights of any particular parts, or details of any size in our line of engines may be determined prior to its design or manufacture.



Industrial Press, N.Y.

Fig. 3.

In the determination of weights, cubic contents and similar processes, the use of "differences," as applied to higher mathematics, will not only prove an efficient time-saver, but relieve much of the drudgery attendant upon such operations.

A brief explanation of the use of "differences" is as follows: When we have a series of numbers connected by a regular, though not obvious law, the nature of that law may be discovered by forming a new series of differences between each term of the original series and the next, and then treating the new series (which we may call the series of first differences) in the same way, until we reach a series of differences the law of which is obvious. In the following table will be found both the arithmetic and algebraic solutions of problems by "differences."

In column 1 of the table is given a series of numbers which we suspect follows some definite, though not obvious law, and which we desire to discover. Having proceeded with the several orders of differences, the law becomes apparent early in the process of determining the values in column 3. Referring again to the table, it is evident that the next term of column 3 must be 11, which gives 68 as the next term of column 2 (the series of first differences) and so 312 for the original series. Note that this series can thus be continued indefinitely, and that ultimately, in any regular series, some one series of differences will become a constant.

Industrial Press, N.Y.

Solutions of Problems by Differences.

It is on the principle of differences that calculating machines are constructed to compute logarithmic tables, etc.

In the algebraic solution of such problems involving the determination of weights and volumes, it will be necessary to calculate these weights or volumes for the 1st, 4th, 7th and 10th terms of our given series. By substituting in the formulas in column 5 the numerical value of W, which is the 1st term in our given series, we may equate these expressions and our calculated values for the 1st, 4th, 7th and 10th terms and determine, by simple algebraic processes, the values of c, x, y, and ultimately, that for which we are seeking the values in the original series, column 5.

The computations concerning the cost of materials logically follow the determination of volumes and weights and are made with comparative ease. However, our next problem concerning the determination of the cost of labor is a more difficult one to solve. Our formula generally expresses this cost as so many cents per pound of product, includes all shop charges, and is established partially by experience and partially by methods suggested in this article.

In many instances it will be found both desirable and convenient to have this cost formula embody the unit dimension. When this is the case, the formula is, as are most cost formulas, established by the tentative methods to which we have just alluded. As the methods employed in the deduction of these formulas render them purely empirical, one or another form of expression may have to be adopted. However, formulas of this class usually assume the form of, or at least may be resolved into, the familiar trinomial of the type form

$$ax^2 - bx + c,$$

where a and b are factors of the unit dimension, and c is a constant.

For the purpose of illustration we will assume that the formula for the cost of labor which we have established is

$$\tfrac{3}{2}D^2 - 15D + 314.$$

In this form the formula gives the total cost of labor in dollars for the size desired. The cost of labor C for our 18-inch engine would then be

$$C = \tfrac{3}{2}(18)^2 - 15(18) + 314$$
$$C = 486 - 270 + 314$$

from which

$$C = 530$$

The computation of a final cost formula, embodying the unit dimension, is the last process in our development of shop formulas; this formula is derived directly from those relative to the costs of material and labor.

When estimating on new work or possibly designs to be submitted, instead of the usual rush in the drafting room with its attendant liability to error, contrast the ease with which our salesman or general manager, substituting in the final formula the current prices of labor and material, accomplishes the desired result. By the use of these formulas surprisingly close estimates may be furnished on sizes not yet designed or manufactured; then, too, we submit to our prospective customer a standard design of known qualities.

I am well aware that the above picture is ideal and somewhat overdrawn, but nevertheless it is an ideal toward which many a shop might strive with much profit to all concerned, and especially to those whose money is invested in the enterprise.

* * *

It would be possible to substitute aluminium for copper in electrical work to a considerable extent—provided the metal can be had in sufficient quantities for the purpose. That is, after all, the most important question. For all immediate purposes the question seems to be answered by the fact that in 1900 the total production of aluminium in the world was 5,570 metric tons, of which the United States furnished 2,053 tons; while that of copper was 492,625 metric tons, of which 272,536 tons were supplied by this country—that is, the total output of aluminium last year was only 1.1 per cent. of that of copper. The price of aluminium at present is about on a par with that of copper, allowance being made for the respective weights. The aluminium quotations, however, have not been regulated by those of copper, but have been based upon the cost of production, and have shown little change during the past year. There is no competition tending to lower them; but, on the other hand, it is to the interest of the producers to keep them as low as possible in order to dispose of their output.—*Engineering and Mining Journal.*

ENGINEERING REVIEW.

A SYNOPSIS OF CURRENT TECHNICAL LITERATURE.

LITHOGRAPHED MARGIN LINES AND TITLES FOR DRAWINGS.

American Engineer and Railroad Journal, October, 1902. p. 317.

Lithographed margin lines and titles for drawings are used in the mechanical engineers' department on the Lehigh Valley. Mr. Gaines has sent a tracing and letter describing the method. When a large number of sheets are lithographed at one time, and the tracing cloth is furnished in rolls, the average cost of cutting the cloth and lithographing the margins and general title is less than two cents per sheet. The average cost of doing the work by hand is about eight cents per sheet, and is not as uniform and regular as when lithographed. In lithographing these tracings, the trimming and margin lines, holes for punching and general titles may be put on as desired, and the tracing sheet is ready for the draftsman, who proceeds with the drawing without delaying to lay out the sheet. He completes the title and fills in the date when the drawing is finished.

PNEUMATIC TUBE SERVICE.

Railroad Gazette, 1902, p. 657.

A pneumatic tube service has been instituted in Boston for delivering parcels from the retail store to the outlying districts. The central station has been erected in the center of the shopping district at the head of Harrison Avenue, and from this station two pairs of tubes have been laid to substations. The tubes are cast-iron water pipes machined at the ends so as to make a close fit. The joints are closed in the same manner as when laying water pipe, using oakum and lead. Curves are laid 12 feet radius to the center line of the pipe. The carriers are metal cylinders provided with five friction wheels at each end to support it in whatever position it may assume in the tube. This is a radical departure from the system commonly used in department stores—in which the carriers are usually provided with felt rings at the ends to act as supports and also as packing to closely fit the tubes. The air pressure required to force the cylinders along the tubes in the Boston system varies from 1.75 to 2.1 pounds per square inch depending on the number of parcels in the tubes at one time. A parcel is delivered by the pneumatic system to the Dorchester station in 10 minutes, a distance that took a team 40 minutes.

THE USE OF ALUMINUM IN METAL PATTERNS.

Aluminum World, September, 1902, p. 231.

Harland Tuttle says that aluminum is a valuable metal for metal patterns, especially small patterns that are carded. On account of its lightness, which is, of course, its chief advantage, much larger patterns can be carded than is possible with the soft metal alloys. For instance, the specific gravity of aluminum is 2.5, while that of the tin-zinc and the tin-antimony alloys is about 7, and of zinc-lead alloy about 9. It will thus be seen that with the same size gates, patterns of aluminum can be carded of three times the volume of the soft alloy patterns with the same liability of breakage. Mr. Tuttle has the care of some three hundred cards, about two-thirds of which are aluminum. There are by actual count between thirty and forty broken joints of the soft metal cards brought in to be soldered to one of the aluminum. The cost of carrying cards to and from the foundry and the repairing of them amounts to quite an item in a year, most of which is saved by the use of aluminum cards.

Another advantage, due to its lightness, is that with fairly large patterns more can be placed on a card, while often patterns which would be too large to card in the heavy alloys can be carded to advantage in aluminum. The necessary amount of rappage to loosen the patterns in the sand is also much less, thereby lengthening the life of the card, while the molders like them much better because of the greater stiffness and ease of handling. The metal is also especially adapted to light, flimsy patterns, as it will not bend out of shape from dropping or by conforming to the shape of a worn-out follow-board, as soft alloy patterns do. In regard to the first cost, aluminum makes a very cheap pattern metal on account of its bulk, aluminum at 30 cents making patterns cost about the same as a tin-antimony alloy at 12 cents. In regard to corrosion of aluminum, patterns have been in continual use for six years, which are in as good condition as the new ones, except more discolored. The patterns grow smoother with use.

COMPRESSING STEEL INGOTS BY WIRE DRAWING IN THE INGOT MOLD.

Engineering News, October 2, 1902. p. 262.

In the production of steel ingots there always exists a tendency toward the formation of a cavity at the center, and gas bubbles entrained in the molten metal at the moment of cooling give rise to blow holes. It has long been a problem for inventors and engineers to procure solidity in the production of these ingots. In the system devised by Sir Joseph Whitworth, the top of the ingot after casting is subjected to heavy pressure. This process has never come into extensive use owing to the fact that in applying pressure at the top, the outer shell of the ingot resists the pressure like a hollow column. What is wanted is to drive the sides of the ingot toward the center, and lateral compression of ingots has been proposed and actually carried out by some American experimenters.

At the recent meeting of the Iron & Steel Institute at Dusseldorf there was described a new method of compressing steel ingots by a so-called wire-drawing process. The ingot mold is made slightly tapering, being largest at the bottom, and is heavily hooped to sustain internal pressure. After the mold is filled with molten metal and solidification has begun the mold is run upon a hydraulic press and a plunger is brought to bear against the bottom of the ingot, forcing it upward, and compressing it by reason of the tapering walls of the ingot mold.

This process has been adopted at the steel works at St. Etienne, France, where a process of ingot compression similar to Whitworth's was in use many years ago.

HEAT TREATMENT OF STEEL RAILS AND STRUCTURAL SHAPES.

American Engineer and Railroad Journal, October, 1902. p. 310.

The temperature at which steel rails and structural shapes are finished bears a vital relation to the character of the product. Rails finished at a high temperature will be coarse in structure, which means rapid wear in service and usually brittleness of structure, although not always the case. Sometimes rails finished at, say, a bright yellow and having a coarse granular structure, will successfully stand the impact of 2,000 pounds falling a distance of 20 or 25 feet. But these coarse-grained rails always give relatively poor wearing service, therefore it behooves the consumer to insist on the finer granular structure as revealed by the microscope.

To prevent rails being produced having a coarse granular structure, it is necessary that they be worked down to the critical point before leaving the rolls to be cut up by the hot saws. In order to have a rail, say, 30 feet long when cold, it is necessary to cut them as much longer as the expansion due to temperature may determine. When the rails are delivered to the saws at high temperatures as was the practice under the old system, it is necessary that these saws be spaced apart about 7½ inches in excess of 30 feet. To insure that the rails be worked down to a lower temperature it has been proposed to limit the excess distance at which the saws may be set to 6¼ or 5¾ inches, but this precaution alone is not sufficient as the rails may be held long enough before the last pass to cool down to the proper temperature and then run through with scarcely any appreciable reduction. The result, of course, is that the structure is coarse since the bulk of the working has been carried on at a too high temperature.

The standard specifications of the P. & R. R. R. require that the temperature of the ingot or bloom be such that with rapid rolling and without artificial cooling after the last pass, the rails may be cut up into 30-foot lengths with the hot saws spaced 30 feet 6 inches. It is desired that thorough working of the steel in the rolls shall not cease until the temperature is as near as practicable to the recalescent point or until about a low red heat has been reached. These specifications also require that a section of rail 4 ft. long taken from the top of the ingot shall stand an impact test of 2,000 pounds falling a distance of 18 feet, the supports being 3 feet apart, center to center. This is for rails weighing 70 pounds per yard. For heavier rails the drop shall fall 23 feet. The anvil block supporting the rail shall weigh not less than 20,000 pounds, and the striking face of the weight shall have a radius of not more than 5 inches. For rails of 70 to 79 pounds per yard, the carbon shall be from .43 to .53; phosphorus shall not exceed .10; silicon not to exceed .20; and manganese .75 to 1.05. The carbon and manganese are allowed to exceed these figures slightly for heavier sections, being .53 to .63 carbon and .80 to 1.20 manganese for 90 to 100 pound rails.

NEW FORM OF PRESSED CAR WHEEL.

Railway and Engineering Review, September 6, 1902, p. 666.

Mr. H. F. Mann, Allegheny, Pa., has recently been granted a patent on a new form of plate-metal car wheel which comprises improvements in the web, tread, and rail-flange, these parts being formed of a single plate of steel or of a single plate of steel and iron, the hub of the wheel being formed separately of suitable material and securely attached to the center of the web. It is claimed that this construction will make a car-wheel which will be light and strong and possessing to a high degree the requisite wearing qualities on the tread and rail-flange. In order to secure the desired results and make a car-wheel which will have the necessary strength and possess the desired degree of hardness on the outer or wearing surface of the tread and rail-flange, the web, tread, and flange are made of a single plate of steel or single plate of steel and iron. If the plate is made of steel, about three-fourths of its thickness is to be composed of low-carbon, tough, and strong steel and about one-fourth of its thickness of high-carbon hard steel. If the plate is to be made of steel and iron, three-fourths of its thickness is to be composed of wrought-iron and one-fourth of its thickness of high-carbon hard steel. In either case the different compositions of metal of which the plate is made are welded together. The hub may be made of wrought steel or iron or of cast metal; but in cases where it is to be secured to the web or washer in whole or in part by welding, it should be made of suitable metal for welding. The accompanying illustrations show a sectional view of a plate, *A*, of steel, or steel and iron of suitable diameter and thickness to form the web, tread, and rail-flange of the wheels; and one form of the web, tread and rail-flange after the plate has been subjected to the operation of suitable dies or other processes to give it the desired form, *B*. In making car-wheels of plates composed of steel or steel and iron, as above described, they should be so formed as to bring the high-carbon hard steel on the outer surfaces of the tread and rail-flange, in order to secure the best and most durable wearing qualities of the plates at these points where it is most needed. The central portion of the web is curved outwardly, so as to furnish a strong bearing in which the hub, *C*, is to be seated and secured. In order to secure additional stiffness to the web, it may be corrugated, and several other modifications are possible.

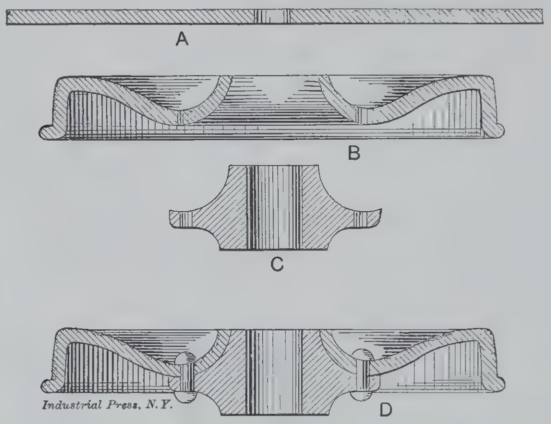

Fig. 1. Pressed Car Wheel.

SAFE SPEED FOR FLYWHEELS.

Monthly bulletin of the Fidelity & Casualty Co.

Wm. H. Boehm.

It is a well understood fact that while an engine pulley or flywheel can be designed to successfully resist the torsional stresses due to any load required of the engine, there is no possible way to overcome the centrifugal force due to speed.

For a given material there is a definite speed at which disruption will occur, regardless of the amount of material used. This is not an uncertain theory, but a mathematical truth easily demonstrated, and is expressed by the following formula:

$$V = 1.6\sqrt{\frac{S}{W}}$$

in which V is the velocity of the rim of the wheel in feet per second at which disruption will occur, W the weight of a cubic inch of the material used, and S the tensile strength per square inch of the material.

In words the formula means that if we divide the tensile strength of the material by its weight per cubic inch, extract the square root of the quotient and then multiply this by 1.6, the result will be the rim speed in feet per second at which disruption will occur.

If instead of the ultimate strength of the material we take its safe strength, the result will be the rim speed in feet per second at which the wheel may be run with safety; the supposition so far being, however, that the rim is made solid in one piece of homogeneous material and free from shrinkage strains.

Applying the formula to determine the safe rim speed for cast-iron wheels made in one piece, we would assume that, if the ultimate strength of small test bars were 20,000 lbs. per sq. in., we could depend upon having 10,000 lbs. in large castings.

Using a factor of safety of 10 on this would give 1,000 lbs. per sq. in. as the safe strength of this material. The weight of a cubic inch of cast iron is approximately 0.26 lb., so that we have for cast-iron wheels:

$$V = 1.6\sqrt{\frac{S}{W}} = 1.6\sqrt{\frac{1000}{.26}} = 99.2$$

per second.

So that 100 feet per second may be regarded as a safe rim speed for cast-iron wheels made in one piece. This corresponds to about 1.15 miles per minute, but as such wheels are likely to contain shrinkage strains, it is not considered good practice to run them faster than a mile a minute.

If the wheel is made in halves, or sections, the efficiency of the rim joint must be taken into consideration. For belt wheels with flanged and bolted rim joints located between the arms, the joints average only one-fifth the strength of the rim, and no such joint can be designed having a strength greater than one-fourth the strength of the rim. If the rim is thick enough to allow the joint to be reinforced by steel links shrunk on, as in heavy balance wheels, one-third the strength of the rim may be secured in the joint, but this construction cannot be applied to belt wheels having thin rims.

Applying the formula to wheels made of cast steel, having an ultimate strength of 60,000 lbs. per sq. in., or a safe strength of 6,000 lbs. per sq. in., and weighing 0.28 lb. per cu. in.; we have.

$$V = 1.6\sqrt{\frac{S}{W}} = 1.6\sqrt{\frac{6000}{.28}} = 234.3$$

per second.

So that a cast-steel wheel made in one piece and free from shrinkage strains could be run with perfect safety at a rim speed of 234 feet per second, corresponding to 2.66 miles per minute.

It will perhaps surprise some of our readers to learn that wheels made of wood may be run at a higher speed than those made of cast iron. Wood, however, is one of the very best materials that can be used for flywheel construction, and many large wheels have been constructed of this material and are giving satisfactory results.

Applying the formula to hard maple having a tensile strength of 10,500 lbs. per sq. in., and weighing .0283 lb. per cu. in., we have, using a factor of safety of 20, and remembering that the strength is reduced one-half because the rim is built up of segments,

$$V = 1.6\sqrt{\frac{S}{W}} = 1.6\sqrt{\frac{262.5}{.0283}} = 154.1$$

per second.

So that a well-made maple wheel may be run with perfect safety at a rim speed of 154 feet per second, which corresponds to 1.75 miles per minute. Or comparing two wheels of the same diameter, one of cast iron, the other of maple, the number of revolutions per minute for the maple wheel may be 54 per cent. greater than for the cast-iron wheel. One hundred and fifty-four feet per second would not, however, be a safe rim speed for the wood wheel if made in halves or sections, on account of the weakness of rim joints.

Of late years wheels for large electric plants have been built up of steel plates riveted together, and wheels for special work or unusually high speed have been specially designed. It is questionable, however, whether the complicated built-up steel construction is profitable for wheels of standard steam engines as commercially built. When an engine runs fast enough to burst a well-made cast-iron wheel it is doubtful whether anything could save it. The small amount of time required for the additional acceleration necessary to burst a steel wheel at that stage would be little, and when the crash did come, it would be all the more disastrous.

From the above formulas it will be seen that the stress in the rim of a wheel increases with the square of the speed, or, to put it another way, the factor of safety on speed is always the square root of the factor of safety on strength.

If the speed be tripled, for example, the stress in the rim becomes nine times as great as before; that is, with a factor of safety of nine on strength, there is a factor of safety of only three on speed. It will be understood from this that the stress increases enormously for even a slight increase in speed.

Let us consider the usual cast-iron, sectional, belt wheel having flanged and bolted rim joints located between the arms. As pointed out above, such joints average a strength of only one-fifth the strength of the rim, and no joint of this kind can be designed that will have a strength greater than one-fourth the strength of the rim.

If this wheel had at normal speed a factor of safety of 12 in the rim, then with joints of maximum strength the factor of safety in the joint would be only 3 on strength or 1.73 on speed. That is, an increase in speed of 73 per cent. would burst the wheel.

The wide gulf in this case between the apparent factor of safety of 12 on strength and the real factor of safety of 1.73 on speed is appalling. This is, however, only another warning that things are not always as they seem.

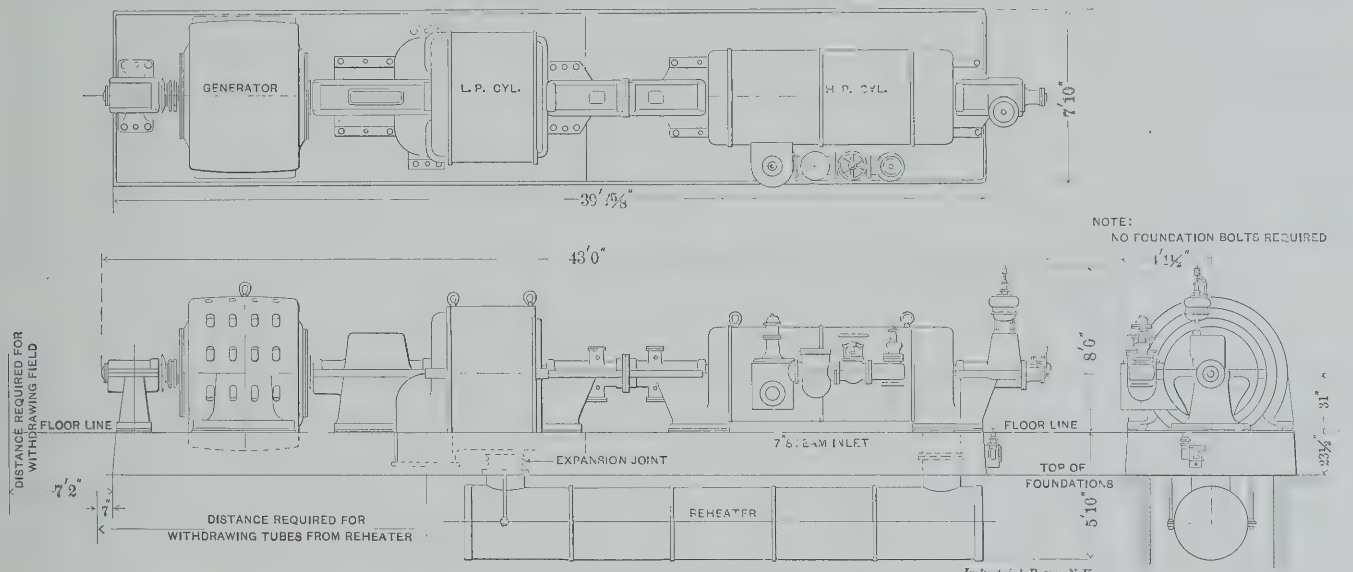
As a matter of fact, few wheels have a margin of safety of 73 per cent. on speed. In the accident at the Amoskeag Mills, in which a 30-ft. wheel wrecked the building, killed two girls and badly injured the assistant engineer, the evidence proved that an increase in speed of only 20 per cent. caused the disaster. Many wheels in use to-day are running on a narrower margin than this.

It will now be understood why racing is so frequent a cause of flywheel accidents. Some slight accident to the governor or valve gear of the engine occurs, and away goes the wheel, causing a costly if not fatal wreck. The stress in the rim increases so rapidly with increase of speed that sound wheels amply safe at normal speed, go to pieces without warning, and apparently without cause.

STEAM TURBINES FOR THE RAPID TRANSIT SUBWAY, NEW YORK.

Power, October, 1902, p. 40.

Steam turbines of the Westinghouse-Parsons type are to be used by the Rapid Transit Construction Co., New York, in connection with the lighting of the subway now under process of construction. There will be three independent direct-connected units, aggregating 3,750 kilowatts capacity, and both turbines and generators will have unique features.



Industrial Press, N.Y.

Fig. 2. Westinghouse-Parsons Steam Turbines for New York Subway.

The most striking constructive feature in the turbine is the separation of the high-pressure and low-pressure sections and the introduction of a reheater between them. This arrangement provides for a center bearing for the turbine shaft, thus reducing the distance between bearings and allowing the use of a much lighter shaft.

The turbine proper is of the multiple expansion parallel-flow type arranged, as above noted, in tandem compound. Steam entering at the throttle valve is passed through a strainer for removing all foreign matter, and thence through the poppet inlet valve, the period of admission being controlled as in former types by a sensitive fly-ball governor. The steam, after admission, expands through successive rows of alternate moving and stationary blades, forming the expansion stages of high-pressure as well as low-pressure cylinders. At a considerably reduced pressure and correspondingly augmented velocity, the working fluid now enters the reheater where it comes in contact with the superheating surface, with the result that entrained moisture is entirely re-evaporated and the low-pressure cylinder is furnished with dry steam. A similar expansion takes place in the low-pressure cylinder with a subsequent reduction of pressure and increase of velocity, and the exhaust steam, entirely deprived of its available energy, escapes through the exhaust port situated underneath the rear bearing of the low-pressure cylinder. As in former types, a by-pass is provided, connecting high-pressure and low-pressure cylinders, by means of which the turbines will be enabled to carry continuously an overload of 50 per cent. with condenser, or full load without the aid of condensing apparatus.

Connection will be provided between the generator shaft and the two parts of the turbine shaft by a special mechanical coupling. The governor will be of the fly-ball type located at the extreme end of the turbine and driven by worm gearing from the turbine shaft. It will be provided with a safety stop which, in combination with an auxiliary valve, will automatically cut off the steam supply should the speed of the turbine exceed a predetermined limit. This stop is adjustable and by its use any speed limit may be imposed upon the operation of the turbine equipment.

The construction of the reheater is entirely similar to that employed by the builders in their many types of vertical and horizontal Corliss engines. It consists of a riveted boiler plate shell, 23 feet in length and 3 feet in diameter, provided with numerous longitudinal charcoal iron tubes expanded into flanged steel tube sheets which are riveted to the shell at a short distance from the ends, thus providing a chamber at each end of the reheater for receiving and discharging the steam on the way from the high-pressure cylinder. This reheater is supplied with live steam from the boilers. To facilitate starting the turbine a small by-pass around the throttle valve will permit the introduction of a small amount of live steam for warming up the cylinder walls and rotating parts.

With 175 pounds boiler pressure the steam consumption is guaranteed not to exceed 15.6 pounds per horse power hour at full load, 18.5 pounds at half load, and 23.3 pounds at 25 per cent. load. With 75 degrees superheat the consumption is guaranteed to be about 2 pounds less than at the different loads.

The three turbo-generator sets will be installed in the Rapid Transit power house at North River and Fifty-ninth Street, Manhattan, occupying the center of the present engine room. They will rest on steel and concrete foundations built up from a solid-rock bed, and will be in line with the main generating units. The floor space occupied will be 1,824 square feet total, inclusive of 3¾-foot passageways, or 945 square feet net, which furnishes a comparative figure of 0.2 square foot per electrical horse power against 0.86 square foot per indicated horse power for three horizontal cross-compound Corliss engines of equal capacity, including generators.

HORSE POWER OF BOILERS.

Power, October, 1902, p. 13.

C. G. Robbins says: In a recent catalogue of a well-known maker of engineering specialties the writer noticed the following approximate rules for calculating the horse power of various kinds of boilers. The rules are intended for use in determining the proper sizes of injectors and other apparatus when the exact dimensions or heating surface of the boiler is unknown or hard to obtain:

Kind.	Horse Power.
Horizontal tubular	$= \text{Dia.}^2 \times \text{Length} \div 5$
Vertical tubular	$= \text{Dia.}^2 \times \text{Height} \div 4$
Flue boilers	$= \text{Dia.} \times \text{Length} \div 3$
Locomotive type	$= \text{Dia. of Waist}^2 \times$ length over all $\div$ 6.

All dimensions to be in feet.

In the first and third cases the length is the length of the tubes or that of a "flush-head" boiler and does not include the extended smokebox. In the second case, the height is that of a plain vertical boiler in which the upper part of the tubes is above the water line; it is not the height of a boiler with submerged tubes.

The extreme simplicity of the rules aroused curiosity as to their accuracy, and comparisons were made between manufacturers' ratings and ratings calculated by the formulas above. The results are given below. They agree very closely, except in a few of the larger sizes of tubular boilers, where the calculated rating falls below that of the manufacturer. And in these sizes it will be noticed that the heating surface per horse power is less than in the smaller sizes where the two ratings practically agree.

It is quite possible that the ratings of other manufacturers would show a better or worse agreement. In any event, the rules prove to be valuable for just what is intended, and will save considerable trouble in measuring up and calculating the power of existing boilers when ordering injectors, feed pumps and the like.

Table of Horse Power of Boilers.

PROPER HANDLING OF COMPOUND LOCOMOTIVES.

Paper read before the Tenth Annual Convention of the Traveling Engineers, Chicago, Ill., September 12, 1902, by W. J. Carroll.

The economy in fuel with the compound locomotive is the result of passing the steam through two or more cylinders, with the object of obtaining, by a succession of expansions, more work from a given quantity of steam than can be obtained from the use of steam through one cylinder, because the range of temperature in each cylinder is less, from the fact that compound engines use less steam than single-expansion engines, and that less water is used and less fuel is required to evaporate the water.

It is not expected that a compound locomotive should haul a heavier train or at higher speed than a single expansion locomotive of the same weight and class. No locomotive will haul more than its adhesion will allow. The compound will, however, keep a train moving at slow speed on heavy grades, where a single expansion locomotive will stall—this being accounted for from the fact that the pressure on the crank-pin is more uniform throughout the stroke.

On all styles of compound locomotives the exhaust is much milder than on single-expansion engines. This is due to the fact that the exhaust pressure is much less, and on this account much better results can be obtained by maintaining a light fire. With a deep, heavy fire the mild exhaust does not create sufficient draft to work the fire.

The fireman need not feel alarmed at any amount of abuse or carelessness on part of the engineer, by using the reverse lever in full stroke, or in slipping the engine, because he cannot tear the fire to pieces, as on a single expansion. It is also noticeable that when a compound locomotive is properly adjusted and fired, the great annoyance of cinders, black smoke, sparks, etc., is overcome to a very great extent. In drifting down grades the ash-pan dampers should be kept closed.

From the experience an engineer has in handling a single-expansion engine, he should not require any further introduction to the reverse lever, but he should use it for what it is intended. The reverse quadrant on all compound locomotives should be so arranged that it cuts off steam in the high-pressure cylinder at about one-half stroke; shorter cut-off will result in excessive compression in the high-pressure cylinder.

Dry steam is to be considered even more necessary with the compound than with the simple engine. To reach this end a desirable depth of water over the crown sheet has been found in practice to be about 11 inches, and it will be found well to keep the water in the water glass at such height as to produce this depth over the crown sheets. Some little difficulty has been encountered with the by-pass valve, due to gum being formed by smoke drawn in. To obviate this, it has been found well to put a ½-inch hole in each end of the valve as near the head as possible, and apply a little valve oil. The blowing of the piston rod packing should receive careful attention, as it not only wastes steam, but the condensation in the winter obstructs the view of the engineer. With more experience on the part of mechanics with compound locomotives, and the higher education of them in this line, the compound will be found, in the opinion of many, to give much better results. The compound locomotive being of a somewhat more intricate design suffers at the hand of the mechanic in the roundhouse more than the simple engine. The steam leakages have not been overcome, and other faults in design have operated to cause the engine men to condemn this form of engine without fair trial.

HISTORY OF THE UNDER-FEED STOKER.

Proceedings of the New England Cotton Manufacturers' Association, September-October, 1902.

In a paper upon under-feed stokers, Mr. Geo. C. Tewksbury gives the following sketch of the history of the Jones stoker:

To Evan William Jones, of Portland, Oregon, is due the credit of first inventing an under-feed mechanical stoker that has been successful to a degree almost unknown to mechanical stokers—not only of the under-feed type, but of stokers in general.

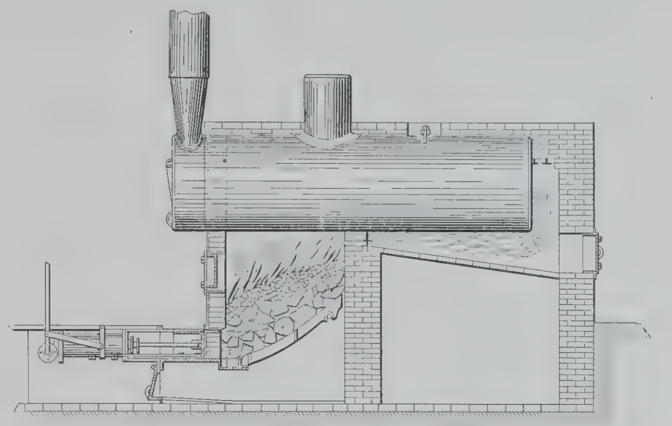
The circumstances leading up to the invention are somewhat peculiar and, I am quite sure, will be interesting in view of the final results obtained. In the State of Oregon, where Mr. Jones resided, wood was more easily obtained than any other fuel; hence, Oregon fir was most universally used for power and domestic purposes. The residents of Oregon—certain portions of which may be classed as semi-tropical—have all the characteristics of residents of semi-tropical countries, particularly in the respect that they are inclined to take life easy and do as little work as possible. The result has always been and probably always will be, so far as the furnishing of wood for fuel is concerned, that up to the time of its delivery no attempt is made to dry the same and consequently it is in a very green state when used. Now, taking into consideration the fact that Oregon fir has a high percentage of moisture and retains same much longer than most other woods, we can readily appreciate the necessity for some means of quickly and effectively drying the wood before using.

Mr. Jones was at the time mentioned, about 1888, president of the Union Iron Works of Portland, Oregon, and was known throughout that section as having more than ordinary mechanical skill. Certain customers of his (interested in the manufacture of paper) found it impossible to keep up steam with the green wood that they were compelled to use. One of these customers took the matter up with Mr. Jones and asked him to devise some scheme by which the wood could to a reasonable extent be dried before it was necessary to use same for fuel.

After giving the matter considerable thought Mr. Jones arrived at the conclusion that the only practicable way was to dry the fuel with the same heat that must be obtained to steam the boilers. After arriving at this conclusion he made up his mind that the only possible way to accomplish the desired end would be to introduce the fuel from beneath the fire line, carrying a fire on top of the fuel instead of on the grates that were until that time used.

After making an attempt to introduce the fuel from underneath by means of levers, he found that such a course would not be practicable and he therefore provided a steam ram for the purpose. The wood used was of the ordinary length (four feet) and was forced from below by means of the ram. After the furnace was once filled with wood (which before steam was obtained in the boilers could be placed in the furnace by hand) a fire was started on top of the wood. The supports for the wood consisted partially of solid iron plates, and at the rear of the furnace, which was inclined upward, grates were used.

The result obtained was more than had been expected. An intense fire was created in the furnace, naturally at the top of the bed of fuel. This intense heat served to dry the fuel that was beneath same. In the drying process a considerable quantity of gas was thrown off, and the same naturally passing upward was consumed. Therefore the fuel—before being passed into the zone of combustion—was quite thoroughly dried and was in a proper state to give forth all the heat units contained therein.



Industrial Press, N.Y

Fig. 3. Original Under-feed Stoker.

The accompanying illustration will give a fair idea of Mr. Jones' invention, which proved to be entirely practicable, and which was used successfully in a number of plants in Portland and vicinity for a number of years. Some of these are probably now in use, although since they were designed coal has been found in the vicinity of Portland that can be used for fuel—and at certain times is cheaper than wood.

Realizing that the field for a mechanical stoker designed solely for the use of wood for fuel was very limited and that equally if not more satisfactory results could be obtained by the use of bituminous coal for fuel under the same system, because of the high proportion of volatile matter contained in same, Mr. Jones naturally turned his attention to the devising of a mechanical stoker for that purpose.

The fundamental principle of under-feeding which had already occurred to Mr. Jones very forcibly now became a fixed idea in his mind. You are undoubtedly more or less acquainted with this principle, that is, the introduction of the air above the fresh or green coal, but below the incandescent bed of fuel, at or about the point where the volatile gases are liberated; which gives a thorough mixture of the gas and air before reaching the zone of combustion and which results in the practically complete combustion and the utilization of the heat of these gases which in ordinary hand-firing is to a great extent lost.

After having made the necessary drawings and after reaching the conclusion that a stoker would operate successfully, he obtained permission from the authorities of the Portland Cable Railway in Portland, Oregon, to equip two of their furnaces with same. Since then various changes and improvements have been made.

While I have stated that it is not my intention to enter into a technical description of the under-feed system of mechanical stokering, a brief statement of the theory will not be out of place.

Properly operated the system represents a gas producer and gas consumer in one furnace. The green fuel being introduced from the under side of the furnace proper, the incandescent fuel resting thereon must necessarily liberate the volatile matter in the green fuel. Air being introduced at the point where gases are being liberated—this point being underneath the mass of incandescent fuel—a thorough mixture of the air and gases at a high temperature is certain to be obtained. This combustible mixture must pass upward through the body of incandescent fuel and must be consumed. The result is the utilization of practically all of the heat-producing elements in the fuel, making more nearly perfect combustion than can be obtained in any other way; and thereby insuring freedom from smoke.

From the writer's experience he believes that an hourly fuel consumption of about 1,000 pounds of coal is as great as should be attempted with one under-feed stoker. Attempts have been made by manufacturers of under-feed stokers to increase the fuel consumption above named, but in the main they have not been, and in the writer's opinion, cannot be successful with all classes of coal. When greater fuel consumption is desired in any one furnace, two or more stokers should be used.

SPEED TESTS OF STEAM AND ELECTRIC TRAINS.

Scientific American, October 4, 1902, p. 216.

The most direct evidence thus far afforded that the New York Central Railroad is taking active steps toward the installation of electric traction for its suburban service in New York City is a series of tests which have recently been carried out on the experimental track of the General Electric Company at Schenectady. These tests were made with a view to determining the relative efficiency of steam and electric traction in such suburban passenger service as is carried on by the New York Central Company. The primary object of the test was to make a comparison of the rate of acceleration of the same train when hauled by a New York Central suburban engine and by a pair of electric motor cars, such as would be used were the suburban lines to be equipped with third-rail electric traction. For the purpose of the test, a train of six cars was made up, which included five standard passenger coaches of the New York Central Railroad preceded by a dynamometer car. The engine selected was one of the big tank engines especially designed for the suburban service of the New York Central Railroad, the engine being provided for this purpose with large heating surface and cylinder capacity and small-diameter six-coupled drivers. These engines have a total weight of 214,000 pounds, of which 128,000 pounds is on the drivers; a total heating surface of 24,065 square feet; cylinders 20 x 24 inches; a boiler pressure of 200 pounds to the square inch and a tractive power of 25,900 pounds. They have proved very successful, the acceleration being unusually rapid. Indeed, for this class of work, where stops are frequent, they are probably the best engines of their kind in this country to-day, and hence admirably adapted for a comparative test of capacity of acceleration with electric motor cars. For the electric test two General Electric motor cars, one weighing 73,000 pounds and the other 70,000 pounds, were used. These cars are 54 feet in length, and are equipped with four "G E 55" motors, all axles being provided with motors and the two cars together giving about the same weight on drivers as the steam locomotive. The test was, therefore, perfectly fair, the acceleration being directly comparable for trains of equal weight. The drawbar pull, speed and time were recorded by the same dynamometer car in all cases, the engine simply being unhitched and the two motor cars coupled up for the alternate trials. In carrying out the tests, the train of six cars with its engine or its electric motors, as the case might be, was started from rest and run over one mile of track, the acceleration being made as rapidly as possible with the power available. These runs were repeated, dropping off one car at a time, and a careful record was kept of the speed attained in 10 seconds, 20 seconds, 30 seconds, etc. The New York Central coaches weighed each from 48,200 pounds to 60,250 pounds, and the total weight of the train behind the engine or electric cars varied from 157 tons down to 23 tons.

The electric runs were made upon the General Electric Company's experimental track against a head wind of 15 miles an hour. In the middle of the run there was a 6½ degree curve, the frictional effect of which was assumed as equivalent to the 1-10 per cent. upgrade of the steam runs, which were made on the New York Central main line adjoining the electric works. In the case of the steam runs there was also a head wind of 15 miles per hour. Although the locomotive was especially built for rapid acceleration, having a large firebox and heating surface, the pressure dropped from 200 pounds at the commencement of the mile to less than 185 pounds during the early part of the acceleration. In starting, the throttle was opened wide and steam was used for the full stroke, the engine being hooked up as acceleration proceeded. In neither case was there any slipping of the driving wheels. Although the steam locomotive was able to exert a tractive effort at starting equal to that obtained by the electric motor cars, this high tractive effort was not maintained, but fell immediately with the increase of speed, in spite of the most expert handling of the throttle and reversing lever.

A comparison of the results proves that the electric motors can better utilize the weight upon their drivers during acceleration than a steam locomotive, the motor covering the same distance in the same time with less energy expended and at less maximum speed than a steam locomotive, owing to its being able to maintain its maximum accelerating rate for a longer period. In making the tests the power was kept on until the three-quarter-mile post was reached, when it was shut off and the brakes were applied so as to bring the train to rest as near the mile post as practicable. The steam train ran from 5 to 15 per cent. over a mile before the train was brought to rest, and the electric train from 2 to 4 per cent.; but, in spite of the longer distance covered, the average speed of the steam runs only approached that attained in the electrical runs over a shorter distance. Since the electrical runs all show a lower maximum speed and a higher average speed than those made with the steam locomotive, the energy consumption of the electric runs should, therefore, be less for the same work done than with the steam locomotive. Since the motors of electric trains may be placed upon the trucks of ordinary passenger coaches, there is a saving of weight due to the elimination of the locomotive and tender, and the authors of the paper point out that, hence, the true basis of comparison between steam and electrically-propelled trains should be the energy per seat mile rather than per ton mile. As an illustration of the advantages, in point of economy of power, of electrical traction over steam, it was found that for a train of six cars the watt hours per passenger required in a steam train are 43.9, as against 29.7 in an electric train. In a three-car train the watt hours for steam would be 77.4, as against 37.5 for electricity. In a comparison of coal consumption, based upon the actual service of a steam locomotive for twenty-four hours covering four trips between North White Plains and the Grand Central Station on the New York Central road, it was found that the coal consumed per effective horse power hour was 15.6 pounds. In comparing this with electrical traction, it is assumed that the ratio of effective horse power output of motors to the indicated horse power of the central station engine is about 50 per cent. The average coal consumption per horse power hour at the electric power stations is assumed at 2½ pounds, and at this figure the coal per effective horse power output at the electric motors would be 5 pounds. Assuming the head air resistance as 10 per cent. and the increased weight of the cars due to their electrical equipment as 20 per cent., the actual comparison of coal consumption works out in the ratio of 6.6 pounds per horse power hour for electric traction and 15.6 pounds for steam traction. Assuming the cost of coal for electrical power is about a third the total cost of that power if maintenance and interest on investment be included, it is concluded that the actual gross cost of electrical power would closely approximate the coal consumption cost of the steam locomotive in this class of service, the maintenance and attendance cost of the electrical equipment being, however, considerably in favor of electrical power.

THE AMERICAN ENGINEER IN ENGLAND.

Journal Western Society of Engineers, Aug., 1902.

About a year ago the British Westinghouse Electric & Mfg. Co. decided to build a plant in England for the manufacture of their product. The plant was to be constructed on the same plans as those used for the Westinghouse plant at East Pittsburg, Pa., with the addition of a steel foundry and of an iron foundry.

The plant was designed by Mr. Thos. Rodd, of Pittsburg, and the work of construction was intrusted to a Manchester architect, but under his supervision the work progressed so slowly that it was evident to those interested that something must be done to hasten the work. It was generally conceded by English builders that it would take five years to erect the works contemplated, but a delay of a year or two years meant an almost inestimable loss, and therefore, a year ago last March, Mr. J. C. Stewart, of the contracting firm of James Stewart & Co., St. Louis and Pittsburg, having gathered around him a party of six American engineers and foremen, sailed for England, and on arriving there took immediate charge of the work. Mr. Wm. G. Sloan, who was one of the party, gives an interesting account of their experiences, in the *Journal of the Western Society of Engineers*, from which we quote:

"The question was, 'How can the plant be completed in the shortest possible time?' The Americans interested in the business naturally looked to America for an answer to this question, and the contracting firm of James Stewart & Company of St. Louis and Pittsburg, agreed to take hold of the work and push it through, saying they could complete the work in fifteen months.

"We found the work in charge (under an architect) of a clerk of works, who had a small office in one part of the grounds. This man had perhaps a dozen assistants, each having his little office in some part of the grounds, each seemingly as far as possible from the others. The first thing done was to build an office large enough to accommodate all the necessary force, so as to bring them under the immediate supervision and influence of the American management.

"All these men had been in the habit of coming to work at nine o'clock in the morning, and leaving about five in the afternoon; they were requested to be on hand when the work started and to remain until quitting time, and this request caused about half of them to seek employment elsewhere, one of them saying in his letter of resignation, 'A man cannot be a gentleman and work under the American administration.' It may be of interest to state in this connection that the average rate of pay of these clerks and inspectors did not exceed fifty dollars per month.

"One custom we had the most difficulty in breaking down, was the old established one of stopping for the breakfast hour. The men started work at seven o'clock in the morning and at half past eight the work stopped for half an hour for the men to eat their breakfast. This consisted of bread and tea, and each man brought his tea and teapot with him to the work, and as I say, right in the best part of the morning, they all stopped work, and gathering in groups of three or four in a place, built little fires on the ground, heated the water and made their tea. You can readily understand, when you consider that at times we had as many as 3,000 men at work, how serious an objection this break in morning work would be; the men losing not only the half hour between 8:30 and 9 but also wasting considerable time in stopping work and getting started again. We helped matters to a great extent by building a furnace and having the water hot for the men; making it a rule that no other fires should be lighted on the grounds. At the same time we discouraged in every way possible the keeping up of the custom, and finally, one by one, the different trades acquiesced to our wishes in the matter, and before the work was done, all but the bricklayers had given up the custom.

"If one department of our work created more comment and discussion than another, it was the work of our bricklayers. Shortly after we had taken hold of the work, the fact that we were laying 900 brick per man per day was published, and from builders in all parts of the country came the cry 'Impossible, the work of our bricklayers does not average over 400 or 500 brick per man per day,' and yet later on as the organization became better, and the men became accustomed to our methods, this average of 900 brick per man per day was doubled on the same class of work. So much comment was made on this, that on the construction of a large brick stack, we went so far as to have the foremen make affidavit each night as to the number of brick laid and men employed on this particular piece of work. The men averaged over 1,900 brick per man per day for a month, and the best day's work was 2,100 brick per man per day.

"In this connection I may say that the brick used in this district are larger than those we have here, being 3 x 4½ x 9 inches. This record was made possible by providing the most approved hoists for material, so as to have no delay on the part of men waiting for brick or mortar, and by the fact that we used a thinner mortar than was commonly used in England, thus saving time and labor in spreading the beds and setting the bricks in place; also that we were able to get and hold the best men by paying more than the union rate of wages, which for bricklayers is only 20 cents per hour.

"I will venture to say, that if you would go to 90 per cent. of the contracting engineers or builders in England, and ask, How many brick are you laying per man per day, or just what is your concrete or masonry costing you per yard in place? the answer would be 'I do not know.'"

Mr. Stewart did better than he said he would. He said it would probably take him fifteen months and the work was practically finished in a year.

The cost of the buildings, with the machinery installed, was about $8,000,000; without the machinery, about $4,000,000 or $5,000,000."

THE RELATION OF THE DRAFTSMAN TO THE WORKSHOP.

Engineering Magazine, October 1902, p. 98.

Mr. W. H. Booth, in writing upon this subject presents it to the reader from the view point of the British draftsman. To begin with, the term "draftsman" is vague; for the name of engineer, which includes it, includes also, in British parlance, a vast concourse of men, ranging from the designer of a Forth Bridge to the manufacture of iron bedsteads or the driver of an engine. His position is by no means a pleasant one, as he very seldom comes in contact with the outside world, and receives but slight recognition from his superiors. It is often said that he gets all the blame when things go wrong and secures none of the credit for what scores a magnificent success. The insistence upon petty details is often a drawback to the draftsman's position.

The chief draftsman of a certain colonial railroad known to me once insisted that the draftsmen under his charge, who were frequently called upon to make sketches in the running shed, should actually make these sketches to scale, and he insisted they should figure these sketches with a particular pattern of figure, fractions being shown thus, ¼ inch, with great regularity of style, and he once ordered the correction of a full-size drawing of part of a Bissel truck because a piece which was correctly dimensioned to 24 inches actually scaled 1-64 inch from truth. The art of drawing nicely is not of particular value to-day in an engineer's office.

Every establishment may be said to possess the kind of draftsmen it deserves. There are too many places where he is expected to lie prone upon his board all day. Such a position is simply ridiculous; it wastes room, impairs the man physically, and is useless. With a little practice any draftsman can acquire facility in working on a vertical board where he can stand upright or use a stool and suffer less in his eyes and none in his chest.

In the old days there was constant rivalry and ill feeling between the drafting office and the pattern shop and machine shop. Such conditions were due to sheer ignorance on the part of the draftsman as to the limits of the machines in the shops, or to indifference resulting from his acting up to the official ordering of his status—that he had no business with the shops.

In a small establishment the draftsman is usually the engineer; he gets out all the plans, supervises construction in the shop and the erection outside, orders every scrap of material and gets out estimates for new work. Now if this man and his methods be taken as a starting point for the organization of a large shop, the engineering department—a wider and better term than "drawing office"—might be placed on a sound footing. When an order is to be executed, it should be left to the drawing office to decide upon the method and materials of construction, what existing drawings and patterns can be utilized, and what stock shall be ordered outside. All steel, bolts, plates or other material kept in stock should be ordered under the supervision of this department.

The present very usual system of getting out estimates for new work in an estimating department quite distinct from the engineering department, is wrong. This estimating should be done by the engineering department which ought to be the intelligence bureau of the establishment, to which all information should be sent, and from which the orders should emanate in respect to the use and purchase of materials and the general methods of construction. The keeping of time costs should come under this department by which also the piece work prices should be established. If all of these duties were organized into one department with one head, friction and red tape would be avoided and there would be harmony between the various branches of the work.

The familiar saying that there are no old draftsmen, is very true. The position is not what the intelligence and training of its best members entitle it to be, and if men are not killed off by the prone position, they leave the drawing board for other work. Better management would place such other position very often within the radius of the engineering department.

A HIGH-DROP TEST OF AN ELEVATOR SAFETY AIR CUSHION.

Engineering News, October 9, p. 295.

A test of an air cushion installed at the foot of the elevator shaft in the Philadelphia City Hall tower was made on September 29. The tower of the Philadelphia City Hall attains the greatest height of any building ever erected. It is 500 feet from the pavement to the base of the statue of William Penn, which surmounts the tower. An elevator in the tower carries visitors from the upper floor of the building to a point just below the base of the Penn statue.

The test consisted in letting the regular passenger elevator car, weighing about 2,500 pounds, drop from the top of the shaft, a free fall of 290 feet, before entering the well-like chamber 75 feet in depth called the air cushion. In the car were a lighted lantern, six rats, 50 incandescent light bulbs, and several dozen eggs. At the appointed time the car was cut loose, and four seconds later it shot like a flash out of sight into the air cushion. Two seconds afterward there was a cannon-like report, accompanying the escape of the suddenly compressed air through the valves. The sliding steel door of the air cushion chamber was then drawn back, and inspection showed that while the lantern was upset, and a few of the eggs were broken, the rats were unscathed save for a bath of kerosene oil, and the incandescent bulbs were unbroken. The elevator car appeared to be uninjured. The test is a remarkable one in that the total fall, 365 feet, exceeded by 65 feet any previous test. The velocity of the car upon entering the air chamber after a free fall of 290 feet, neglecting air and guide friction, was about 136 feet a second, or nearly 93 miles an hour. A 2,500-pound car after falling 365 feet, friction neglected, would possess 912,500 feet pounds energy; and if this energy was overcome by opposing a uniform resistance during the 75 feet of fall in the air cushion, its necessary resistance would be more than 12,000 pounds. The area of the car floor was approximately $5 \times 6 = 30$ square feet, so that the pressure upon the floor under the conditions assumed would be 400 pounds per square foot, or about 3 pounds per square inch. The maximum pressure was, of course, much greater than this, probably more than double, for the pressure starting at zero increased as the car descended until a maximum was reached. A 150-pound man under similar conditions of uniform retardation would experience an upward pressure of 720 pounds upon the soles of his feet, and probably not less than double, or say 1,500 pounds at the moment of stopping, while the pressure upon the hip joints would be about two-thirds that on the feet. A Sandow would readily sustain such a load without weakening at the hips or knees, but an ordinary man would almost surely collapse, although, of course, with injurious results by no means comparable to those that would follow a free fall of much less height. Mr. F. T. Ellithorpe, president of the Ellithorpe Safety Air Cushion Co., has himself many times dropped six stories without the least injury.

Relative to the egg as a means for testing the effect of the sudden stopping of an elevator car, *Engineering News* has several comments to make. In one series of tests upon the strength of eggs it was found that to crush an egg, placed between two flat boards, a pressure of 4 1-3 pounds was required, or 38 times the weight of the egg. Another series showed that, with the major axis set horizontal, the average crushing force was 12.2 pounds, or 97.6 times the weight of the egg. Still another series with the axis vertical gave 18.1 pounds, or 144.8 times the weight of the egg.

From the results of these tests it is quite evident that, provided no jar took place, an egg would stand a drop in an elevator car falling a distance of at least 38 times the depth of the air cushion and possibly of 95 to 145 times the depth of the air cushion, assuming a uniform retardation in the air cushion. In the 365-foot fall in the Philadelphia City Hall tower where the ratio of air cushion depth to total drop is about one to five, it is manifest that the few eggs which broke were broken by jar at the time the car struck the bottom, and not by pressure developed by their inertia.

While pressure developed by inertia would not crack the eggs, it would, as we have shown, cause a man to feel as if he literally weighed a ton, and might result in serious injury.

The egg test is, therefore, very unsatisfactory, as proof of the effectiveness of the air cushion as a safety device. The fall of animals in the car without injury is much more convincing.

In proportioning the air cushion it has been found necessary to make its depth from 1-6 to ¼, usually 1-5, the maximum possible drop of the elevator car. The sides of the air cushion chamber in the Philadelphia City Hall tower are of 5-16 sheet steel, stiffened with horizontal 5-inch I-beams, 19 inches c. to c. At the bottom is a heavy sliding steel door which is, of course, closed after the entrance of passengers into the car. There is a clearance of about ½ inch between the elevator car and the sides of the air cushion. An air escape vent is provided in one side of the air cushion and is triangular in shape. Its base, 4 inches wide, is located at the top of the air cushion, and its vertex is 35 feet below. Fifteen feet below the vertex of the escape vent is an escape valve having a circular opening 15 inches in diameter, and 10 feet from the bottom of the air cushion is another similar escape valve. The springs of the valve are so proportioned that at a pressure of about 3 pounds per square inch on the valve surface it will begin to open, and at 9 pounds per square inch the valve will have reached its maximum opening. Near the bottom of the air cushion is a check-valve which permits air to flow inward and prevents the formation of a vacuum under the car when it begins its ascent.

Four ordinary compound elevator springs are provided at the bottom of the air cushion to act as bumpers. The springs are about 5½ inches diameter, 16 inches high and susceptible of a 7-inch compression.

It will be evident that in case the car should fall into the air cushion from some point below the top of the shaft and the valves were the only means of escape, the car would be stopped before it reached the bottom of the air cushion or more quickly than necessary. As actually installed, however, there is a narrow air space all round the sides of the car between it and the walls of the chamber and the air escapes here as well as through the air valves in case a car falls into the cushion.

SPUR GEAR PLANER.

A MACHINE FOR PLANING LARGE SPUR GEARS BY THE USE OF A SINGLE-POINTED TOOL AND TEMPLETS.

The Newton Machine Tool Works, of Philadelphia, have recently furnished the R. D. Nuttall Co. with a gear cutting machine of unusual capacity and embodying many new and interesting features. While the operation of the machine is similar to that employed in some of the bevel gear shapers, this is an original application of the principle to the formation of spur gears. A good general idea of the machine is gained from the half-tone, which was taken before the machine left the shop. When in place, the top of the dividing table will be nearly flush with the shop floor and most of the indexing mechanism will be below the floor line. The gear, lying flat upon the dividing table, is accurately spaced around by the dividing mechanism shown at the left of the cut, and the teeth are shaped to templets by a tool carried in the vertical slotter. This slotter has a stroke of five feet and is driven by a spiral gear connected to the bevel gearing shown on the countershaft. The countershaft itself is driven by a motor enclosed within the column. The vertical column can be moved in and out to any desired position on the extension bed and will accommodate gears up to 30 feet in diameter. If a greater capacity was required, the bed could be extended indefinitely to take any size of gear.

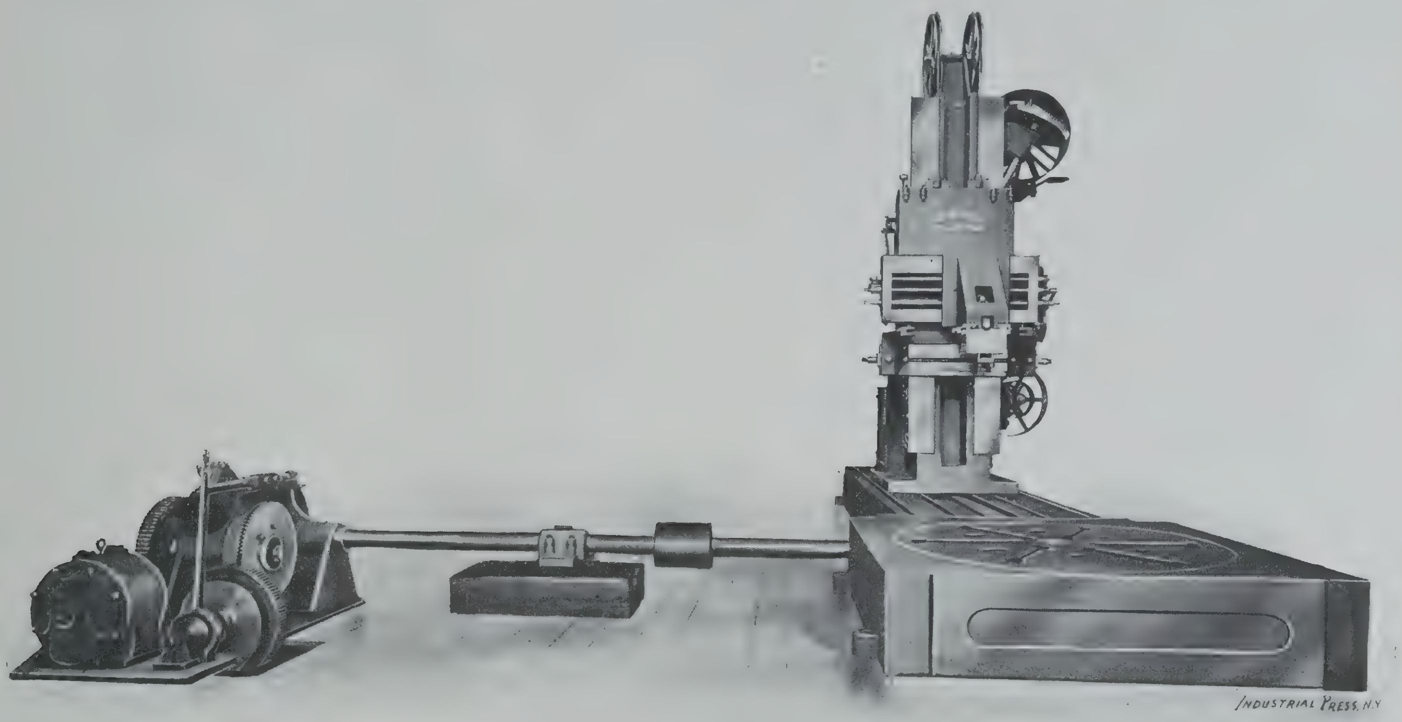


Fig. 1 Spur Gear Planer.

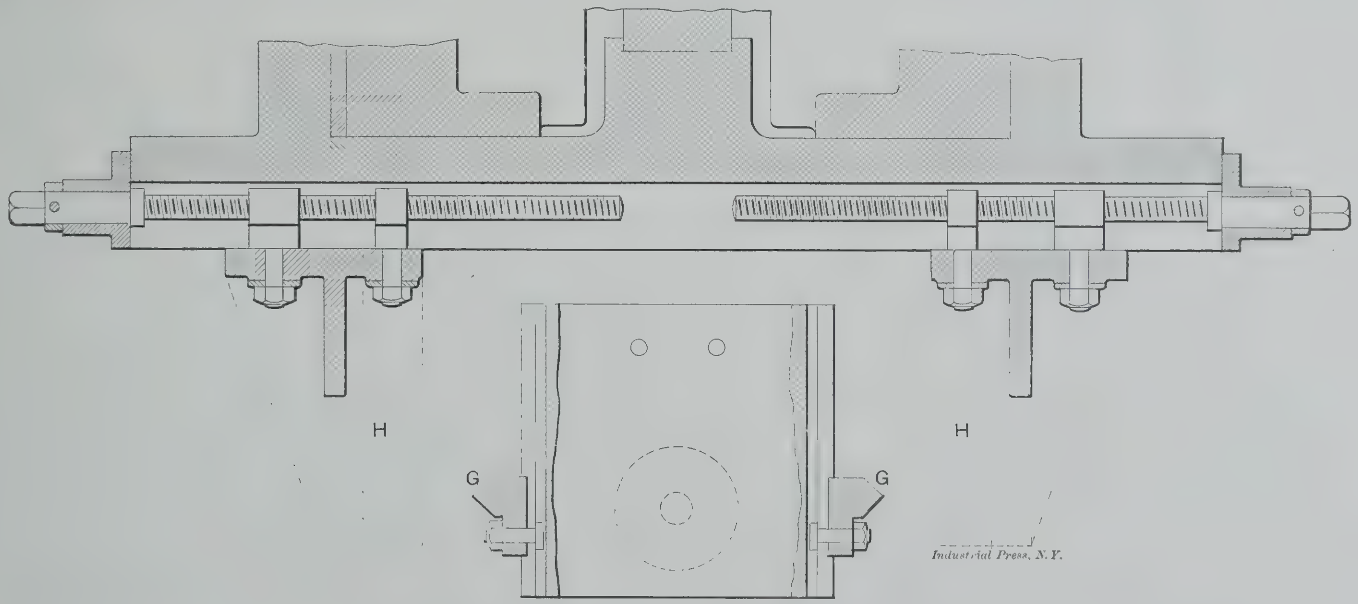

Fig. 2. Section through Guides and Templet Holders.

Figs. 3 and 4 show a section through the tool apron, or saddle, and the mechanism by which the tool is fed. As the saddle is raised and lowered the star wheel *A* is revolved by engaging with the pins *B B*. During the upward stroke no motion is produced, owing to the star wheel working on a ratchet, but as soon as the apron begins to descend, the pin gear, operating through the feed gears, causes the screw *C* to revolve and thereby feed the apron across the face of the column. With the feed gears *D* and *E*, shown in Fig. 4, in use, the apron would be fed to the right, but if these are removed and the combination shown in Fig. 3 substituted, the introduction of the extra gear *F* causes the apron to be fed to the left. Upon either side of the apron are the steel points *G G*, Fig. 2, and as the carriage is fed to one side or the other, these points come in contact with the templets which are held in the templet holders *H H*. This guides the movement of the tool to conform with the shape of the templet. As the revolution of the star wheel would have a tendency to feed the apron farther than the templet allows, a friction clutch, *I* in Fig. 5, on the star wheel shaft allows the feed to slip as soon as the point *G* touches the templet.

While the head is being fed crosswise, the tappet *J*, striking against the top of the lug *K*, revolves the gears *L*, *M* and *N*, and then through the chain of bevel gears *O*, *O*, *O*, the screw *P* is revolved, thus feeding the tool in the tool-post up to the work. A hinge and spring mechanism on the tool-post allows the tool to spring downward on the return or upward stroke.

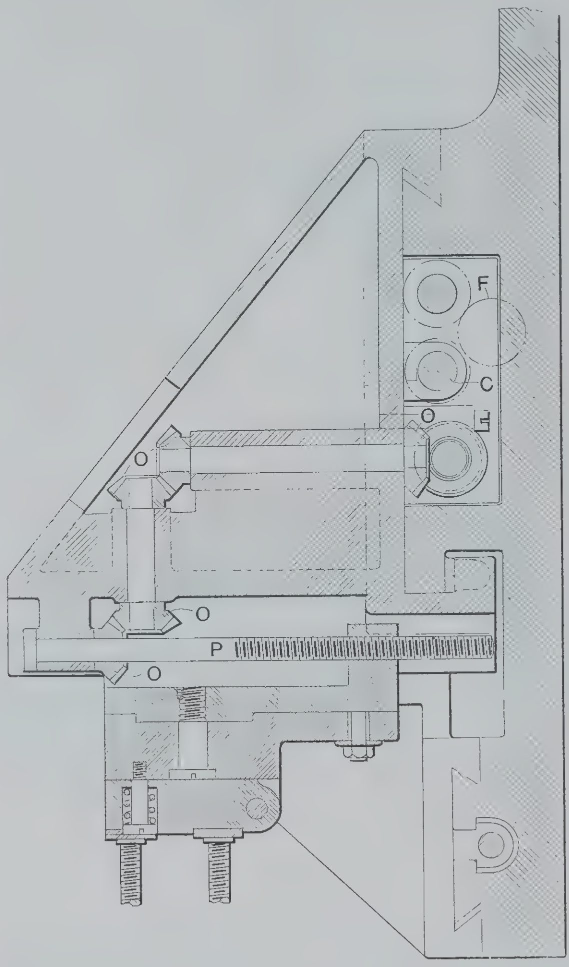

Fig. 3. Section through Tool Apron.

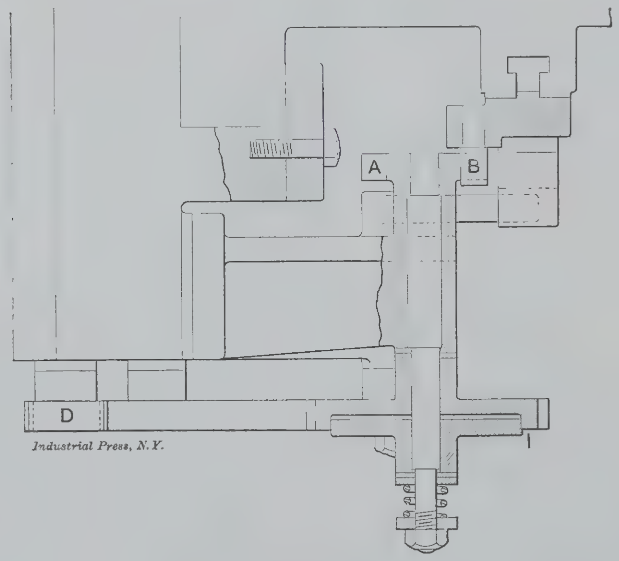

Fig. 5. Section through Star Wheel and Friction Clutch.

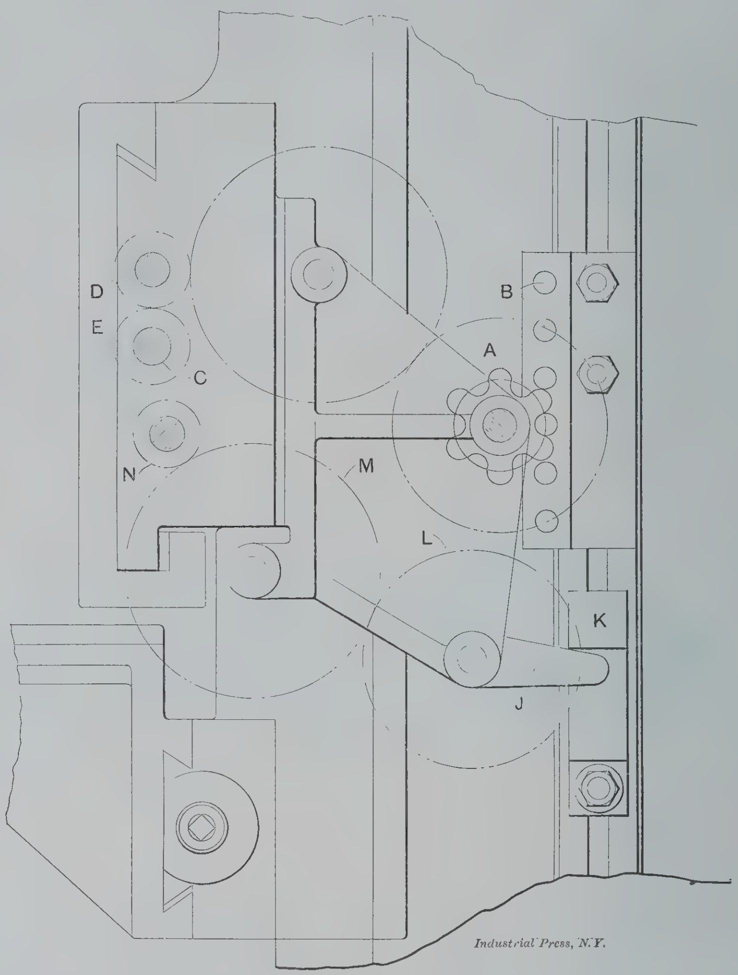

Fig. 4. Feed Mechanism.

A section through the dividing table is shown in Fig. 6. This table is, in effect, the upper side of a large worm gear which is driven by a worm on the shaft *P*. Fig. 7 shows the indexing mechanism for revolving this table. The motor having been started, the plunger *Q* is raised by means of the lever *R* and this leaves the gear *S* free to rotate. The friction lever *T* is now thrown over, putting the friction clutch in mesh, and the worm wheel *S* then revolves until checked at the end of a complete revolution by the plunger *Q*, which has by this time reached its former position at the bottom of the slot, thus preventing further rotation of the wheel *S*. The friction clutch then slips and the motor is stopped. Motion is transmitted from the worm *S* to the worm shaft *P* through the intermediate gears *U* and *V*, the sizes of which are varied to give any desired divisions to the revolution of the gear that is being cut.

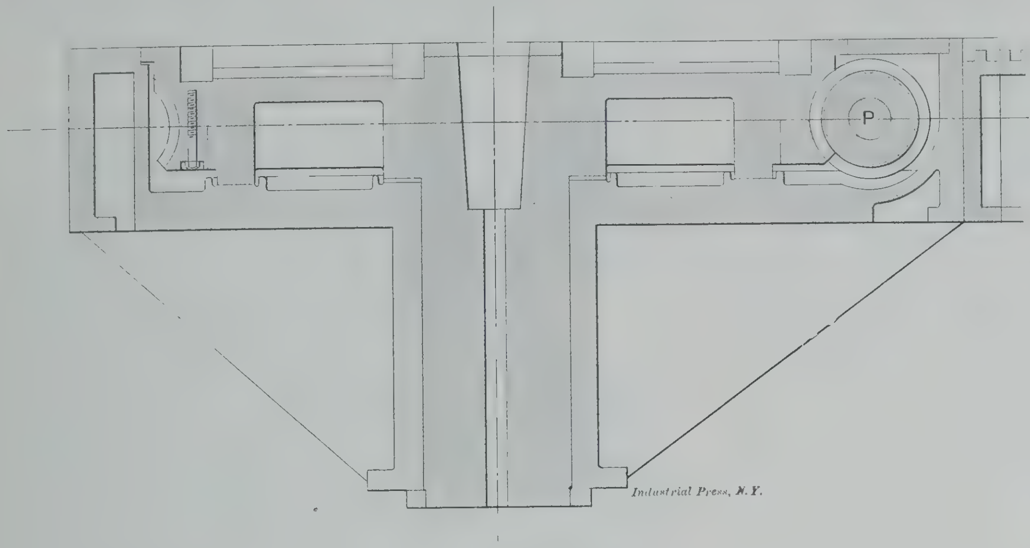
When internal gears are cut the vertical column is transferred to the dividing table, the internal gear remains stationary, and the slotting machine itself is indexed around to each tooth. When completed, this machine was tested by means of a transit placed on the dividing head. This was sighted on a point about 40 feet distant so as to multiply the error, which proved to be almost imperceptible.

* * *

NEW INDUSTRIAL CENTER.

The plants of the affiliated Westinghouse companies, Pittsburg, have become so extensive that there is little available room at their present locations for future building extensions. To provide for future growth it was necessary to go outside of the city limits and a new industrial center has been opened up about 17 miles east of Pittsburg. The new settlement is on the Pennsylvania Railroad and is to be known as Trafford City, where extensive factory sites have been laid out and every provision made for a comfortable and healthful residence section for the employees. The manufacturing plants will be located on a fairly level area between the Pennsylvania Railroad and the residence portion of the city, which will be reached from the railway station by a steel viaduct 1,100 feet long. The residence district has been laid out upon hillsides and on a generally level plateau, high enough above the factory sites to render it free from smoke and dirt. The city consists of two oblong areas, one of which is about ½ mile by 1-5 mile and the other ½ mile by 1-7 mile, the two areas meeting in such a way as to form a reversed letter "L," the corner of which is the most northerly part. The town has been laid off into about 800 building lots, each with an average frontage of about 30 feet and a depth of 100 feet.

In addition to this, space has been left for six parks. The new town is connected with Pittsburg both by the Pennsylvania Railroad and by street railroad.



Industrial Press, N.Y.

Fig. 6. Section through Dividing Table of Spur Gear Planer.

The factory site, located in a bend of Turtle Creek, provides room for nine factory buildings, each about 200 feet by 800 feet. A system of railway yards and tracks serving this area has been laid out in a very thorough manner, providing a track alongside of each building and transversely through each end. The storage tracks, in connection with this, occupy an area of about 300 feet by 200 feet.

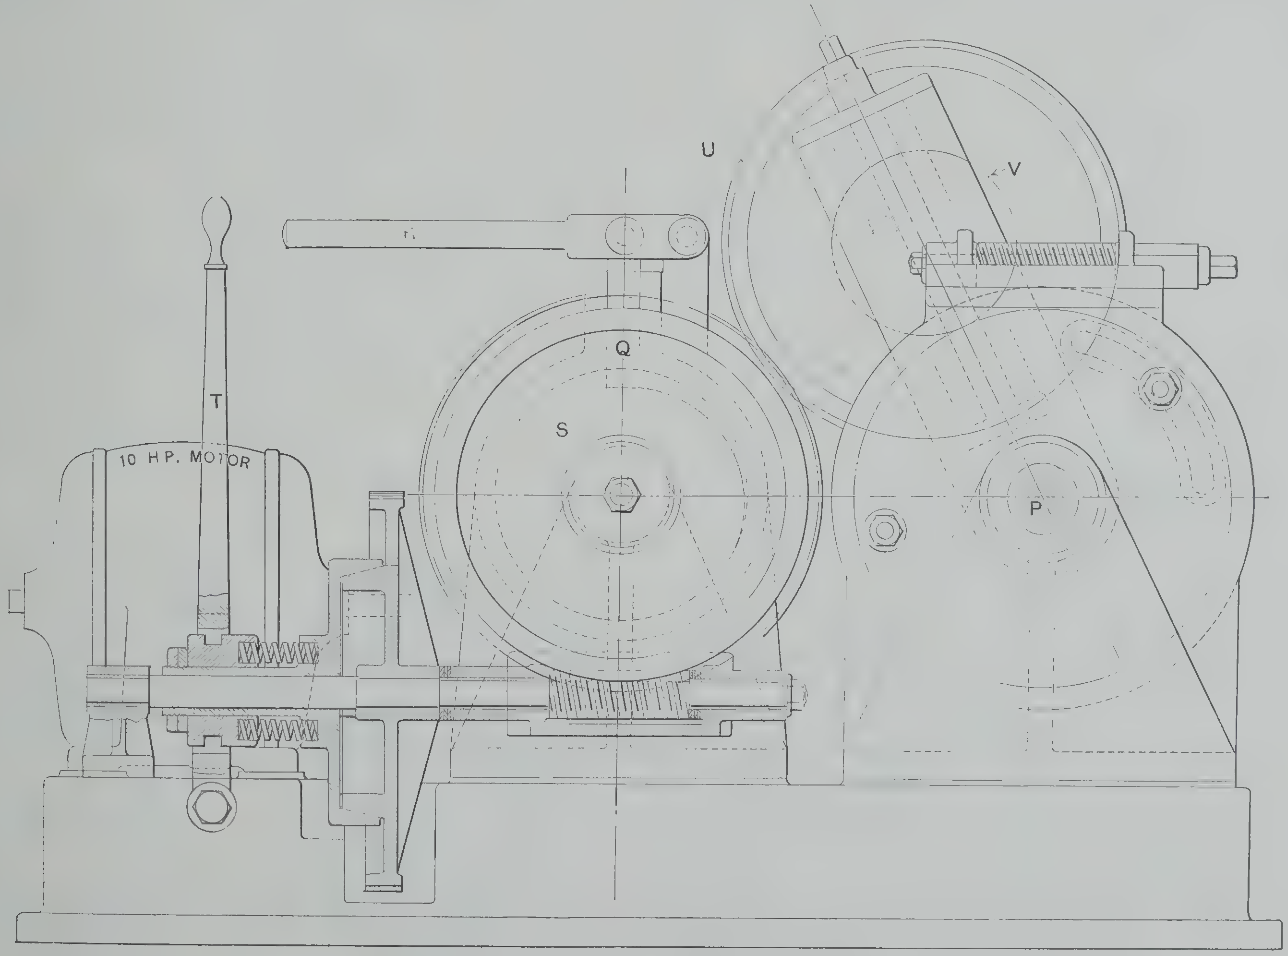


Fig. 7. Indexing Mechanism of Spur Gear Planer.

The first of the Westinghouse companies to erect buildings in the new city is the Westinghouse Foundry Co., which is putting up an extensive and model foundry plant and pattern shop. The immediate necessity for this comes from the increase in the engine and turbine business of the Westinghouse Machine Co. The pattern making and storage building is to be of steel and brick, 605 feet long and 80 feet wide. The pattern shop occupies two floors at one end of this building, the second floor being suspended from the roof trusses in order that the first story may be free from columns. The other end of the building is to be used for pattern storage and will have three floors. The foundations are of concrete and the superstructure of steel and brick. The foundation of the ground floor is made up of 8 inches of concrete into which the floor sleepers are bedded and on top of these is a layer of 2-inch maple flooring. The upper floors in both the pattern shop and storage building are supported on steel beams and steel girders, and are made up of 3-inch yellow pine flooring. The roof purlins are steel I beams spaced 8 feet center to center, and covered with 3-inch roof sheeting which is covered with slate.

The foundry building is 611 by 184 feet, and as in the case of the pattern shop, the foundations are of concrete and the superstructure of steel and brick. The foundry is divided transversely into three bays, the center bay being 80 feet between centers of columns and having runways for electric traveling cranes of 150 tons lifting capacity. The two side bays are 50 feet wide and have runways for 50-ton cranes. At one side of the foundry building runways are provided for yard traveling cranes of 100-foot span and a lifting capacity of 75 tons.

At the middle of one of the side bays, where the cupolas are located, is a charging floor about 50 feet square, constructed entirely of steel. The melting equipment of the foundry will consist of two air furnaces, each having a capacity of 30 tons, and three cupolas capable of melting 18 tons per hour each. This will enable a casting weighing as much as 100 tons to be easily poured and the casting can afterwards be lifted out of the sand by one of the 150-ton traveling cranes.

LETTERS UPON PRACTICAL SUBJECTS.

REGARDING LETTERS UPON PRACTICAL SUBJECTS.

Editor MACHINERY:

It is a noticeable fact that among practical mechanics, those who work at the bench, those who stand day after day at the machines, and those who as foremen have the active direction of everyday work, the features of a mechanical publication which are intended to give "the greatest good to the greatest number" are more or less misunderstood.

The "letters on practical subjects" are generally from men of ripe experience who endeavor to write on such matters as may be useful to many of the younger mechanics who are ambitious to profit by the experience of their elders, as well as to "find out things for themselves." A letter may sometimes seem to have been written to fill up space, when in reality nothing was farther from the author's thoughts. To another reader the same letter may prove to be of the greatest value.

Those who write these letters usually have something to say worth reading by a large number of people. They do not aim to write of matters absolutely *new*, or of subjects upon which no one has ever written before. Very few things are really new. Solomon said there was "no new thing under the sun." But there are a great many things learned by experience that are of considerable benefit to younger students and mechanics.

We often hear the remark, by experienced men in the shop: "Why, I see lots of things in that paper about my business that I knew twenty years ago; I don't see anything new in that and never thought anyone would think of writing about such a simple thing."

The good man forgets that while many of these things are not new to *him*, there are hundreds of young men in the business to whom they *are* new, and who gladly avail themselves of the opportunity thus afforded to obtain new ideas. The articles were not written for the older men who *know*, but for the younger men who do *not* know.

The older and more experienced man might as well say to the younger, "What is the use of studying school books? We knew all about the subjects in them years ago." Certainly. But there are thousands of young persons who do not know these things and must learn them. The school teacher might as well say: "Everybody knows the things I teach, why should I go on teaching the same things year after year?" Simply because *everyone* does not know these things.

It would seem to be the duty of those who have, through education and experience, learned of these special matters pertaining to their business or profession, to "pass along" the information to the many younger persons who have not had their experience, and to many who have not had their opportunities.

And it would seem to be a most worthy ambition on the part of the editors of mechanical papers to try to teach practical subjects to young mechanics and thus extend "the greatest good to the greatest number," as well as to record the new inventions and discoveries, and to publish wise dissertations on deep and erudite scientific subjects.

OSCAR E. PERRIGO.

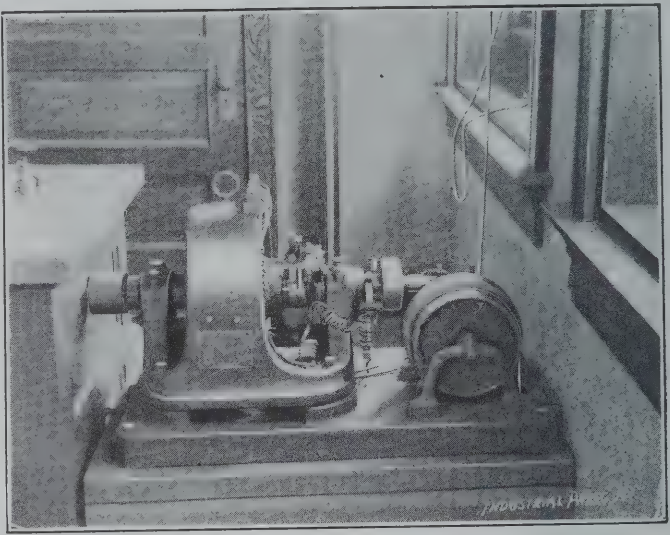
AN AUTOMATIC ELECTRIC CURTAIN HOIST.

Editor MACHINERY:

In every college lecture room as well as in many high schools and institutes the electric stereopticon is frequently employed in connection with the regular day courses of work. It is then necessary to darken the windows by means of shades, as well as to draw down a prepared white screen for illustrative purposes.

The accompanying illustration shows a very unique electrical hoisting apparatus which is used for drawing down the shades and the stereopticon screen at the same time by simply pressing a button or turning a switch. The apparatus was devised by Chas. W. Carman, of Chicago, formerly the professor of physics at the Lewis Institute.

This automatic electrical device makes it possible for the operator at the lantern to open all the opaque shades of the lecture room or laboratory in an instant by a special switch close at hand. The same device raises the screen out of the way while another daylight demonstration or lecture is taking up a portion of the time. The curtains are all raised or lowered in less than half a minute from the time the switch is closed, and when fully opened or closed the mechanism is automatically cut out of circuit. The operator after manipulating the switch may therefore immediately give his attention to other work.



Electric Curtain and Screen Hoist.

The drum is connected to the motor through a worm gear and a magnetic clutch. It is a reversible motor and by means of a double-throw switch is operated in one direction or the other, depending upon whether the curtains are to be raised or lowered. The limit stop provided breaks the circuit through the motor armature and the magnetic clutch, and changes the connections when the curtains are in their extreme position. The magnetic clutch ceases to act and the curtains are held in position while the armature comes to rest after its momentum is overcome.

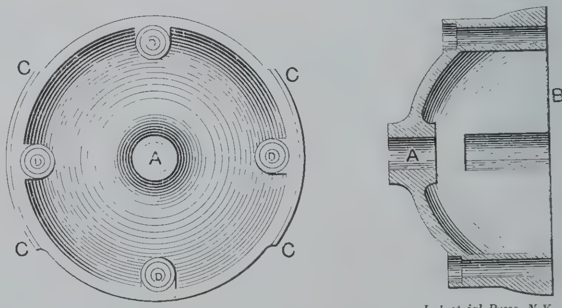
The stereopticon screen is connected to the drum by a rope and the various shades about the room are connected by cords through pulleys to the rope which extends around the room below the windows. A weight is arranged at the end of the rope which keeps it taut regardless of the action of the curtain rollers. There are two portions on the drum, one of greater diameter than the other, and the curtain roller cords are connected to one and the stereopticon screen rope to the other so as to provide for the different ranges of travel. The motor used is of the multipolar direct current type, as noted in the accompanying view.

Buffalo, N. Y. FRANK C. PERKINS.

TOOLS FOR MACHINING A SPECIAL CASTING.

Editor MACHINERY:

The hood-shaped casting shown in Fig. 1 formed part of an electrical appliance which was being manufactured in large numbers and, as it is a characteristic piece of duplicate work, the method employed in its production may prove of interest to MACHINERY readers.

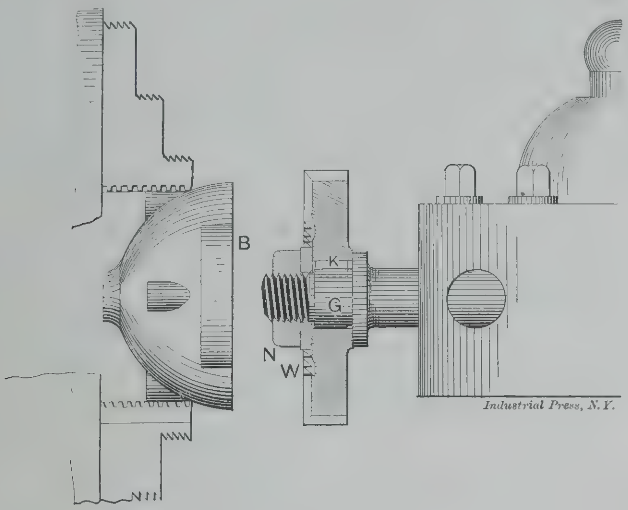


Industrial Press, N. Y.

Fig. 1. The Casting to be Machined.

The operations necessary for machining this casting were:

First, to drill and ream the ½-inch hole *A;* second, face the base *B;* third, finish the circular portions *C C* to given diameter and taper; and finally, to drill the ¼-inch holes through the center of each of the four posts *D D*. The first and second operations were both performed on a turret lathe with the casting held in a four-jaw chuck, as shown in Fig. 2. The hole *A* was first bored with the usual turret boring tool and reamed to size with a floating reamer. The work was then driven slowly, by throwing in the back gears; and the second operation, that of facing the base *B*, was performed by the use of a large face milling cutter, placed on an arbor which was held in the turret head, as shown in Fig. 2. This cutter was of the ordinary type of facing cutter except that the teeth, on the facing side, were staggered to prevent chatter. The cutter, which was driven by the key *K*, was held in place on the arbor by the nut *N* and the washer *W*.

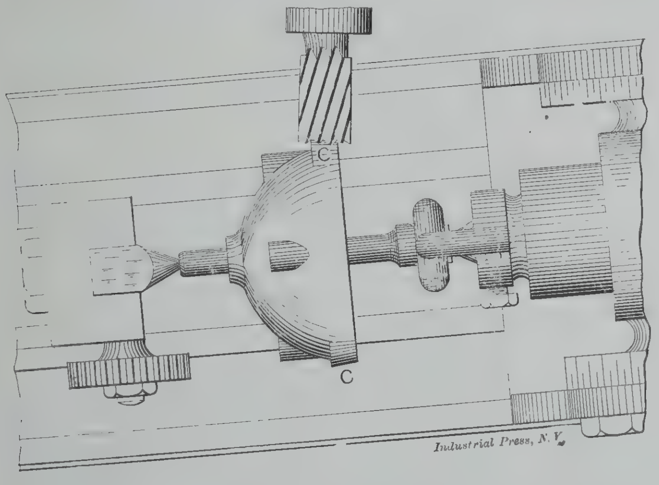


Industrial Press, N.Y.

Fig. 2. Facing the Base.

With this cutter it was possible to machine a large number of castings before it required to be ground.

The third operation, that of finishing the circular taper surfaces *C C*, was accomplished as shown in Fig. 3 by the use of an end mill in a universal milling machine. The work was held on an arbor between the tail and dividing-head centers and the swivel carriage moved around until the table and arbor stood at the desired angle with the face of the milling cutter. After setting the work so that the desired amount of stock would be removed, the cross-feed screw was clamped, and the work fed against the cutter by revolving the dividing head by hand. For the last operation, that of drilling the holes *D D*, the jig shown in Fig. 4 was constructed. This jig was made in two parts, a body casting in which the work was located, and a lid *W*, which was hinged at one side and carried the four tool-steel bushings *R R* by means of which the holes were located and drilled.

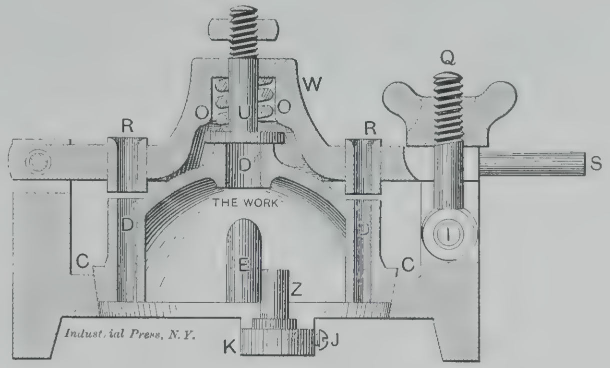


Industrial Press, N.Y.

Fig. 3. Milling the Sides.

A hinged bolt and thumb nut *Q* served to clamp the two parts together when the jig was in use.

The bottom of the body was bored out to correspond in taper and diameter with the taper surfaces of the work at *C C*. Extending inward from one side of this hole was a lug *K* in which was fitted the stop pin *Z*. The stem of this pin, where it fitted into the lug, was eccentric with the body of the pin so as to provide for adjustment, while the screw *J* locked the pin in place when the proper adjustment was attained.



Industrial Press, N.Y.

Fig. 4. Jig for Drilling.

This pin was brought against one of the inner lugs of the casting, as at *E*, and thus located the lugs in the proper position to be drilled.

When in use the swinging clamp *Q* is released and the lid *W* thrown back. The work is then slipped into the body and located within the taper seat and against the stop pin *Z*. The lid is then brought down by grasping the handle *S*, and as the spring pad *U* strikes the work the tension of the spring *O O* enables it to force it tightly down on the locating seat. The lid is then held down on the body casting with one hand, while the swinging clamp is swung up and fastened with the other. The casting is then drilled through the bushings *R R*. One of the best features of the jig is the impossibility of the chips and dirt interfering with the accurate and positive locating of the work.
Fred J. Bryon.

Brooklyn, N. Y.

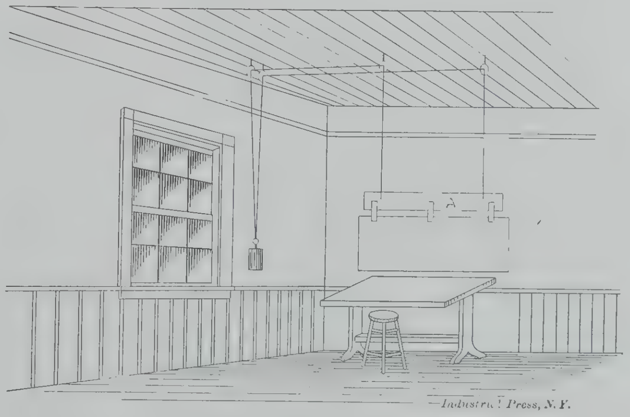
A DRAFTING-ROOM CONVENIENCE.

Editor Machinery:

How often it is that a draftsman is required to use another drawing for reference which he must continually consult, and if it is a large sized drawing it is generally kept on the consulting table beside his drawing board. This compels him to keep forever stretching to see it or constantly getting on and off his stool.

In a place where I was once employed, having much of this to do, I devised a scheme which caused some ridiculing from the boys, but which proved to be very useful as well as cheap, and it may prove of interest to some other draftsman.

The illustration will make it clear without much explanation. *A* is a pine stick ⅜ inch by 1½ inch and about 40 inches long. Onto this stick are screwed three ordinary spring clothes pins. Two strings are fastened to the stick and pass up to two screw eyes placed in the ceiling the same distance apart as the strings on the stick.



Industrial Press, N.Y.

Hanger for Reference Drawings.

Two more screw eyes are placed in the ceiling near the wall, or any out-of-the-way place, and through these the strings pass down to a weight. This holder is placed parallel to the drawing board about one inch back of it.

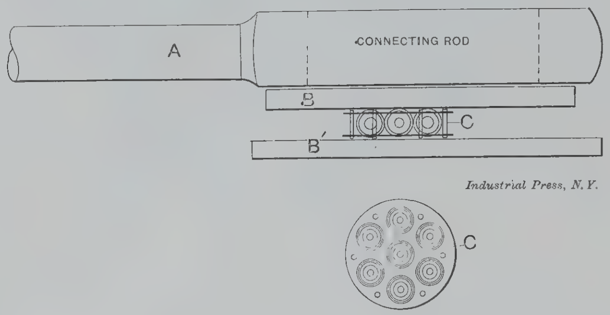
This holds the drawing where it can be easily referred to by the draftsman, and it can be easily raised or lowered to suit his convenience.

Ernest W. Duston.

BALL BEARING FOR SUPPORTING LONG WORK ON A SLOTTER.

Editor Machinery:

Recently while passing through the shops of a large concern in Philadelphia that builds blowing and high-speed engines, I noticed an application of the ball bearing to a rather unusual purpose and one that was new to me. Like many other simple things its use for the purpose is quite obvious when it is once known.



Ball Bearing Support for End of Connecting Rod.

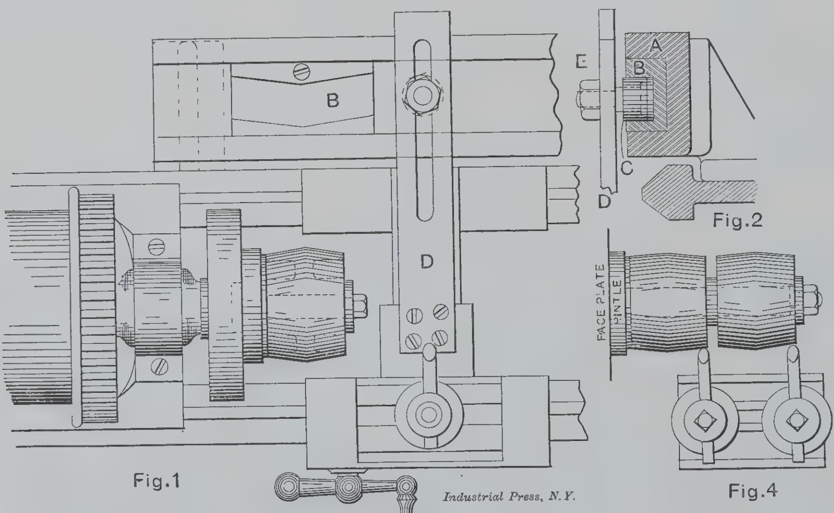
A large connecting-rod was being machined on a slotter and the ball bearing was used to support the outer end so that it was free to move in all directions with the feeds. The usual plan that I have seen followed in such cases, is to support the outer end of a long piece by a rope tackle or a chain hoist attached to an overhead support, but in some cases, as here, such an arrangement is inconvenient. The connecting-rod on the slotter was of the solid-end type, 12 or 15 feet long and weighing probably not less than 1,500 pounds. The work being done was squaring up the interior surfaces for the adjustable brasses so that the feeds were in two directions. If a roller bearing or a carriage with wheels had been used it would have been necessary to turn it one-quarter around when changing from one feed to the other. The ball bearing *C* was placed between two surface plates *B B'* under the rod *A*, as indicated in the cut. The balls were about 1½ inch diameter and were six or seven in number. They were held in a cage made of two disks of sheet iron held in proper relative position by rivets and distance pieces. The disks were, of course, perforated with holes through which the balls projected in order to bear on the plates.

Newark, N. J. F. Emerson.

TURNING PULLEYS IN THE LATHE.

Editor Machinery:

Considering the large number of excellent machines that are now made for turning pulleys it may seem a little behind the times to say anything about doing this class of work in lathes.



Lathe arranged for Turning Pulleys.

There are, however, many shops in which a large number of pulleys have to be turned, yet not enough to warrant the installation of an expensive pulley turning machine. In such shops the pulleys are turned in a lathe, the tail stock being set over to give the taper which is required to give the pulley its crown.

As this involves several objectionable features, a number of expedients have been devised whereby the pulley may be turned crowning, at the same time keeping the centers in line.

The method here described has been in use for about six years and has been very satisfactory as it is extremely simple and does the work rapidly.

A grooved rail, *A*, Fig. 2, is fastened onto the back of the lathe bed and in this groove slides the guide block *B*, in which are cut two grooves making the same angle with the center line of the lathe as it is desired that the faces of the pulley shall make with the axis. In this groove runs a roller *C*, which is fastened to the under side of the arm *D*. This arm *D* is in turn attached to the tool block. The cross feed screw is removed from the carriage so that the motion of the roller in the guide block imparts a similar motion to the tool in the tool post. The guide block *B* is clamped within the rail *A*, in such a position that when the tool is at the point of the crown of the pulley the roll will be at the apex of the groove. The tool is set by moving the tool block in and out, with the nut *E* loose, allowing the shank of the roll to slide freely through the slot in the arm *D*. The tool and guide block having been set properly, are clamped in their respective positions, and the pulley is turned in the same manner as if the face were straight. When this attachment was used to turn pulleys that had been forced on an ordinary lathe arbor it was necessary to alter the guide block for each pulley in order to bring the center of the crown coincident with the center of the pulley; so for the stock sizes of pulleys, the faceplate arbors, or pintles, were made as shown in Fig. 3. These pintles consisted of a cast iron base *F* into which was securely screwed the arbor *G*, of the same diameter as the bore of the pulley. The pulleys were held on the arbor by the washer *H* and the nut *K*, and were driven by means of the pin *L* which engaged one of the arms. The nut *K* is of such size that the distance across its corners is less than the bore of the pulley and the washer *H* has one side open at *O*. By making the nut and washer in this way, when it is desired to remove a pulley, the nut is turned only enough to release the washer which can be slipped off by the slot *O*, after which the pulley can be pulled off over the nut.

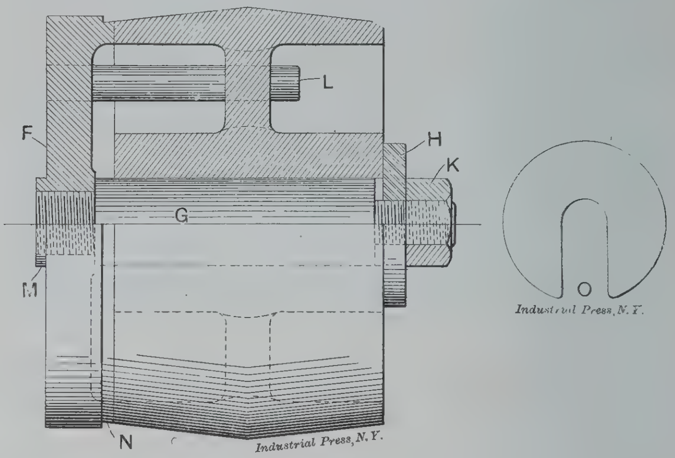


Fig. 3. Pintle for Turning Pulleys.

The pintles were held to the faceplate by two clamp bolts and were centered by the boss *M*, which fits a corresponding recess in the center of the faceplate. A little step will be noticed on the rim of the pintle at *N*. This is for setting the lathe tool and is of the same diameter as the pulley to be turned will be at the edge of the rim. This is of the greatest convenience, for in using this attachment the cut always begins at the outside edge of the pulley, and if we did not have this gage it would be necessary to calculate each time what the diameter should be at the edge in order that the pulley should have the required diameter at the crown. As it is, we have only to set our tool to the gage and we know that the pulley will have the proper crown diameter. A separate pintle must, of course, be provided for each diameter and face of pulley.

To turn a pulley with this attachment, we first set the tool to the gage on the pintle, then the carriage is run by hand, away from the pintle sufficiently to allow the pulley to be put on. After this the tool is run up to the edge of the pulley, the longitudinal feed is thrown in, and the pulley is turned, the tool feeding toward the headstock. When the turning is completed, the lathe is stopped and the pulley taken off. The carriage is then run back out of the way and the next pulley put on the pintle, the carriage brought up to the starting point, and the operation repeated. The tool having once been set for a given size need not be altered except for sharpening.

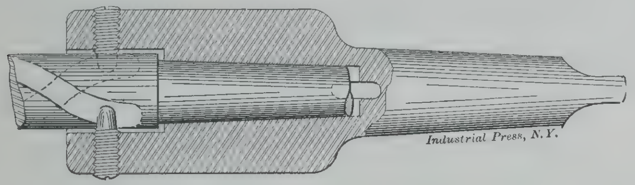
Two small pulleys may be turned at the same time by using two tools as shown in Fig. 4.

New York, N. Y. GEORGE HENRY.

HOLDER FOR BROKEN SHANK DRILLS.

Editor MACHINERY:

Like most tool-makers, I have had a great amount of trouble in trying to use drills from which the tang has been broken. These drills are too good to throw away, so I devised the socket shown in the sketch for holding them. The taper shank of the drill fits its corresponding taper hole in the socket and is thus sure of running true. After the drill is pushed into the socket the headless set-screws are screwed down into the flutes of the drill and thus keep it from turning in the socket. This arrangement works very satisfactorily and soon saves its cost in the value of the otherwise useless drills that can be used with it.



Holder for Broken Shank Drills.

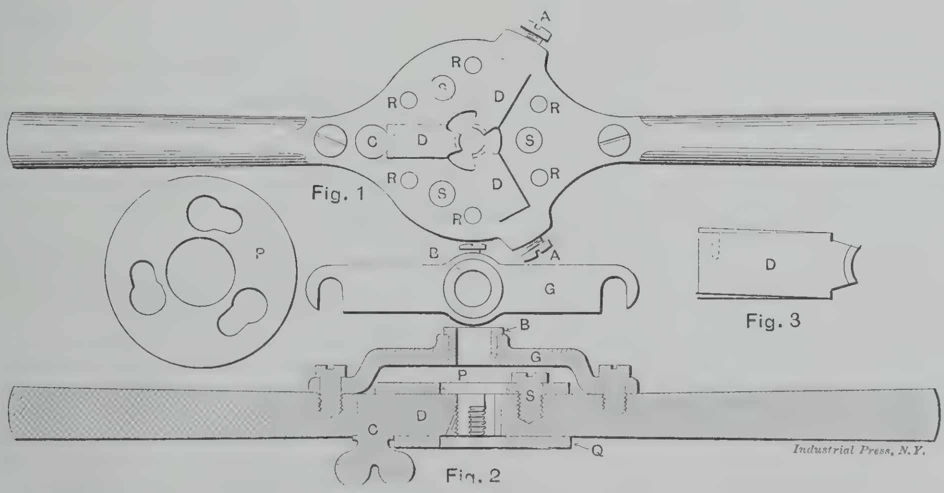
Philadelphia, Pa. FRED HARRISON.

AN ADJUSTABLE HAND THREADING DIE.

Editor MACHINERY:

The accompanying sketch shows a hand threading die, the cutters of which are backed off slightly, making it a very easy running die, and it is also provided with a way of opening the cutters to back it off of the thread that has been cut and closing them again to exactly the same size.

The stock with plate *P* removed is shown in Fig. 1 and a sectional view with all parts in position in Fig. 2.



Hand Threading Die and Die Stock.

The plate *Q* is firmly riveted to the stock by the six rivets marked *R*. The plate *P* drops over the heads of the three screws marked *S*, and after turning the narrow part of slots under these heads the screws are run down and hold the plate in position.

The cutters *D D D* are made to fit the slots in the stock, are threaded, and then tapered off on the cutting side as shown in Fig. 3 (a taper of about .006" per inch) and a thin piece of steel riveted to the opposite side with a small rivet and worked down until the cutter and wedge is the size the cutter originally was.

This throws the cutting edge in enough so that the thread following does not drag or bind on the work.

The cam *C* has a flat side and when the die is to be backed off of a thread its flat side is turned to the cutter, allowing the cutter to slide back enough for the die to run freely off the threaded bolt. It is kept in place by a small screw (not shown), the head of which is seated on the small collar beneath the butterfly head.

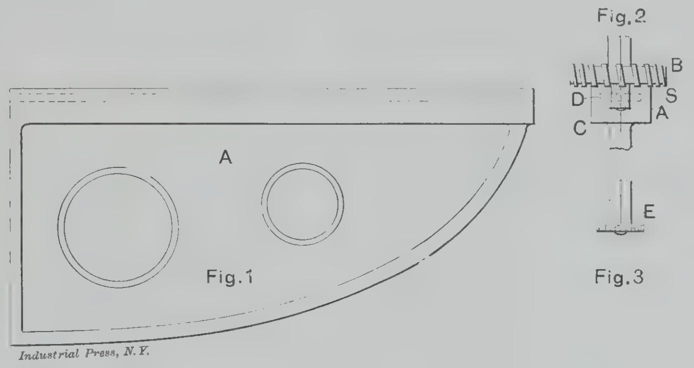
The adjusting screws *A A* are to adjust the other two cutters and need not be moved except when sizing the first thread cut. The guide *G* with its bushing *B* is plainly shown and, I think, needs no explanation. M. H. BALL.

Watervliet, N. Y.

A PROFITABLE OPERATION.

Editor MACHINERY:

The tail piece casting, *A*, Fig. 1, of the Binsse Machine Tool Co.'s boring mill, has a long undercut groove on the upper side for the feed slide to which the cutter bar is clamped. This groove was formerly machined on the planer, but at considerable trouble and expense on account of the narrowness of the undercut portions. These are squarely cut for the wings of the feed slide. Anyone having experience in planing under ledges will appreciate the difficulty of producing square accurate work with slim bent planer tools working in a narrow space. These grooves are now milled on a Brown & Sharpe No. 5 vertical milling machine which has been recently installed. They are finished in four operations, two roughing and two finishing cuts. The first operation is indicated in Fig. 2. The milling tool is a compound cutter, consisting of the surfacing cutter *B* and the grooving cutter *C*. Two of these tools are provided, one for roughing and the other for finishing. After the finishing cut has been taken, the undercut portion indicated by the dotted lines *D* is milled with the cutter *E*, Fig. 3. Two of these cutters are also provided for roughing and finishing. These cutters are made with "staggered" teeth, that is, say a tooth is located so as to cut on the upper side of the groove, then the next one on the lower side and so on. The shanks of cutters *E* are made to closely fill the groove previously milled so as to steady them sideways. The work produced in this manner is highly satisfactory, both in quality and cost. F. E. R.



Milling Tail Piece of Boring Mill.

PUNCH AND DIE MAKING.

Editor MACHINERY:

In the September number of MACHINERY Mr. Joseph V. Woodworth had an article describing the construction of a double punch and die. Now with all due respect to Mr. Woodworth, my experience as a toolmaker leads me to take exception to some parts of his method employed for constructing this die.

Mr. Woodworth states that no great care need be exercised in planing the die, as it is to be ground; but it has been my experience that it is better to plane the die carefully so as to have the top and bottom parallel. I have also found it better to bevel the sides of the die last, for by leaving the edges square it will stand squarely on edge and a surface gage can be used for laying out, which I consider much better than using a try square. In using the try square, if the diemaker tilts the beam of his square the least amount, it places the blade of the square on an angle across the face of the die.

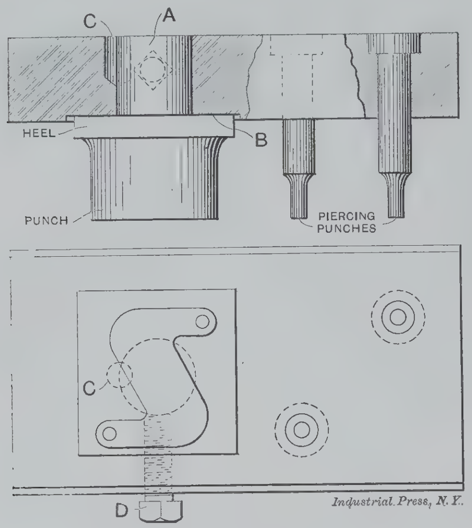


Fig. 1. Punch and Punch Plate.

Fig. 2. Prick Punch.

For outlining the blank on the face of the die, he describes the use of a female templet formed by bending a piece of brass over the face of the die and working out the center to exactly fit the male templet. Now in Mr. Woodworth's use of a female templet he introduces several opportunities for an error. In bending his sheet brass to fit the die, an *exact* fit is necessary, and this is not an easy thing to obtain. Then consider the time required for filing an irregular shaped hole to fit a templet perfectly. Supposing that the toolmaker in filing this female templet should get the edges of the profile on a slight angle (such a thing happens quite frequently), then when he scribes the outline on the die from this templet, he is scribing an outline that is not a counterpart of the master templet. Therefore, considering the chances of error in bending, filing and scribing and the time that this requires, I would suggest doing away with the use of the female templet altogether. To do this, clamp a thin parallel—a scale does very nicely—to the face of the die. Against this parallel, place the master templet, clamp and scribe the outline. Then slide the master templet along the parallel to proper position, and transfer the piercing holes directly from it. In transferring these holes, Mr. Woodworth advises the use of a center drill which fits the holes in the male templet. In making the center drill, one turns the drill to fit the hole in the templet and points it at the same time without removing it from the lathe until it is completed. But in filing the clearance of the drill it is a very easy matter to carry the point to one side, making it run eccentric to the body of the drill. True, it will spot a hole central with the drill but the eccentric motion has a strong tendency to crawl along the face of the die, thereby changing the position of the templet. A greater objection is the undeniable chance of error when starting another drill in the place spotted, for a center drill will not allow spotting deeply, as a long point would touch the die before the body entered the templet. I very much prefer to use a piece that has been turned to fit the templet and a very small prick punch turned in the center, at same turning, as shown in Fig. 2. By placing the prick punch in the templet when it is in proper position and giving it a light tap, it will prick the face of the die sufficiently to "wiggle up," as toolmakers term it, with the center indicator.

As to the punch, Mr. Woodworth advocates machining it "so that its entire length will be the shape of the blank." I think it is much better to make it as shown in Fig. 1, the reason being that the shoulder or heel left on the punch tends to keep all the weak parts from spreading during the process of hardening. I submit the following method for aligning the punch and die as an improvement on that described by Mr. Woodworth:

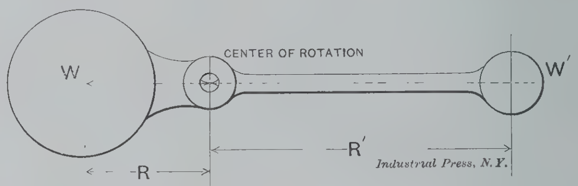
Clamp the punch plate on the face of the die and with the prick punch, shown in Fig. 2, which fits perfectly the piercing holes in the die, prick the face of the punch plate; then without disturbing the plate, scribe the outline of the blanking die upon its face. Remove the punch plate and find the approximate center of the outline scribed from the blanking die and prick punch same. Now "wiggle up" and bore the hole for the shank of the punch *A*, and at the same time face off a seat for the back of the punch at *B;* also bore the holes for the piercing punches. Make these punches as shown to fit tightly the holes in the punch plate. In making the piercing punches they should be left 1-32 inch longer than the blanking punch. Insert the two piercing punches and the blanking punch into the punch plate and fit the dowel *C* in the shank of the blanking punch. Enter the two piercing punches into the die until the face of the blanking punch rests on the face of the die; then scribe the outline of the blanking die on the face of the punch, care being taken to scribe close to the die. Remove the punch and mill as close to the line as possible, return punch to holder after beveling the edges slightly, and shear the punch, being guided by the piercing punches. Work off the stock curled up and repeat the operation until finished. If the punch is to work heavy stock, a setscrew, *D*, against the shank of the punch would be advisable.

New Haven, Conn. Frank E. Shailor.

BALANCING REVOLVING BODIES.

Editor Machinery:

Having had several discussions with mechanics of the question of the balance of unsymmetrical bodies, I have found that many have erroneous ideas on the subject. For instance, many contend that a body like that shown in the figure might be in perfect balance at one speed but not at all speeds of rotation, owing to the action of centrifugal force. I trust that the following discussion from a mathematical standpoint may help some to get the correct view of the subject.



In the figure let

W = number of pounds in larger weight.

R = number of inches from center of gravity of W to center of rotation.

W^1 = number of pounds in smaller weight.

R^1 = number of inches from center of gravity of W^1 to center of rotation.

For W and W^1 to balance each other, it is obvious that WR must equal W^1R^1, when they are at rest. Now let:

F = centrifugal force in pounds set up by W when revolving at n revolutions per second.

F′ = centrifugal force in pounds set up by W′ when revolving at n revolutions per second.

Then, of the revolving bodies balance F = F′; also

$$F = \frac{4\,\pi^2\,W n^2\,R}{g} \text{ and } F^1 = \frac{4\,\pi^2\,W^1\,n^2\,R^1}{g}$$

Therefore,

$$\frac{4\,\pi^2\,W n^2\,R}{g} = \frac{4\,\pi^2\,W^1\,n^2\,R^1}{g}$$

and cancelling the equal terms we find $WR = W^1R^1$. So we see that a perfect standing balance is a perfect running balance at all speeds, for the weight on one side multiplied by its radius always equals the weight on the other side multiplied by its radius and the speed factor drops out entirely.

It will be seen from the foregoing equations that the centrifugal force varies as the square of the speed; hence if the speed is doubled the centrifugal force is increased four times.

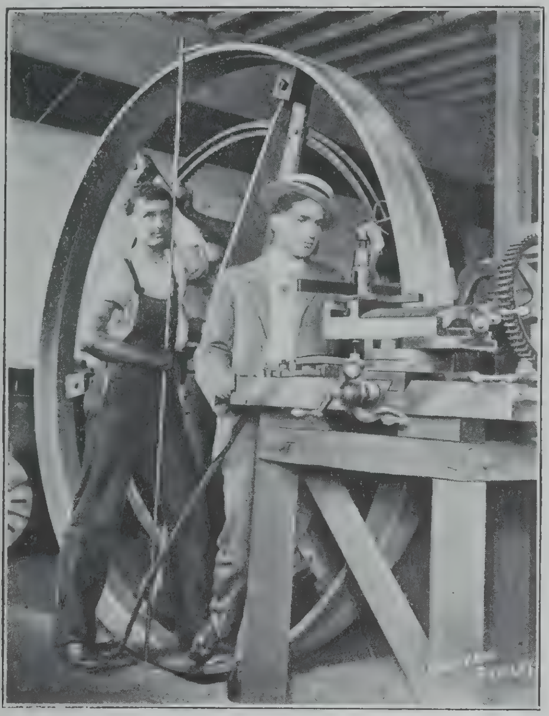
If we suppose the difference between the centrifugal force of W and W^1 to be very slight, when revolving at 100 revolutions per minute they would appear to balance. If now they were revolved 500 revolutions they would at once be seen to be out of balance, since the difference in centrifugal force would be 25 times as great as at the former speed.

Grand Rapids, Mich. G. E. Miles.

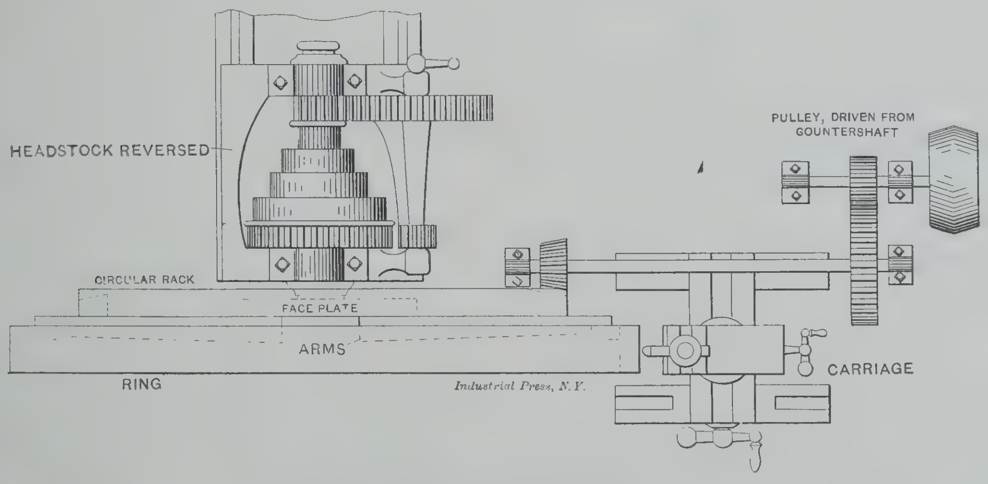
TURNING NINETY-INCH PISTON RINGS.

Editor Machinery:

In the works where I am employed we recently had occasion to re-bore a compress cylinder 90 inches in diameter and make new rings for the same. The re-boring was easily accomplished with a 6-inch bar pulled with a rack, but when it came to turning the rings we were somewhat puzzled, as the largest lathe in the shop would swing but 32 inches. The manner in which we finally accomplished the job will be clearly seen in the accompanying photograph and sketch. We reversed the headstock of the lathe so that the faceplate would overhang the end of the bed and to the faceplate we bolted six ribs or arms. Near the outer end of these arms and concentric with the center of the lathe we bolted a circular rack. The rings were cast with six lugs which were bolted to the ends of the ribs. The ring was driven by a gear and pinion arrangement clearly shown in the sketch. The carriage was mounted upon a wooden frame and the tool fed by hand. With this rig we were able to turn two rings, each 3 inches wide and 90¼ inches in diameter, in 30 hours.



Turning the Rings.



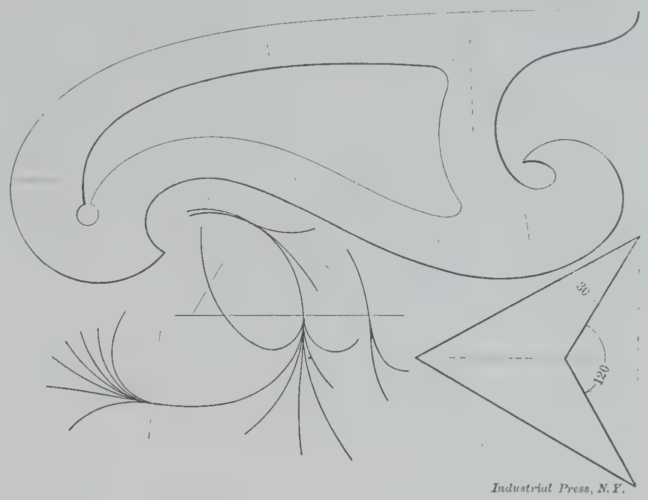
Arrangement for Driving the Casting.

Dallas, Texas. Otto P. Downing.

DRAWING COMPOUND CURVES.

Editor Machinery:

In making up double curves or reverse curves by means of compasses, or the so-called "French curve" templets, it must be remembered, that no two curves can join neatly except at points where their tangents are common, and that any two or more curves can be joined end to end gracefully, if they be tangent to the same line. This is true of two or more convex or of two or more concave curves, or of one or more convex and one or more concave.



Compound Curves and Isometric Triangle.

To facilitate this work it is well to draw at various points on the templets, lines perpendicular to the tangents thereto and in laying down compound curves to see to it that these perpendiculars coincide.

I send herewith an outline of such a templet with some perpendiculars marked thereon; also some "traces" made in accordance with this system.

Machine frames made with outlines which do not sweep into each other on this plan will be neither so strong nor so graceful as where the curves have common tangents at their points of meeting.

As in isometric drawing the main axes which are not vertical are at 30 degrees to the horizontal, there may be used to advantage to facilitate rapid drawing in of the inclined lines such an "arrow-head" device as is shown in sketch. From the base of an equilateral triangle (preferably of transparent celluloid) there is cut out an isosceles one of 120 degrees apex, care being taken to keep the sides of the large triangle equal. The piece cut out may also be finished and used for angles of 30 degrees.

Another way of making the same thing is to cut two equal isosceles triangles of 120 degrees, glue them together at the short sides, and strengthen the joint with a double dovetail or double clover-leaf key.

Robert Grimshaw.
Hanover, Germany.

GET-AT-ABLE BOILERS.

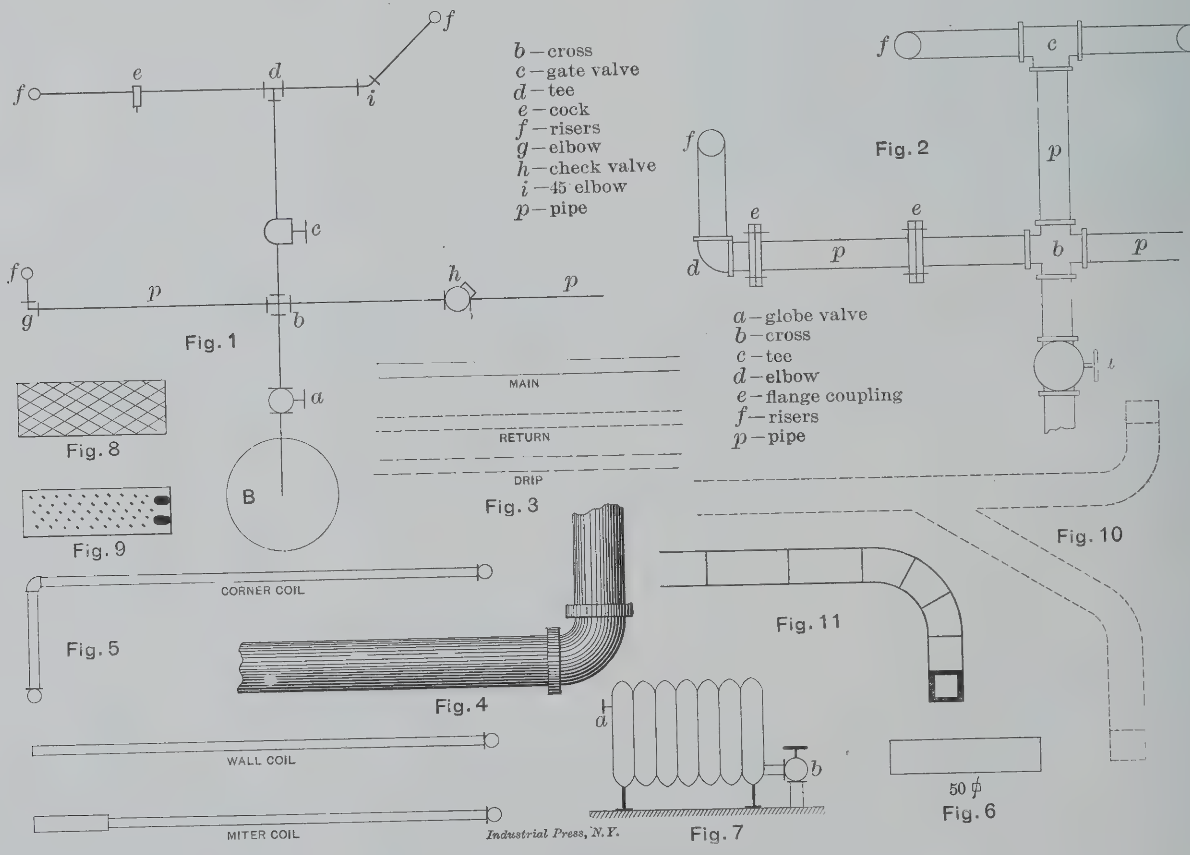
Editor Machinery:

It is a good maxim in any kind of construction that hidden work is apt to be, or become bad. It may start out good, when the maker is competent and honest; but sooner or later if you cannot get at it to inspect it, and repair it, there will be trouble. How few things give out when you can see where they are "going?" Somewhere back or below or within, where the eye cannot reach or where light never penetrates, there is a leak or a crack, or something wrong. A boiler, being an affair which may be highly dangerous, should be of a kind which will permit a man of moderate size not only to look it all over but to go all through it. His eyes should be able to see, his hand to feel every portion. If possible there should be room for a hammer to strike every part, in order to determine whether it gives a ring or not, and whether or not things are right. The boiler that you can get into, under and around is, other things considered as equal, more desirable than one which cannot be got at. There is a great deal of human nature in mankind, and the average man is not going to break his back and strain and twist his neck and break his shins crawling under and over and by obstructions more or less sharp, hard and dirty. If he owns the boiler, he will do all of this perhaps under a sense of duty to himself; but remembering that, after all, the duty is principally due to himself, he will postpone paying it until the last possible moment. Sometimes he waits until the "last horn blows," and the last horn is an explosion.

Accessibility is a source of economy, because the boiler that can be got at easily will be kept clean, and the clean boiler will make steam more cheaply than a dirty one. The accessible boiler is more safe, other things being equal, than the one which cannot be got at without a great deal of trouble. Eternal vigilance is the price of safety no less than of liberty.

The boiler which can be got at will be less likely than any other to break down suddenly and stop a whole establishment. And in these days the stoppage of steam supply may throw out of work hundreds and even thousands of hands; for steam is not only the source of power, but also the heating agent.

All things being considered, and considered in their true light and in their true weight, it pays in every way to provide in a boiler a fair degree of accessibility; and the boiler which is get-at-able is the one which can be trusted, day in and day out, to give better money's worth and cause less anxiety than the one which offers a premium on neglect. R. E. Verse.



Conventional Pipes and Fittings.

CONVENTIONAL METHOD OF DRAWING PIPES AND FITTINGS.

Editor Machinery:

The drawing of plans for a steam heating system is not usually done in strict accordance with the principles of mechanical drawing. To do so would be a mere waste of time as conventional methods of representing the various pipes and fittings are just as intelligible to the steam fitter as a correct representation would be.

Before commencing the drawing the draftsman should measure the building carefully. It is not safe to rely entirely on the architect's plans of the building, as frequently a wall is made a little thicker or thinner than the plan calls for. In a case like this the waste of time in recutting and threading pipe may amount to as much as the expected profit. Another point to be considered is the height of the various floors; these are frequently different, sometimes on the same floor there is a difference of a few inches in the height. Upper floors have usually more area than the lower floors, due to the thickness of the walls decreasing toward the top. If this is not taken into account a riser that is about 4 inches away from the wall at the first floor may be 12 inches away at the top floor.

The simplest conventional way to represent a piping system is shown in Fig. 1. The pipe is represented by straight lines *p*, the fittings by crossing the former with short lines and by circles or parts of circles.

When it is desired to have the drawing represent a pipe a little better than done in Fig. 1 we may use two lines. In this way the various fittings will, of course, look better, but in the writer's judgment, all this extra labor is in most cases merely time wasted. In Fig. 2 is shown an arrangement of piping in which the pipe is represented by double lines.

Frequently there are three lines of piping, one under the other, or alongside. In the drawing they are shown side by side. These pipes are usually steam, return, and drip. To prevent misunderstanding they may be drawn in different colored inks; say black for steam, red for return, and blue for drip. For blue-printing the use of colors is not recommended, therefore black alone should be used; the steam pipe may be represented by solid lines, the return by dots, and the drip by dashes, as shown in Fig. 3. In every case, however, an index should be given on the drawing.

A very important point is to see that the size of each length of pipe is distinctly marked.

When a drawing is to be made for "show" the piping may be shaded something like Fig. 4.

Fig. 5 shows conventional ways of representing various coils.

Fig. 6 shows a plan of a radiator; it is merely a small rectangle. The number of square feet of heating surface it is to have should be stated; the symbol given after the 50 (in Fig. 6) stands for "square feet," it is simply a small square with an *f* drawn over it.

Fig. 7 represents an elevation of a radiator, it consists of a number of vertical lines joined, freehand, at bottom and top so as to represent the various sections. An air valve is shown at *a* and a radiator valve at *b*.

Fig. 8 shows a conventional way of showing a register, Fig. 9 a pin radiator. Figs. 10 and 11 show ways of representing air ducts. Where a riser is to be shown leading up to a register it is merely necessary to make a small rectangle as shown.

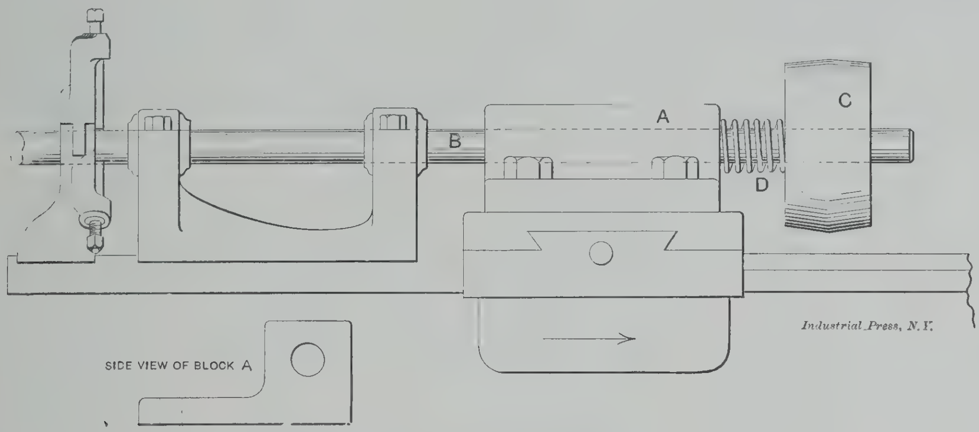
Many other conventional methods could be shown but the ones illustrated above are perhaps the best, as they are quite simple. CHARLES G. PEKER.

New York, N. Y.

RE-BORING HEADSTOCK BOXES.

Editor MACHINERY:

In the September MACHINERY, "Connecticut" asks for a method of re-boring headstock boxes. I send the accompanying sketch to show a very simple way in which this may be done.



Arrangement for Re-boring Headstock Boxes.

Before dismantling the lathe, the block *A* is bolted to the tool post and bored out to carry the boring bar *B*. The cross slide gib screws should be set tight to prevent the block from getting out of line after it is bored. The headstock is then dismantled and set forward on the ways sufficiently to allow the steady rest to be placed on the end of the bed as shown. The boring bar is centered in the steady rest and is fed by moving the carriage in the direction indicated. It is driven by the pulley *C* and the spring *D* is provided to keep the bar from jumping in feeding. C. P.

* * *

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published

3. C. Payton.—Will you please inform me whether or not there is a standard for threading steam and gas pipes which gives the number of perfect threads each respective size should have?

A.—We reproduce the following extract from a table of standard wrought iron pipe sizes, published by Morris, Tasker & Co., Philadelphia, and which may also be found in Kent's Mechanical Engineers' Pocket-book.

Nominal size of pipe.	No. of threads per inch.	Length of perfect thread.
⅛	27	.19
¼	18	.29
⅜	18	.30
½	14	.39
¾	14	.40
1	11½	.51
1¼	11½	.54
1½	11½	.55
2	11½	.58
2½	8	.89
3	8	.95
3½	8	1.00
4	8	1.05
4½	8	1.10
5	8	1.16
6	8	1.26

The taper of the thread is ¾ inch per foot for all sizes.

4. W. J. D. I have a plate bearing a series of knives which are about 7-64 inch thick, and from 9-16 to 11-16 inch wide on the end. Both plate and knives are malleable iron. I wish to harden these knives in the shortest time and cheapest way, the case-hardening to extend back about ⅜ inch from the end, the balance of bar and knives to remain soft and the points not to be brittle. Will you advise me as to the best way to do this?

A.—Melt some cyanide of potassium in a crucible or an iron dish. A comparatively shallow dish would answer the purpose. It must, of course, be large enough to receive all the projections. The cyanide must be heated to a red heat. The blades may be immersed in it and left for a sufficient length of time for the cyanide to penetrate to the desired depth. (This must be a matter of experiment, with a scrap of the same metal.) When heating in the cyanide the blade should be worked up and down a trifle, to prevent a fire crack. When heated for the proper length of time it may be removed and plunged in a bath of water. Should this, however, make the metal too brittle, use a bath of sperm oil and tallow—equal quantities. If this does not make them hard enough add alum to the oil until the desired result is obtained; although I should say the bath of water would harden them all right; malleable iron is a variable quantity to consider, as no two foundries turn out a product exactly alike, and no one foundry (so far as I know) turns out a product that runs uniformly right along—if considered from a hardener's point of view. It is best to get a good quality of cyanide, being careful *not* to get one made expressly to produce colors. There is a brand made which, when malleable iron gun frames are heated in it and dipped in water, will produce the most beautiful colors, but will not harden the work. But that is a *special* brand, and is not used for ordinary purposes. Cyanide is a violent poison, and care should be taken not to allow any moisture to get into red hot cyanide, as this would cause it to fly and perhaps severely burn the person using it.

5. Subscriber.—"Kindly state through your columns how a double helical gear (herring-bone gear) is cut, especially how the corners where the angle formed by the meeting of the teeth of the two parts of the gear are worked out so sharp and neat."

A.—If the gear is to be in one piece and the teeth must meet at a sharp corner we know of no other way than to work out the corners by hand. As this entails a great amount of work, several methods are employed in order to avoid the hand work. It is very common practice to use two gears side by side, as shown in Fig. 1. One is cut with a right-hand spiral and the other with a left-hand spiral and they are driven from the shaft by the same key. If thought necessary they can be fastened together by bolts or pins running parallel with the shaft. Another method, which permits of the gear being made in a single piece, is shown in Fig. 2. It consists in omitting a small portion of the teeth where the corner comes, which permits the teeth to be milled in the usual way.

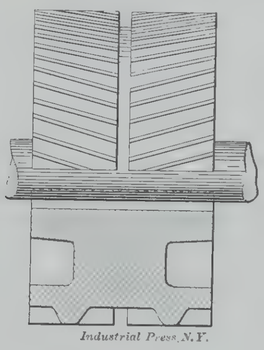

Fig. 2.

ITEMS OF MECHANICAL INTEREST.

GERMAN GLOBE VALVES—TAP SCREWS IN TAIL SHAFT LINERS—EXPANDING PULLEY—WORM GEARING—RECOIL OF GUNS.

The availability of petroleum as fuel depends on its price relative to that of coal. Roughly speaking, four barrels of petroleum are equal in heating capacity to one ton of good coal. It is quite probable that one pound of petroleum cannot be made to evaporate much more than 16 pounds of water from and at 212 degrees F. The evaporative capacity of one pound of good coal under the best conditions may be safely put at 10 pounds of water from and at 212 degrees F. So the practical calorific value of good bituminous coal may be said to be about five-eighths that of petroleum, pound for pound. A barrel of petroleum weighs, say, 330 pounds, or six barrels to the ton. At $1 per barrel petroleum is no cheaper than coal at $3.75 a ton.

The following note is taken from a recent report of the British Admiralty Committee on Naval Machinery:

Submitted, that for lining bearings, crankpins, bushes and other parts, exclusive of crosshead bushes, the following alloy has, in hard ocean steaming, been found, after extended experience, to give good results: 12 parts tin, 1 part copper, 1 part antimony, mixed in the following way: Six parts tin alloyed with 1 part of antimony, and 6 parts tin with 1 of copper, and the two mixed together. For lining crosshead brasses the following harder alloy has been found to give good results: 85 per cent tin, 5 per cent copper and 10 per cent antimony.

Clear glass is objectionable for the sunny side of a shop having large windows extending to the eaves, or in skylights. The sunlight pouring through on hot days makes a glare and heat that are unendurable. Ground glass is expensive, but a good substitute for it may be easily made by stippling clear glass with white lead and oil. This can best be done by a brush whose bristles are cut off short and square. The bristles of such a brush are dipped into a shallow dish containing the white lead and oil and then struck end on against the glass. Each bristle leaves a small dot of white on the glass that is permanent when once well dried. In this way the light passing through may be broken up without greatly reducing its total volume.

Where steam pipes are carried underground they should, of course, be covered with some insulating material to reduce the losses from condensation, and also as a measure to prevent rapid deterioration by rusting. The general experience of steam-heating companies in cities seems to indicate that the best covering for underground steam pipes is a casing made of white pine having about a 4-inch shell. The casing is built up of staves which have been thoroughly kiln-dried and coated with asphaltum. The lengths should be joined by mortise and tenon joints well made, so as to exclude all moisture. The loss from condensation with such a covering is said to range from 1½ to 6 per cent per mile of pipe of, say, 6-inch size. The loss is, of course, proportionally smaller for larger pipes when the circulation is the same, and greater in both cases when the circulation falls below normal.

The *American Engineer and Railroad Journal* relates two unusual examples of rapid cutting that were recently made at the Bethlehem Steel Company, with Taylor-White steel tools, which well illustrate the phenomenal qualities of that steel. In one instance a cut 1 3-16 in. deep was taken on a nickel-steel electric power house shaft mounted in a 90-in. lathe and revolving for a cutting speed of 25 feet per minute, the rate of feed being 3-16 in. per revolution. In the other, a nickel-steel crank shaft for a protected cruiser was machined in a 50-in. slotter by a cut 1⅛ in. deep and a feed of 1-16 in. per stroke, the cutting speed being 18 feet per minute. The former case corresponds to a removal of 66.78 cu. in. of metal per minute, or 2.318 cubic feet per hour. The great capacity of such rapid cutting can be better appreciated when it is considered that the rate mentioned corresponds to the removal of 1134.9 lbs. of steel per hour, or of 5.67 tons per day of 10 hours steady cutting.

OIL GROOVES IN SHAFTS.

The persistency of an idea that has been instilled by early training, whether in religion or in trade, is quite remarkable to say the least. No trade or avocation is without its traditions and precedents, and it sometimes requires considerable courage to oppose them even if a variant practice is obviously better. One of the most persistent ideas in the machine business is that oil grooves for lubricating bearings should be cut on the inside of the boxes. Probably not one machinist in a hundred ever thinks of cutting them in the shaft, and it is hard to convince the average machinist that such is the best practice. Once in a while some writer in a technical journal will point out that the old practice is inferior to cutting the grooves in the shaft, but it makes little impression and the average machinist goes on in the same old way. It is somewhat refreshing to find a machine tool building concern that follows the shaft-grooving practice for distributing the lubricant and to know that they have been doing it for some years. The Binsse Machine Co. groove all shaft bearings with spiral grooves, usually two in reverse spirals. This is done on short shafts by the milling machine, and the results are eminently satisfactory. There may be other manufacturers following the same practice, but they are not so common as they should be. Let the shaft be its own oil distributor; gravity is too uncertain.

GLOBE VALVES WITH LEVER AND SCALE.

A frequent cause of boiler explosions is the too sudden opening of the throttle, especially where the machine to be served is a "steam-chewer" like a steam hammer.

To prevent this and other annoyances of greater or less magnitude and to enable one to see just how far the valve is open, the globe valves shown in Figs. 1 and 2 have been brought out by a German manufacturer, Dreyer, Rosenkranz & Droop, of Hanover.

This design has also the advantage of rendering the opening and closing of large valves more easy.

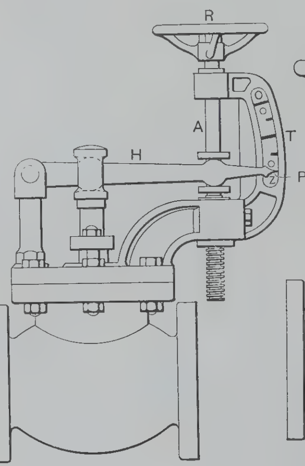

Fig. 1.

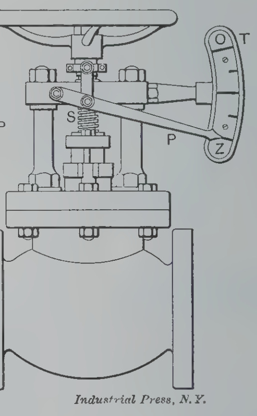


Industrial Press, N.Y.

Fig. 2.

As will be seen in Fig. 1, the stem is not threaded but is a straight, plain rod playing up and down in the stuffing-box.

The work of opening and closing the valve is performed by the screw *A* and its handwheel *R*. Any desired degree of leverage may be gained by proportioning the arms of the lever *H*, and the degree of rapidity of opening and closing is regulated by the pitch of the thread on the spindle *A*.

The position of the double pointer *P* as regards the double-faced scale *T* shows the degree of opening attained.

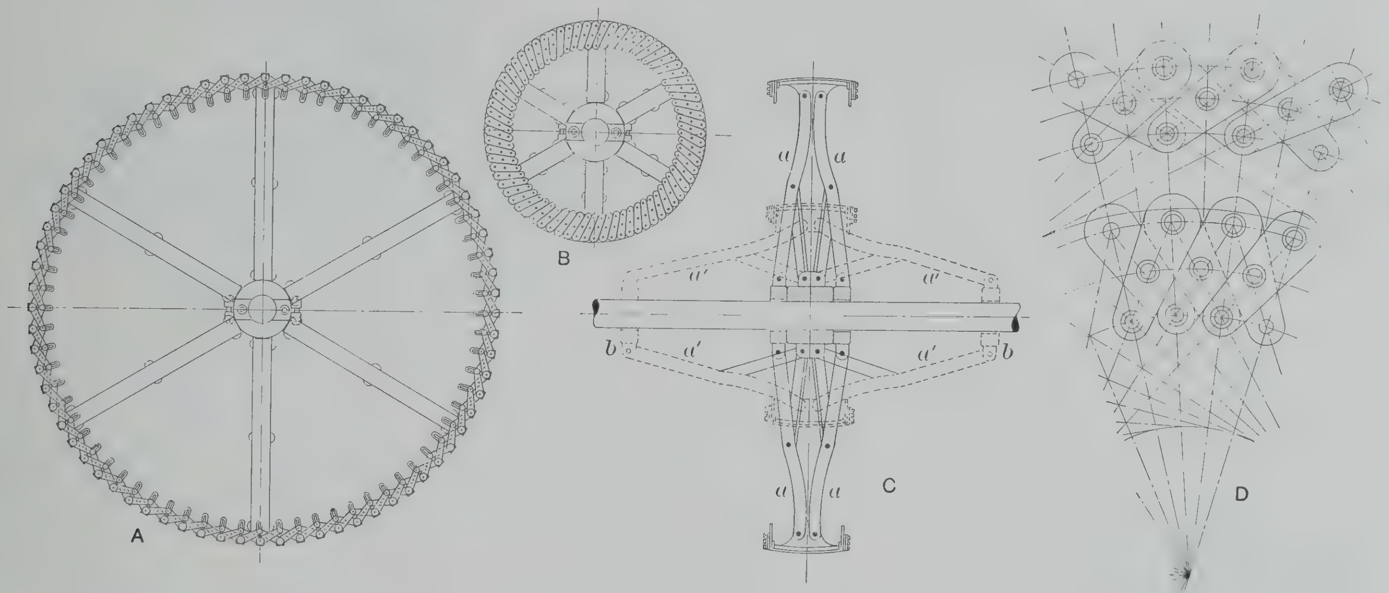
Fig. 2 shows a valve having double pointer *P* and double-faced scale *T* without the lever.

THE USELESSNESS OF TAP SCREWS IN TAIL SHAFT LINERS.

In an article, "Tail Shafting for Marine Engines," which recently appeared in *Marine Engineering*, the writer, Mr. J. P. Badenhausen, quite properly condemns the common practice of putting screws through tail shaft liners to hold them to the shafts. He says tail shaft liners must be made of specially good composition, since the stress set up by shrinking them in place has sometimes been sufficient with common alloy to split a liner from end to end. Notwithstanding the fact that the liners are shrunk in place, some marine engine builders make it a point to additionally secure such liners by countersunk tap screws. In his opinion this practice is not only unnecessary but is often the cause of great injury to the shaft. If the liner becomes loose so that the screws are the sole dependence for holding the shaft and liner together, great harm may be done, since the liner is loose and salt water will get between it and the shaft and cause corrosion. The liner being held in place by the screws it becomes doubly dangerous, as the corrosion may proceed indefinitely before it is detected. If a liner gets loose the sooner it is known and remedied the better. Again, the holes drilled into a shaft for the screws tend to weaken the shaft and form the starting point of cracks that otherwise would not have been developed.

EXPANDING PULLEY.

The illustrations, *A*, *B*, *C* and *D*, show the principle of a novel expanding pulley made by Delagneaux, of Paris, for varying the speed of automobiles. *A* shows the pulley expanded to its largest diameter, and *B* contracted to its smallest diameter. The ratio of the largest diameter to the smallest diameter is 2⅛ to 1. So if the two pulleys like *A* and *B* were belted together, the variation of speed possible would be about 4.5 to 1. *C* shows how the arms are jointed so as to collapse to the smaller diameters. When the arms are in the position indicated by *a a a a* the pulley is expanded to its largest size; when they are in the position indicated by *a′ a′ a′ a′* it is contracted to the smallest diameter. The principal novelty of construction, however, is the structure of the rim. It is made up of short sections mounted on short levers, which are jointed together in pantagraph form. The upper part of illustration *D* shows the position these levers take when the pulley is expanded; and the lower portion when it is contracted. The same action is also illustrated in the views of the two pulleys *A* and *B*. The obvious advantage of this somewhat complicated structure is that the pulley is always approximately circular in form no matter in what position it is. This produces a smoother action than is possible with the type of expanding pulley having the rim divided into a small number of sections.



Industrial Press, N.Y.

An Expanding Pulley.

WORM GEARING OF HIGH EFFICIENCY.

The *Electrical Review*, in a recent article, gave a short account of some experiments with worm gear transmission which were made by Messrs. Rosling & Fynn, Limited, of Bradford, Yorkshire, England. Starting with an efficiency of 67 per cent, which was considered good only a few years ago, by careful selection of material, design of pitch and thread, and good workmanship, they have been able to produce a worm gear with a reduction of 40:1, having a guaranteed efficiency of 90 per cent, in the case of a 4 H. P. set and 91 per cent in the case of a 10 H. P. set. In both of the above cases the worm wheel ran at a speed of 40 revolutions per minute. The worm wheel is of a special mixture of phosphor bronze and the worm is of tool steel, both accurately ground and polished; they run in an oil bath of ample size, the end thrust being taken up by ball bearings. Messrs. Rosling & Fynn, Limited, have had some of these sets running for over two years, working steadily 8 to 10 hours a day, and so far there are no appreciable signs of wear.

These sets are used to give the required reduction in electrical driving.

RECOIL OF LARGE GUNS.

It is a well-known principle of mechanics that action and reaction are equal and in opposite directions. The momentum of the gun and the shot fired are equal. The boy who has just fired a musket for the first time realizes the truth of the principle although he may not greatly admire it. When the musket becomes a rifled gun weighing 50 to 60 tons, firing a shot weighing a ton or more, the same principle still applies. J. F. Meigs in an article "Ordnance Engineering" in the *Engineering Magazine* illustrates the immensity of some of the forces called into play on a great battleship by a statement of the quick recoil of big guns. He says that one of these guns weighing as much as a fair-sized locomotive, is projected to the rear at a rate of 25 feet per second when fired. The hydraulic recoil plunger brakes stop it in a distance of about 36 inches and powerful springs instantly return it to the firing position. So quick is the movement that the eye usually fails to note it, and devices are used in gun turrets to prevent guns being loaded twice on account of the inability of gunners when in action to tell whether a gun has been fired or not. Nothing, perhaps, gives an idea of the great forces in action so well as the snapping of a 50-ton weight to the rear and back again so quickly that the human eye can scarcely see it.

* * *

The New York *Sun* publishes some interesting figures regarding the capacity of the two mammoth steamships now building at New London, Conn., for the Great Northern Steamship Co. When completed these vessels will ply between Seattle and the Orient and will have a larger capacity than any vessels in the world.

Each vessel has deck room of over five acres, available for carrying freight and can carry over 900,000 bushels of wheat. Taking the average 36-foot car, with a capacity of 60,000 pounds, this would make a railroad train nearly seven miles long. To transport a full mixed cargo of one of these vessels would require 2,500 ordinary railway freight and passenger cars. The vessels will each be 630 feet long, 73½ feet extreme beam, 55 feet 6 inches in depth; have a gross tonnage of about 21,000 and an extreme load displacement of about 38,000 tons.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

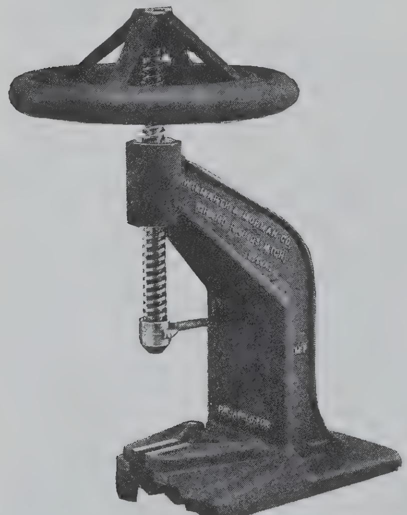
The L. S. Starrett Co., Athol, Mass., have recently brought out a test indicator which can be attached to the needle of a surface gage or to any flat or round support up to ⅜ inch in diameter. With the indicator is furnished a holder to go in the tool post of the lathe. The head of the needle has three working points so that the indicator may be used on work in front, above or below it. The gage is graduated to read in thousandths of an inch.

The Whitman & Barnes Mfg. Co., Akron, Ohio, have brought out a wrench which is a combination of a nut and pipe wrench. In general appearance it is similar to an ordinary machinists' wrench except that it has two sets of jaws, one set having the usual flat faces for use on nuts and bolts while the other set is grooved for gripping steam or gas pipes. The lower jaw on the pipe side is mounted on a pivot which enables it to engage or release the pipe in the same manner as an ordinary pipe wrench.

Nutter, Barnes & Co., Boston, Mass., have just placed on the market a new metal cutting off machine and an automatic grinder for sharpening the saws which are used. The machine uses a 13-inch saw ⅛ inch thick, and is capable of cutting iron or steel of any shape up to 4 inches in diameter. The saw and the gear mechanism by which it is driven, are mounted on a slide which has a forward feed, variable from ¼ inch to 1 inch per minute, and a quick return motion. The saw grinder automatically sharpens the 13-inch saws in about six minutes. The teeth are spaced by an accurately cut index having the same number of teeth as the saw.

"YANKEE" ARBOR PRESS.

The screw press shown in the cut is designed for forcing arbors, straightening work, or any of the purposes for which an arbor press is used. It is built by the Wilmarth & Morman Co., Grand Rapids, Mich. The screw has a coarse pitch, is double threaded, and has a handwheel with heavy rim, the inertia of which is utilized to force the arbor tightly into the bore of the work. By the use of this combination as great a driving effect is produced as with a sledge, but without the results so injurious to the ends and centers of the arbors. The inertia of the handwheel is made use of for giving the arbor two or three final impulses after it has been forced down as far as can easily be done by turning the handwheel in the usual manner, the leverage being 47 to 1. The thread is of so coarse a pitch that the screw will never lock on the work, but when turned down quickly on a tight fitting arbor, it will be repelled and turn in the opposite direction. The arrangement of the jaws on the anvil to accommodate different diameters of arbors is very convenient; they open and close in unison so that the work is always central under the screw, and arbors can be readily forced in and out of thin bushings. To straighten shafts, etc., the jaws are opened some distance and the pressure applied centrally between. With one hand on the work and the other on the wheel, the ram may be brought down with an easily gaged force and the work quickly straightened without leaving a mark on it. Hardwood strips are inserted in the bottom, so that when bolted to a lathe bed no damage will be done to the ways, while lugs keep the press forward to prevent arbors from marring the front edge.



Screw Arbor Press.

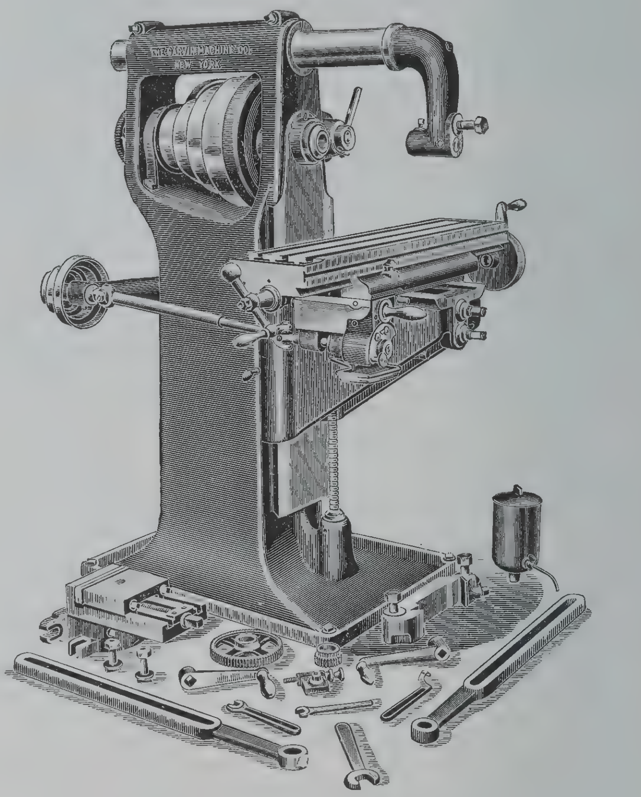


Fig. 1. No. 13 1-2 Garvin Plain Milling Machine.

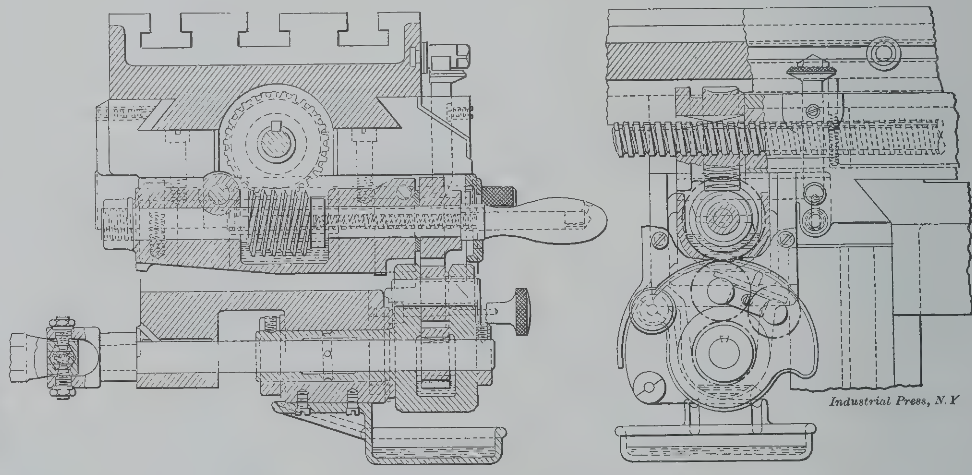

Fig. 2. Section through Feed Mechanism of Garvin Milling Machine.

GARVIN MILLING MACHINE NO. 13½.

Fig. 1 shows one of a new line of plain milling machines made by the Garvin Machine Co., New York, and embodying several recent improvements. The machine is back geared, which enables it to carry heavier cuts and at a faster rate than the usual plain miller and also provides double the number of feed changes. The table is provided with three T-slots and has a quick return, consisting of an internal gear and pinion, that is placed at the end of the slide and is entirely enclosed on all sides. The knee is of the box construction and has extra long in-and-out adjustment. The feed mechanism is shown in Fig. 2. The most direct system of gear ing is employed with a minimum number of separate parts so arranged as to respond instantly to the trip under the most severe strain when going in either direction. The drop block, carrying the worm shaft, is in one piece pivoted on a line with the top of the worm. As will be seen in the diagram, this block forms a pocket in which the worm runs in oil both when working and when tripped. The reverse motion is combined in the box and operated by a small knob at the front where most convenient.

The reversing mechanism is of the usual rocker, three-gear type. The rocker is locked in position by a plunger operated by the knob seen in front of the rocker casting and can be thrown over instantly while the machine is running. The trip and latch parts are of the plunger type. The trip button on the side pushes down the vertical plug and this acts by means of an inclined notch to withdraw the horizontal plunger from under the pin, on the side of the drop block, and allows it to fall. A noticeable feature of this machine is the universal joint. This has adjustment for taking up all wear and a center hole in the block, filled with felt, serves as an oil reservoir for the pins.

A NEW DRILL COLLET.

Figs. 1 and 2 illustrate a new tool recently patented by A. S. Davis and assigned to the Seneca Falls Mfg. Co., Seneca Falls, N. Y. This tool, which is designed for use in the spindle of upright drills can also be used in lathes and other horizontal spindle machines, for the easy and rapid change of drills, reamers, counterbores, taps, etc., without stopping the machine.

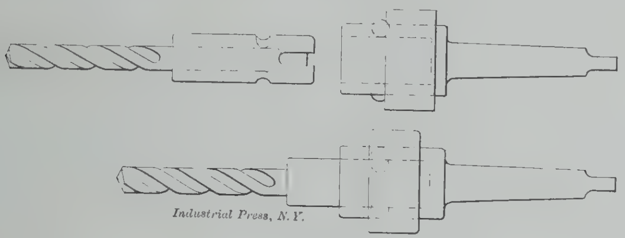

Fig. 1. Chuck, Drill and Collet.

The chuck consists of a socket piece with two steel balls, also a locking ring mounted loosely on the body of the chuck, which may be held in the hand while the chuck is revolving.

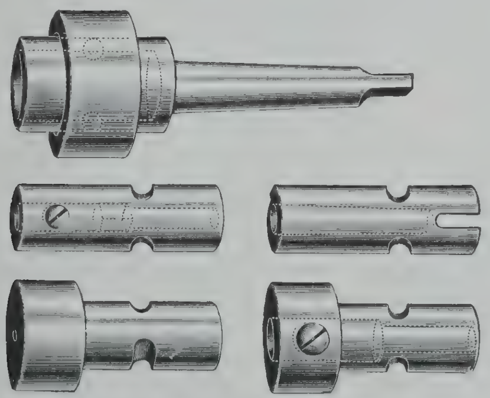

Fig. 2. Chuck and Collets.

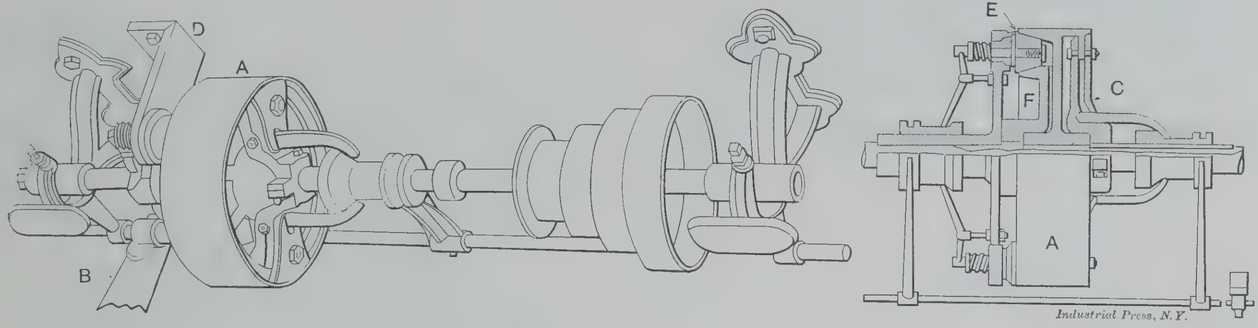
The collets are provided with two segmental grooves for receiving the balls which perform the double duty of holding the collets in place and driving same.

To change the collets, it is only necessary to raise the locking ring which instantly releases the balls, allowing the collet to drop out, when another can be inserted, and by dropping (or releasing), the locking ring, the balls roll into place, instantly locking the collet.

It is claimed that owing to the peculiar construction of this chuck, collets can be conveniently and safely changed when machine is running at the highest speed, as there is nothing to catch or shock the operator.

Fig. 1 shows the chuck, collet and drill, both before collet is inserted in chuck and with the collet in place. Fig. 2 shows the chuck and various styles of collets that may be used.



Friction Reversing Countershaft.

A FRICTION REVERSING COUNTERSHAFT.

The cut illustrates a new countershaft reversing mechanism that has been brought out by Upton & Gilman, Lowell, Mass., for use with lathes and machines of a similar character.

The noticeable feature of this countershaft is, that it is driven by a single belt but may be reversed by the same motion of the shifter that is employed for reversing the ordinary countershaft with open and crossed belts. The use of such a countershaft reduces the amount of driving belt required and also the overhead room occupied. The method by which the reversal is accomplished will be clearly seen by reference to the cut.

The pulley *A* runs loosely on the shaft but by throwing the shifter *B* to one side the friction clutch *C* engages the pulley causing it to drive the shaft in the same direction in which the pulley is revolving. On the opposite side of the pulley is the auxiliary hanger *D*, carrying two or more conical rolls *E*. When the shifter is moved in the reversing direction, these cones are forced between the beveled disk *F* and the bevel on the under side of the rim of the pulley *A*. The introduction of the cones causes the pulley to drive the disk *F* and consequently the shaft, to which it is keyed, in a direction opposite to that in which the pulley is revolving.

Owing to the difference in diameters of the bevel on the pulley and the disk the usual increase of speed is obtained that is desired for quick return.

UNIVERSAL BOX TOOLS.

The accompanying cuts show a universal box tool which has been brought out by the Bayldon Machine & Tool Co., Jersey City, N. J.

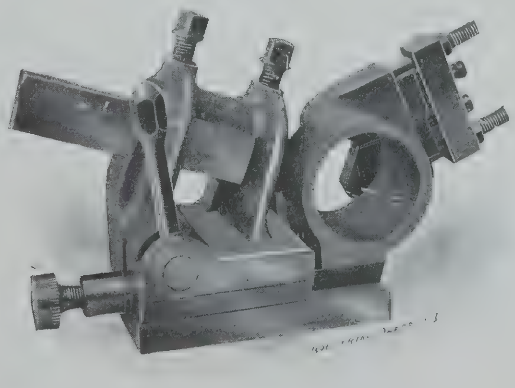


Fig. 1. Universal Box Tool. Back View.

It was originally designed to go with the interchangeable tool posts manufactured by this company, but it is also universal in that it may be used in any turret or bolted directly to the lathe carriage. The steady rest is in two pieces and adjustment is provided by means of backing-up screws. The tool is held in a gibbed slide by two set screws and an up and down adjustment is obtained by withdrawing the slide from, or pushing it toward, the work. A micrometer screw adjusts the tool to cut to size, and a cam, operated by a lever, draws the tool back from the work when the cut is finished.

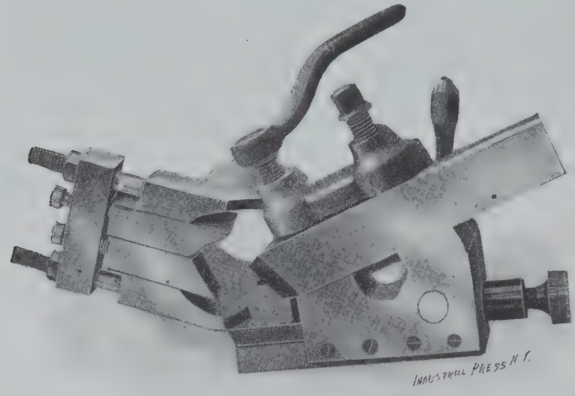

Fig. 2. Universal Box Tool. Front View.

These tools operate stock up to 2 inches in diameter, and use ordinary lathe tools 1 inch x ½ inch.

EMMERT'S UNIVERSAL VISE.

The Emmert Manufacturing Co., Waynesboro, Pa., have just placed on the market a new universal vise for use of toolmakers, jewelers and metal workers. This vise is universal in that it can be placed in every conceivable position. As will be seen in Fig. 1, there are three sets of jaws, any one of which can be swung into any position desired for holding work. One set of jaws is made rough for heavy work, another set is smooth for finished work, while the third set is provided with round projections, upon which may be fitted jaws for taper work, round work, copper work, jaws for holding any size of ring, or pipe jaws. All of these styles of jaws are furnished with the vise. Fig. 2 shows the vise with the jaws for holding taper work, in use.

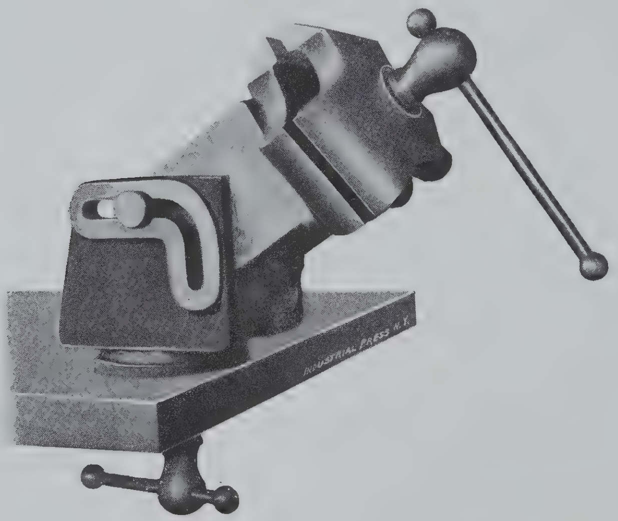

Fig. 1. Universal Vise set at Angle.

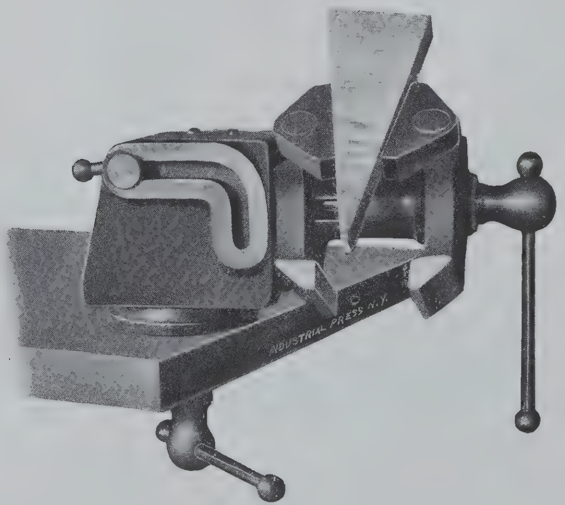

Fig. 2. Universal Vise holding Tapered Work.

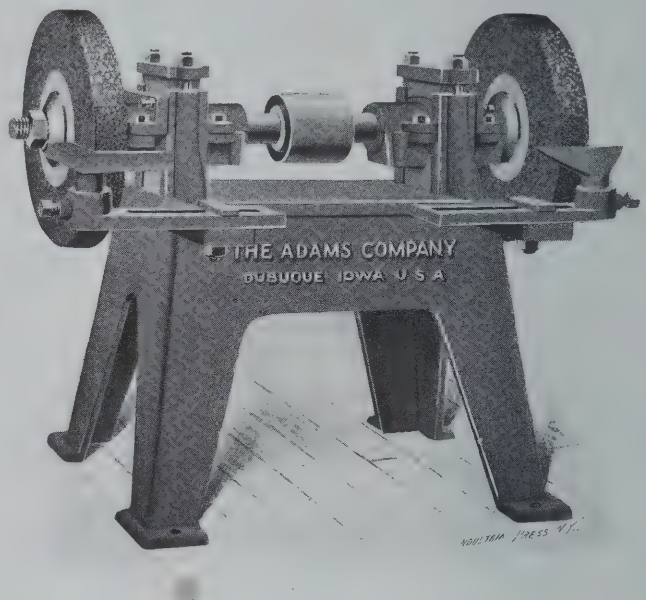
NEW HEAVY GRINDER.

The Adams Co., Dubuque, Iowa, have brought out two new grinding machines, one of which is shown in the engraving. These machines are designated as their No. 1, carrying two wheels 12 inches in diameter, and No. 4, the one illustrated, which carries two wheels up to 24 inches in diameter.

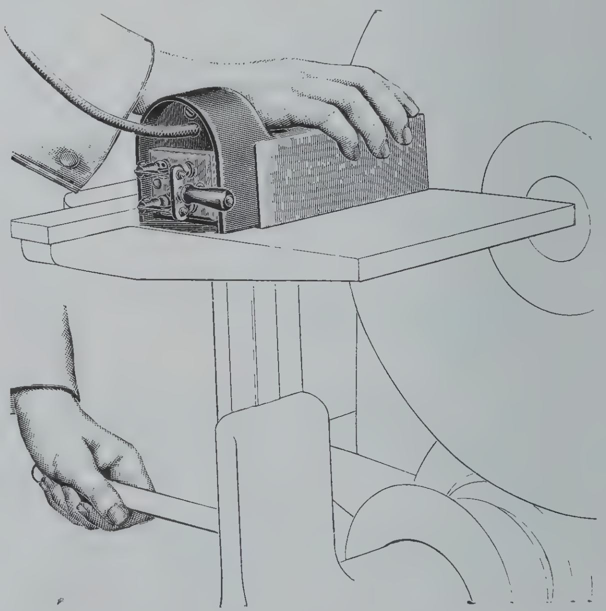


Twenty-four inch Grinder built by Adams Co.

These machines are built for heavy grinding and are provided with long self-oiling bearings which are rendered more serviceable by having the boxes held in position by elastic rubber cushions. The cushioning effect relieves the bearings from the destructive pounding which results from wheels that are running out of true.

MAGNETIC HAND CHUCK.

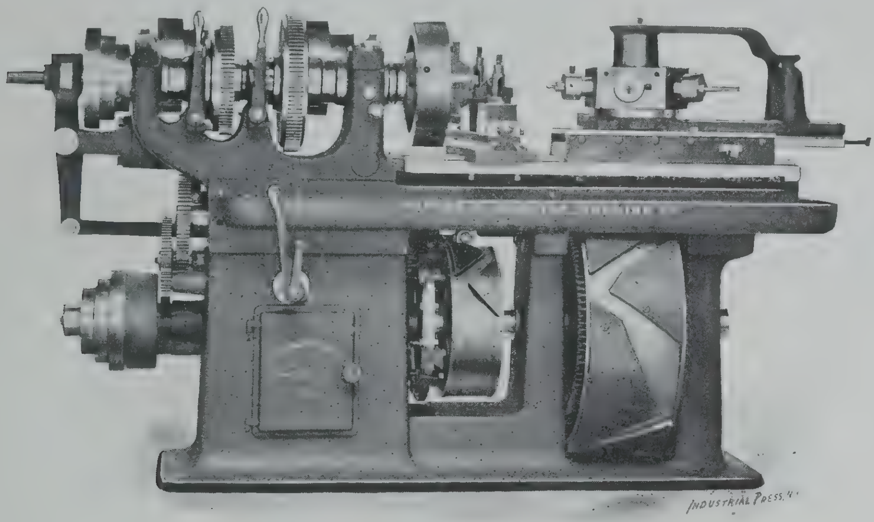
O. S. Walker & Co., Worcester, Mass., have just brought out the magnetic hand chuck illustrated in the accompanying cut. This chuck is designed for holding pieces of work that are being ground on a disk grinder. It is held by hand as shown in the cut, and is aligned by the squaring bar of the regular swinging rest characteristic of the grinders referred to. The electric connections are made by attaching the chuck to any convenient lamp socket of a 110-volt, direct current circuit.



Magnetic Chuck holding Work for Grinding.

MANUFACTURING AUTOMATIC CHUCKING MACHINE.

The cut shown herewith represents the latest improved automatic chucking machine which has recently been placed upon the market by the Potter & Johnston Machine Co., Pawtucket, R. I., who were the pioneers in the development of automatic machinery for the production of duplicate parts from castings. The machine is designed and built for the automatic production of all kinds of castings, either cast iron, steel or bronze, up to 10 inches diameter and 6 inches long. It possesses several new features heretofore unknown to this particular class of machinery. The turret has five sides, with 2½ inch holes, and it withdraws, revolves and advances at forty times the feeding speed. The feed is driven and controlled by the spindle. The cross slide can be operated automatically at any time in conjunction with the turret. The turret slide is operated by a large cam drum driven by spur gearing, the power being applied near the periphery of the drum. This arrangement is very substantial and prevents any springing of the working parts. The tool blocks on the cross slide have a travel of 4½ inches in each direction, and have screw adjustment. The standard set of cams furnished with the machine covers all ordinary pieces up to 6 inches in length and requires no adjustment. The automatic back facing attachment shown in cut is a very valuable addition to the machine. This attachment enables the hubs of gears, pulleys, etc., to be finished on both ends at one setting, and in this manner a large variety of pieces which would ordinarily require to be done in two holdings, can be finished complete at one. Another very interesting feature in connection with the machine is the automatic chuck. By the use of this chuck pieces which can be handled with one hand can be placed into the chuck and removed without stopping the spindle. Thus the machine is running all the time and requires very little attention from the operator, hence he can readily run from four to eight machines, according to the class of work being done, making the labor cost of production a very small item in comparison with the increased output thereby obtained. For gripping extra heavy or eccentrically-shaped pieces, a heavy scroll chuck is furnished. A pair of universal turning and facing tools is provided as part of the standard outfit of the machine, and takes care of all ordinary pieces up to 10 inches diameter. The machine is made in three types, viz., machine with geared automatic change speed head, which is the one shown; machine with belt driven change speed head, and machine with plain head. With geared automatic change speed head, the spindle is driven by two trains of gears, each train having four changes of speed; with the belt driven automatic change speed head, the spindle has four changes of speed; with the plain head machine the speed of the spindle is constant, but has four grade cone. The machine is of liberal dimensions, has plenty of power, strength and rigidity; and all working parts are simple and easy of access.



Automatic Chucking Machine.

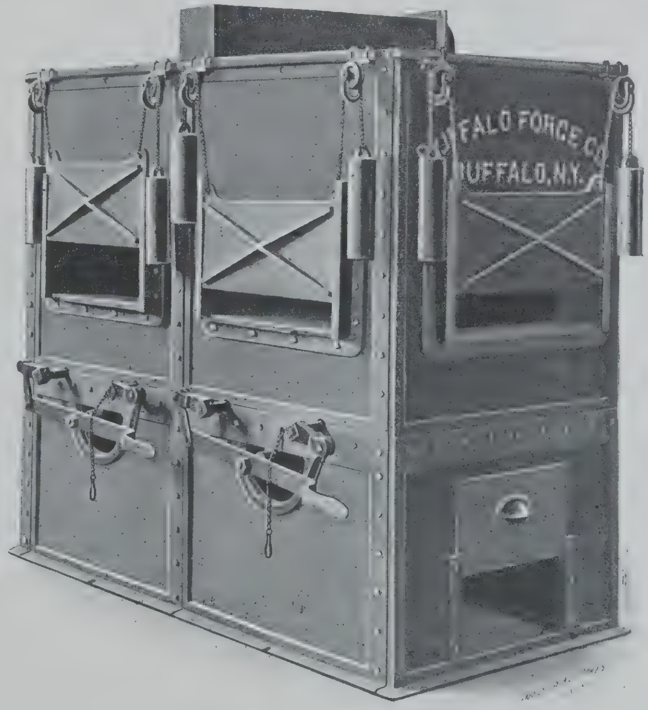
While, of course, automatic chucking machines show up their true value to better advantage when run in groups of, say, half-a-dozen or more, yet if a concern had not a sufficient amount of work to keep several of these going, this machine requires so little attention, that it can easily be run in connection with some other machine, say an engine lathe or a turret machine, and the additional product obtained upon the automatic chucking machine is secured without extra labor cost.

Although this new designed tool has been on the market but a comparatively short time, yet it has been favorably received by the trade, who fully realize the advantages to be gained by the use of such machines. They have already found their way into a number of shops, including the following lines: Textile machinery, printing presses, cream separators, woodworking machinery, pumping machinery, power transmission machinery, electrical machinery, sewing machines, punches, presses, pneumatic hammers, air brakes, etc.

A DOWN-DRAFT FORGE FURNACE.

The accompanying half-tone illustrates a forge furnace recently brought out by the Buffalo Forge Co., Buffalo, N. Y. It is especially adapted for heating work in connection with a steam hammer or similar heavy forging.

A new idea has been introduced in building this forge in sections. Two of these sections are shown in the engraving. In this way the capacity may very easily be increased at any time by installing additional sections. The first or original section is 30 inches long, and each additional section adds 36 inches to the length of the forge, making 66 inches the usual length. Each section is furnished with balanced slide doors on all four sides. When these doors are opened, access may be had to any part of the forge without the least trouble.



Buffalo Down-draft Forge Furnace.

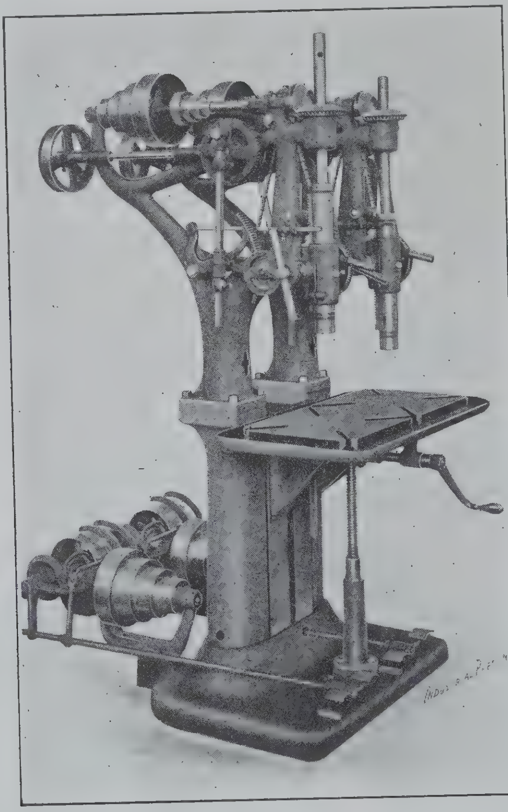
The height from the floor to the top of the grate is 36 inches—the door sills in turn being set slightly above the grate, which is of the improved rocker-grate type 24x66 inches. The cut shows the lever attachment for rocking the grate and removing the ashes, and also the chain which is connected to the air box.

The Buffalo down-draft principle of smoke removal is incorporated in this forge. In the illustration, the stationary exhaust hood is shown at the top of the forge. It carries away all smoke and exhaust gases, allowing none to escape into the shop. The smoke and gases are immediately and completely withdrawn by down-draft suction through underground tile pipe, there being no escape from even the heaviest fires. This does away with all overhead galvanized iron piping, which is subject to frequent renewal, and always obstructs valuable light and space.

A clean-out door is placed at the bottom of each section, allowing of easy access below the grates. The forge is completely lined with fire-brick, and in the roof there is an additional strip of asbestos. The weight of the forge alone, i.e., the two sections without the brick lining is 5,000 pounds.

NEW MULTIPLE SPINDLE DRILL.

The B. F. Barnes Co., Rockford, Ill., have just placed on the market a new multiple spindle drill which is furnished with two, three, or four spindles as may be desired. It is particularly adapted for rapid work in manufacturing plants where there are duplicate pieces to be drilled. The characteristic feature of this drill is that it requires but one performance of the operator for each complete operation of a spindle; that is, when started the spindles go down to the work, drill through and return automatically. All of the spindles run independently, so that one man can easily operate a four-spindle drill.

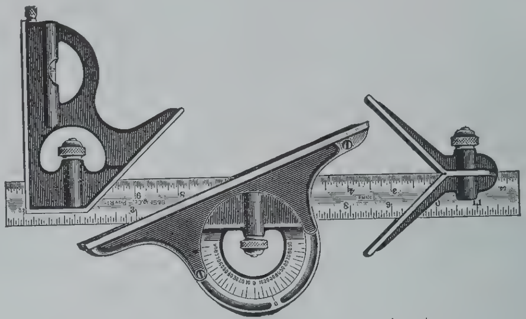


Multiple Spindle Drill.

This machine will drill to the center of a 19-inch circle. The table has a vertical travel of 14 inches and the spindles a vertical travel of 12 inches. It also has quarter-turn countershafts, and many other special features, as will be seen from the photograph.

A NEW COMBINATION SET.

The Brown & Sharpe Mfg. Co., Providence, R. I., have recently placed on the market the new combination set illustrated in the accompanying cut. This set embodies all the essential features of their combination squares with the addition of the protractor head. As all parts are interchangeable, the head can be used on the same blade as is furnished for the combination squares. The revolving turret is engine divided accurately to 90 degrees either side of the zero line and every care is taken to insure this line being at right angles to the face of the head; this, of course, is very essential to the accuracy of the tool. An important feature that has been added is the indication of a second zero line opposite the one shown at the top of the head. This greatly enhances the utility of the tool, making it more convenient for use in setting work and laying out angles, as many times the zero on the upper part of the head will be hidden by the blade and the other zero can, in such cases, be used to read from.



Combination Square, Level and Protractor.

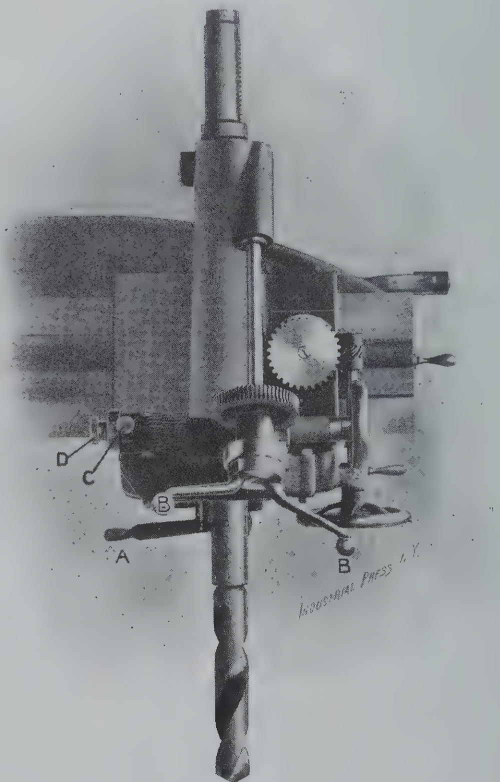
The clamping groove of the blade, instead of being square and having sharp corners, as is usual in tools of this kind, is round. This, beside allowing the rules to be made stronger, also insures the blade being drawn up against the side of the head square with the face when clamping. This form of groove also prevents the accumulation of dirt, as there are no sharp corners, a feature much appreciated in tools of this character.

Each head is furnished with a level, which forms an important adjunct to the protractor head, allowing same to be used as an inclinometer. The level is accurately set for parallelism and after the adjustment is made it is rigidly clamped into position.

Another feature that has been added to these protractors is a reversible head. This allows either side of the tool to be used in transferring angles and avoids, in many instances, the necessity of resetting. The face of the head projects about ½ inch each side of blade, making the face in all about an inch wide. The length of these heads is about 7 inches.

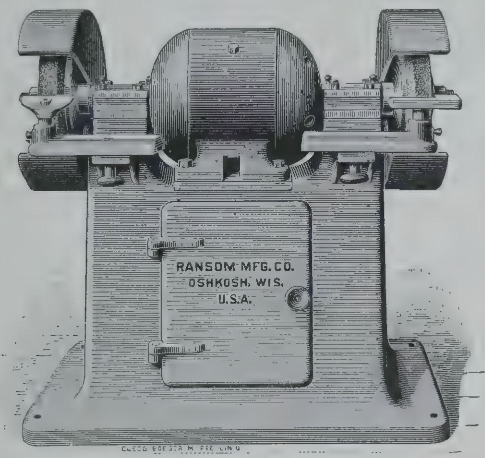
IMPROVED HEAD FOR RADIAL DRILL.

The Wm. E. Gang Co., Cincinnati, Ohio, builders of the five foot radial drill illustrated in the September number of MACHINERY, have perfected a new head and feeding mechanism which they are applying to this drill.



New Head of Radial Drill made by Wm. E. Gang Co.

The feeding mechanism is so designed as to eliminate the necessity of added weight for counter-balancing the spindle. It will be seen that the lower part of head is formed into a casing which entirely surrounds the driving gears on and near the spindle. Gear covers, not shown in cut, are placed over all other gears. The arm is of the usual oval section, enclosed, with web across the front, and heavily ribbed and braced. Two trains of gears connect spindle with shafts at back of head so that a slight up or down movement of lever *A* gives a slow or fast speed. The spindle gear is placed in the lower part of the head so that power is applied to largest diameter of spindle and close to the work. Ratios of gearing between spindle and shaft at back of arm are 18 and 3¼. All handles are conveniently located and easily and quickly manipulated. The machine is provided with an ample number of spindle speeds and feeds.



RANSOM MFG. CO.
OSHKOSH, WIS.
U.S.A.

Electrically-driven Emery Grinder made by Ransom Mfg. Co.

BB are handles which, when used as cranks, give means of quickly traversing the spindle in either direction. A light pressure up or down on one or both of these handles instantly connects or disconnects the feed by means of a powerful friction. *C* is a knob, by turning which, any one of the feeds is quickly obtained when the drill is working. The knob *D* operates a friction for disconnecting the feed gears so that when not in use, all these gears and shafts are at rest. The lower handwheel is for traversing the head along the arm by means of spiral gears, rack and pinion, while the upper wheel is for feeding the spindle by hand.

Another improvement that has been made on the drill is to so construct the column that it is raised from its seat onto roller bearings when the arm is revolved.

This machine has successfully tapped 6-inch iron pipe flanges with evidence of considerable power to spare.

RANSOM EMERY GRINDER

The Ransom Mfg. Co., Oshkosh, Wis., have brought out an electrically-driven emery grinder designed to carry two wheels up to 18 inches in diameter. The motor is entirely enclosed and the armature is wound upon a sleeve which is keyed directly to the spindle of the machine. The journals are of cast iron and are provided with ring-oiling devices which supply oil on top of the shaft when the grinder is running.

The motive power is furnished by a 5 H. P. motor, which is capable of carrying an overload of 50 per cent. Careful tests show that to run this machine free with two 18 x 2-inch wheels, 1,200 revolutions, on a 220 volt current, requires ¾ H. P. To run it with one man grinding very hard requires 3 H. P., while with two men pressing as hard as possible 6 H. P. is required. As the motor is capable of 50 per cent overload it will be seen that the power of the motor is sufficient for any load that can be put upon it.

ELECTRICALLY-DRIVEN BOILER TUBE CUTTING MACHINE.

The Bignall & Keeler Mfg. Co., Edwardsville, Ill., have recently made a number of machines illustrated in Figs. 1 and 2, which are used in tube mills for cutting boiler tubes. These machines are designed to cut tubes from 2 inches to 5 inches in diameter, and from 8 feet to 20 feet in length. The bed is provided with two movable carriages, each carriage being equipped with a heavy steady rest, cutting off tools, and reaming lever, the steady rests having interchangeable blocks which are babbitted for the several different sizes of tubes; they thus hold the tube firmly around the greater part of its circumference, and provide almost perfect rests.

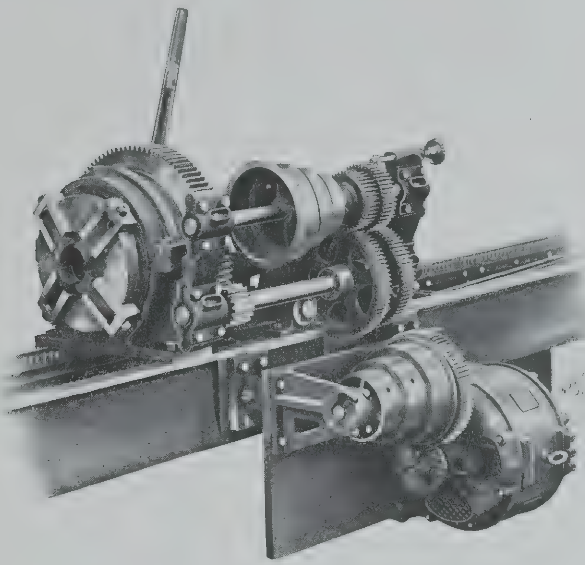


Fig. 1. Electric Drive of Boiler Tube Cutting Machine.

The headstock is built with a lever chuck which is operated while the machine is in motion; in other words, after the grips in the chuck have been set for a certain size of tube, the machine can be run continuously while working on that one size of tube, and as the machine is run for a day or several days on the same size of work the lever chuck accomplishes a great saving in time. A separate set of grips is used for each size of tube. The grips are made of tool steel, tempered, and are turned to the exact outside diameter of the tube. The inside of the grip is left perfectly smooth and they hold the tube by friction only, but as they grip the tube around almost its entire circumference there is no likelihood of its slipping.

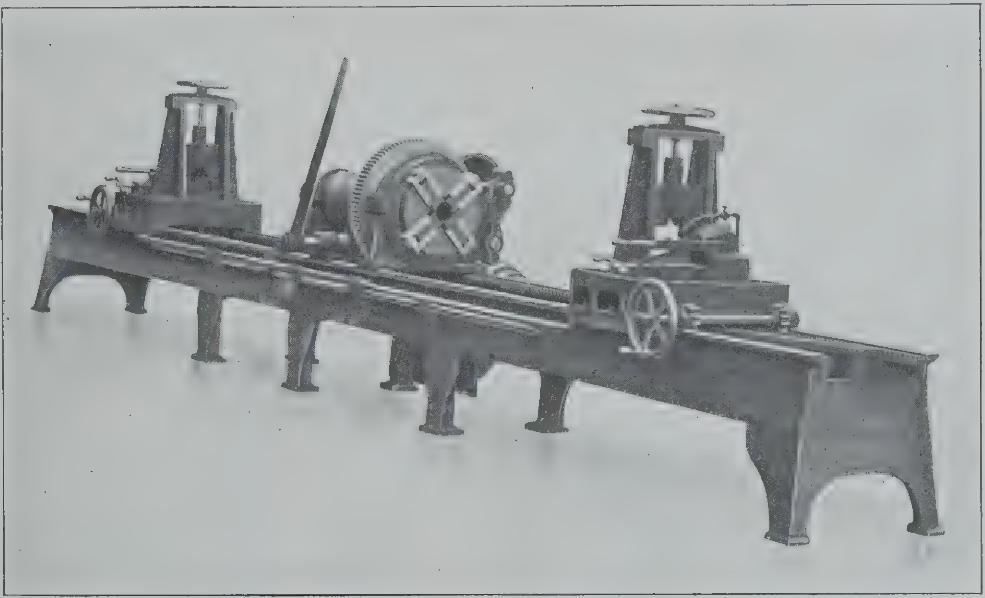

Fig. 2. Double End Boiler Tube Cutting Machine.

The machine is equipped with a 3 H. P. Westinghouse induction motor. The motor, shown in Fig. 2, is held on a swinging table which is hinged to the side of the bed. It is geared into a countershaft supported on this same table. A short belt is run between the countershaft cone and the machine cone. The weight of the motor and the countershaft provides the necessary tension.

The machine is provided with an automatic oiling system, which keeps the cutting-off tools of both carriages continuously supplied with oil.

NUT MACHINE AND ANNEALING BOX.

The Ray Automatic Machine Co., of Cleveland, Ohio, have brought out an automatic nut machine, which is the invention of Mr. A. D. Ray.

The machine provides for punching the nut, piercing the hole, chamfering the corners and tapping the thread. The stock is fed to the machine from a coil upon a reel. The machine is fitted with two tapping spindles working alternately, that is, while a nut is being tapped under one spindle another nut is being punched and carried forward to the other spindle, so that no time is lost. Any style of nut can be made on this machine and by the addition of an extra spindle it will work irregular shapes.

It is capable of producing finished nuts at the rate of 30,000 per day.

This company has also placed on the market a steel annealing box, 18 x 10 x 10 inches, made of 18 gage sheet steel. This box is for use with "Vulcan" annealing putty which is produced by them. With it Mushet or self-hardening steels are easily brought into workable condition without in any way impairing the life of the material. Steel to be annealed is heated to a cherry red; then with the box about half full of the putty, it is placed as near the center as possible and covered with more putty until the box is full. It is then tightly packed down, the cover put on and the steel allowed to remain until it is cold. By this process the most stubborn steels may be readily and thoroughly annealed.

* * *

A number of readers desire to see drawings and descriptions of tool chests fitted for the tools that a tool- or die-maker should have. Photographs would add to the value of such contributions as they would give a better idea of the appearance and finish.

ADVERTISING LITERATURE.

The Garvin Machine Co., New York. "List No. 26" of new and second-hand machine tools.

The Star Dynamo Works, Jefferson City, Mo. Pamphlet descriptive of the company's direct-current dynamos and motors.

L. S. Heald & Son, 222 M. St., Barre, Mass. Pamphlet entitled "Nothing Succeeds Like Success," calling attention to the American center grinder of their manufacture.

The Tanite Co., Stroudsburg, Pa. Circular of emery wheels. This describes the Tanite emery wheel, its productive capacity, its strength, evenness of wear, and other advantages.

Wyman & Gordon, Worcester, Mass. Circular advertising the company's forgings, and containing a short story of Sir William Siemens. This is the seventh pamphlet with short accounts of the lives of noted engineers published, and we are informed others are to follow.

The Akron Electrical Mfg. Co., Akron, O. Reprint in pamphlet form of an address by F. B. Duncan on the "Electrical Equipment in Modern Machine Shop Practice." Mr. Duncan is now connected with the Akron Co.

The Laidlaw-Dunn-Gordon Co., Cincinnati, O. Catalogue of pumping machinery. A full line of compressors is listed and illustrated and a number of useful tables on air, its weight, the flow of air in pipes, etc., are given.

The Chicago Pneumatic Tool Co., Franklin plant, Franklin, Pa. Standard illustrated catalogue of the air compressors manufactured by this company. These are designed for riveting, drilling, chipping, hoisting, but are also suitable for all other purposes where compressed air is used.

The Jeanesville Iron Works Co., Jeanesville, Pa. "Advance Sheet No. 15," containing much information regarding the Jeanesville pump. Many half-tones and line cuts are used showing the different sizes and styles of pumps, and there are tables giving working data on simple and compound pumps.

The Link-Belt Engineering Co., Philadelphia, Pa. Bulletin No. 1001, of the Renold silent chain gear used with electric motors. This chain and its several parts are fully described and illustrated, and it is shown in connection with motors for driving drill presses, boring machines, punches and a number of other tools.

The American Blower Co., Detroit, Mich. Illustrated sectional catalogue No. 141, of "A B C" pressure and volume blowers. These are shown in a large variety of styles. The "A B C" countershafts are also described and illustrated. Eight pages are devoted to a number of useful tables.

The Cincinnati Shaper Co., Cincinnati, O. Catalogue A, Sept., 1902, of "Cincinnati" shapers. These include 16- to 24-inch crank shapers, single-geared and back-geared; 26- to 30-inch rack shapers, triple-geared; and a number of electrically-driven shapers. The "Cincinnati" traverse shaper is also described, several sizes and styles being illustrated by a number of fine half-tones.

The Pratt & Whitney Co., Hartford, Conn. Pamphlet describing the new profiling machines recently brought out. These are made in two sizes, and are for finishing gun parts, sewing machine parts, etc. They are built with one or two spindles, the one-spindle profiler being made for manufacturers who do not need a machine for both roughing and finishing cuts at a single setting of the work.

The Detrick & Harvey Machine Co., Baltimore, Md. Illustrated catalogue of open-side planers. This is a newly issued catalogue and gives a description and excellent half-tones of the company's 30-, 36-, 42-, 48-, 60-, and 72-inch planers. A number of views of the work that is done on these planers are also given. The company also manufacture drilling machines, bolt threaders, nut tappers, saw setting and filing machines, etc.

The Crocker-Wheeler Co., Ampere, N. J. Pamphlet entitled "A Crocker-Wheeler Trolley Trip." This describes a trip by trolley car over the Flint Division of the Detroit United Railway. The pleasant journey takes in Royal Oak, Rochester, Romeo, Oxford and Flint. The power station in Rochester, which furnishes the power used on this line, is described, together with the Crocker-Wheeler machines used therein, and several interesting illustrations of picturesque spots along the line are given.

The Crane Co., Chicago, Ill. 1902 pocket catalogue of steam goods. This is a very complete catalogue, cloth bound, and containing 464 pages, 12 of which are devoted to a very complete index. Valves, cocks, brass and iron fittings, steam and gas fitters' tools, engineers' and engine builders' supplies, wrought pipe, etc., are listed in this catalogue. The standard goods are first described and illustrated, then come the extra heavy goods; next the hydraulic and lastly, wrought iron and steel pipe—an arrangement which greatly facilitates the search for any particular kind of goods. Some useful tables are also given. It will be sent, upon request, to any one interested.

"An Industrial Problem" is the title of a pamphlet upon cost keeping, gotten up by W. S. Rogers, Keene, N. H. It is designed primarily to call attention to the universal cost system devised by Mr. Rogers, but it contains reproductions of the various cost, material, record and other cards required, with an exposition of the system, and full directions for placing it in operation. The system is to be used in connection with a time clock; and for those who desire to adopt it in its entirety sets of cards, a time clock and accessories needed for a full shop equipment will be furnished by the inventor. In working out the system, the effort has been made to reduce the cost in the office, one clerk being required for a plant of considerable size. Further information will be had by addressing W. S. Rogers, Keene, N. H., and the pamphlet will be sent to those interested for 10 cents.

The Cleveland Automatic Machine Co. (formerly the Cleveland Machine Screw Co.), Cleveland O. Handsomely illustrated catalogue entitled "The Cleveland Automatic." This is devoted to a description and illustration of the line of automatic machinery manufactured by this company. Some forty half-tone cuts are used to show the varieties of machines built, which include automatic turret machines from ¼-inch to 6 inch chuck capacity; automatic plain machines of from ⅜- ⅝- and 1¼-inch capacity; 2-inch and 18-inch automatic chucking machines, and the parts made on these; a two-hole turret machine for the rapid making of parts where only two tools in the turret are required; a tool and surface grinder; 4-inch and 6-inch worm milling machines, with samples of the work done on these machines, etc. Thirty pages are devoted to the description and illustration of the attachments to be used on the company's machines and which they carry in stock. These include magazine attachment, independent cut-off attachment, cross-drilling attachment, etc. Altogether this catalogue will prove of the greatest interest to those requiring this class of machinery.

MANUFACTURERS' NOTES.

The Detroit Graphite Mfg. Co., Detroit, Mich., report that their factory is working to its fullest capacity in taking care of current orders.

The Uniform Steel Co., formerly of Newark, N. J., have recently completed a new factory at Rahway, N. J., for the manufacture of high-grade crucible steel for lathe and planer tools, etc.

The J. F. Towsley Mfg. Co., Evans, Gest and Berlin Sts., Cincinnati, O., manufacturers of wood-working machinery, are building an addition to their shop that will nearly double its capacity.

The Nazel Machine Tool Works, Philadelphia, Pa., have moved into new quarters at 1046 Ridge Ave., and are making a full line of portable drills, portable keyseating machines, centering machines and pasteboard box machines.

The National-Acme Mfg. Co., Cleveland, O., manufacturers of screw machinery, have opened an Eastern office at 510 Arch St., Philadelphia, under the management of Mr. L. M. Waite; also a Western office at 2 and 4 South Canal St., Chicago, with Mr. Geo. D. Grant as manager.

The Hendey Machine Company, Torrington, Conn., manufacturers of lathes, planers and milling machines, are adding a three-story brick building, 63 x 140, to their works. Connected with this is a tower five stories high for water tank, etc., to supply the sprinkler with which their plant is equipped.

Pawling & Harnischfeger, Milwaukee, Wis., who manufacture electric cranes and hoists, state that the demand for their products remains very satisfactory. They have recently received a large number of orders from well-known firms for cranes and hoists of various sizes, ranging from 3 tons to 30 tons.

The Diamond Drill & Machine Co., Furnace St., Birdsboro, Pa., builders of grinding machinery, have almost completely recovered from their recent fire and expect to have their new steel plant and iron foundry in operation within the next two months. They are also building a large blacksmith shop and doubling the capacity of their electric plant.

H. B. Rockhill, who for the past two years has been employed as superintendent for the United Cigarette Machine Co., Ltd., Lynchburg, Va., has purchased a two-story brick building, 50 by 100 feet, in Roanoke, Va., to be equipped as a general first-class machine shop. This will be known as the Rockhill Machine Works, with a capital of $10,000. The works will be in operation December 1st.

The Crocker-Wheeler Co., Ampere, N. J., held at their works in that city on Sept. 25 and 26 their annual managers' convention. A banquet took place on Sept. 25, for the officers of the company. Many interesting speeches were made. The object of the convention is to bring all the men closer together for the purpose of comparing notes and planning methods for handling the largely increased business.

The Philadelphia Pneumatic Tool Co., Philadelphia, Pa., builders of pneumatic tools, report that the amount of goods shipped by them in August surpassed all previous records. They have had large orders recently from the Cambria Steel Co., the Pennsylvania Steel Co., two large shipbuilding companies, and the Grand Trunk Ry. Co., and also a number of orders from foreign parts. They have just added quite extensively to the machinery in their machine shop.

The Lucas Machine Tool Co. Cleveland, O., manufacturers of horizontal boring, drilling and milling machines and power presses, are now occupying their new shop on Robison Ave., Cleveland. This has been entirely equipped with up-to-date tools, and the increasing demand for their product has made it necessary for them to consider a further extension.

Foote, Burt & Co., Cleveland, O., manufacturers of drilling machines. Cleveland, O., are just getting settled in their new shop, 1301-1303 St. Clair St. The building is 55 x 120, two stories, with boiler house outside, and contains a number of new machines, including a Dreses radial and several Reed lathes. A Maris electric crane has also been installed.

MACHINERY.

December, 1902.

THE RENOLD SILENT CHAIN IN CONNECTION WITH MACHINE AND STRUCTURAL TOOLS.

J. O. Nixon.

Recent articles in Machinery about motor-driven shops, current advertisements of motor-driven tools and the ever-present motor salesman, all remind the machine-shop manager that this is an age of electricity. If his shop is already equipped with motors, he can probably cite endless figures to show the correctness of his judgment in the particular system selected, and if he is only trying to decide on a system he is probably seemingly mixed up inextricably in figures on first cost, interest and depreciation, power factor, speed-regulation, etc.

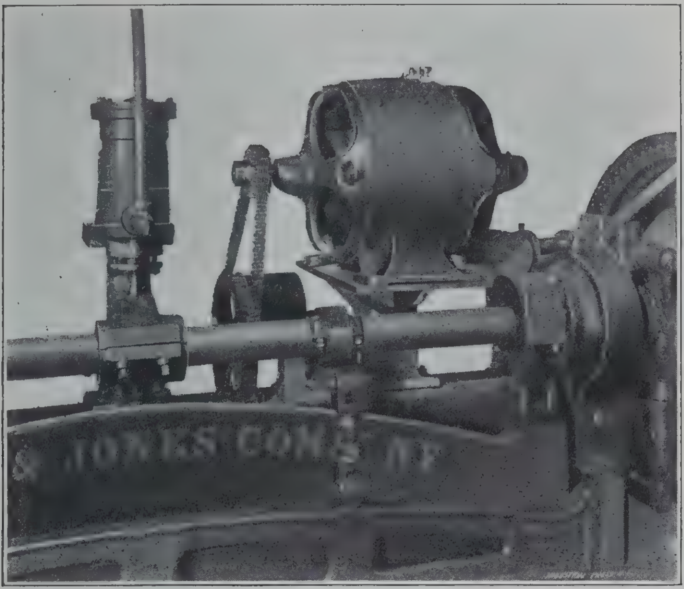

Fig. 1. Hilles & Jones Gate Shear. Driven by General Electric Motor and Renold Chain.

After the system to be adopted is decided on, there next arises the question of how far to carry the individual motor and when to start grouping small tools on line shaft. The character of the work to be done will have something to do with this decision. If the work is miscellaneous then the individual motor is desirable, because one of the greatest advantages to be derived from electrical drives is ease in speed control. If, however, the processes are essentially the same day after day, then countershafting and the group system may be desirable, having in mind always, however, the necessity for clear space for crane service.

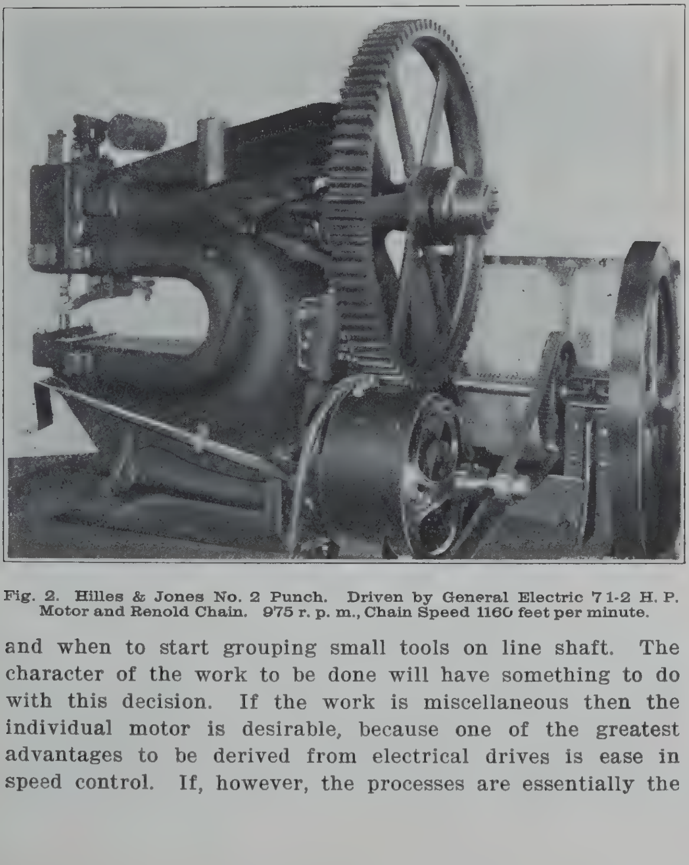

Fig. 2. Hilles & Jones No. 2 Punch. Driven by General Electric 7 1-2 H. P. Motor and Renold Chain. 975 r. p. m., Chain Speed 1160 feet per minute.

When a decision has been reached as to the most desirable distribution of the motors, the next problem is how to connect the motors to the tools and the line shafting. It is probable that when this point is reached many modifications of the original scheme will be necessary. There need be no surprise if tools designed before the direct electrical drive was thought of should present seemingly insurmountable difficulties in motor attachment. It is as a simplifier of these problems that the Renold silent driving chain is important. Its use in connection with machine tools may readily be divided into two classes. In the first it is used as an integral part of the machine, for driving the spindles and feeds and for the general transmission of motion within the ma-

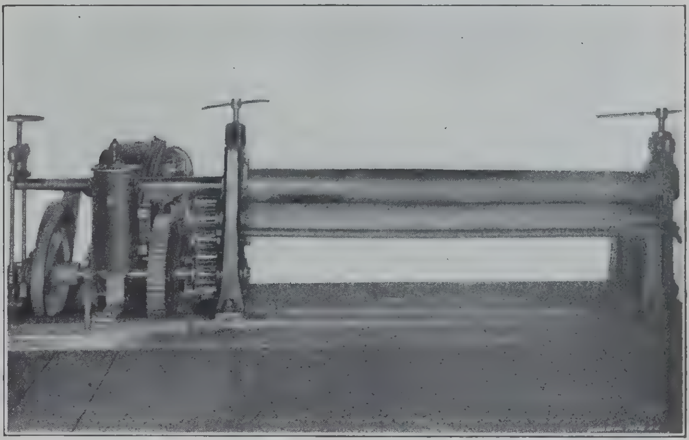

Fig. 3. Bending Rolls. Driven by Series Motor and Reversing Controller. 7 1-2 H.P. Motor, 750 r. p. m. Renold Chain Drive. Chain Speed 950 feet per min.

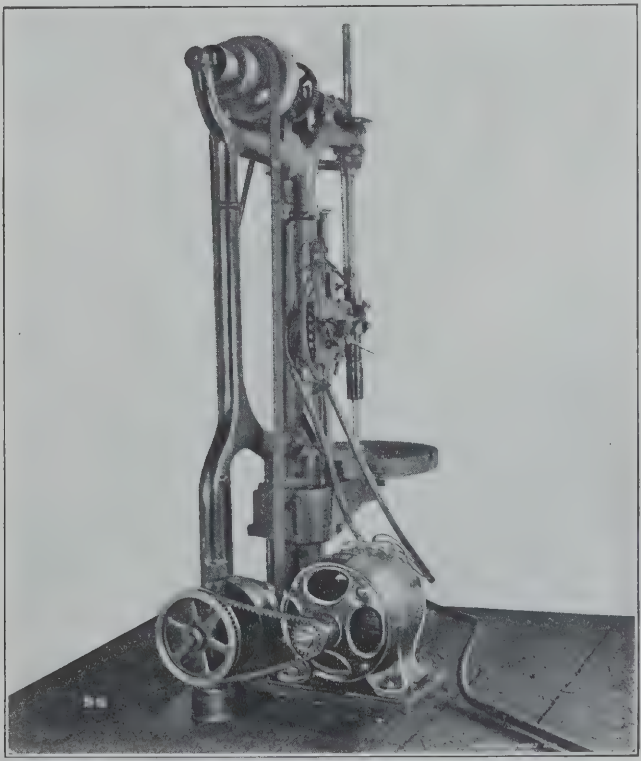

Fig. 4. Snyder Drill Press. Two-H.P. Motor, 1000 r. p. m. Renold Chain Drive. Chain Speed 1100 feet per minute.

chine itself. In the second it is used for driving the machine and with this last we are now concerned.

As has been inferred above, the application of motors to machine tools is sufficiently difficult where the tools are being designed for electrical drive; where motors are to be applied to old tools, the problem is greatly complicated.

The advantages of Renold chains for such work arises from their convenience and adaptability. For spur gearing the motor must be provided with an absolutely rigid support, rigidly attached to the tool. The center distance is dictated more or less by the gears and not by convenience. The noise made is generally objectionable. Rawhide pinions are often used and vary greatly as to durability. A worn raw-hide pinion, however, is noisy and also causes a chattering that tends to make the brushes jump, with a consequent burning out of the commutator.

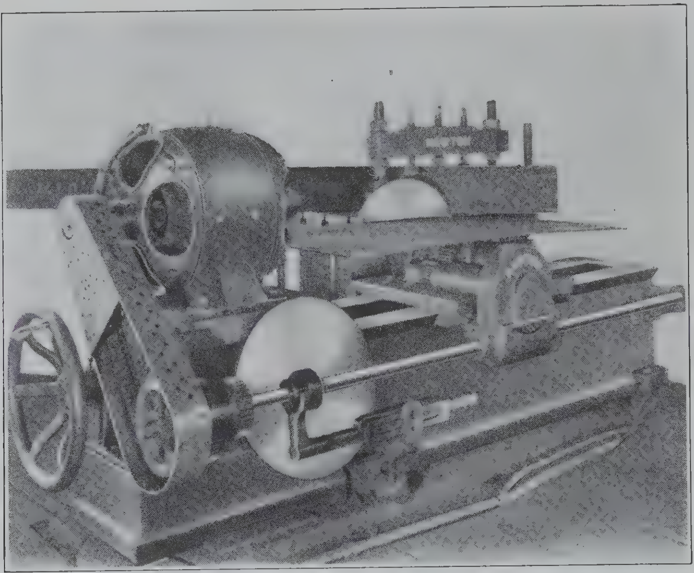

Fig. 5. Newton Cold Saw with Renold Chain Drive. Five H. P. Motor, 975 r. p. m. Chain Speed 1160 feet per minute.

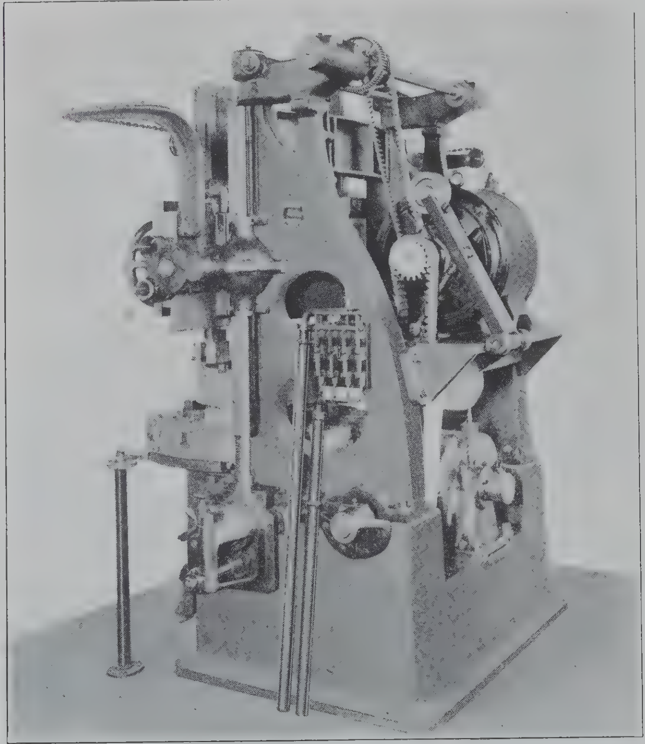

Fig. 6. Bullard 37-inch Boring Mill, Bullock Variable Speed Motor, Renold Chain Drive.

The other alternative to the chain drive is, of course, the belt. If a belt be run on short centers an idler must be used. with a corresponding loss of efficiency and convenience. A belt also lacks the advantage of positive connection possessed by spur and chain gearing. Many unexplained failures to get expected output are due to slipping belts. The Renold chain, in contrast to belts, or other method of connection, is thus silent, efficient, positive and convenient.

When it was decided to equip the shops of the Link-Belt Engineering Company electrically it was concurrently decided to do it in the best possible way in the light of the information then obtainable. Some things were done, of course, that would be done differently if the job were to be done again; but in the main the change has been eminently satisfactory from every standpoint. Every tool was studied as a separate problem, and it is now possible to show, by comparative records, the very substantial gains made by the change.

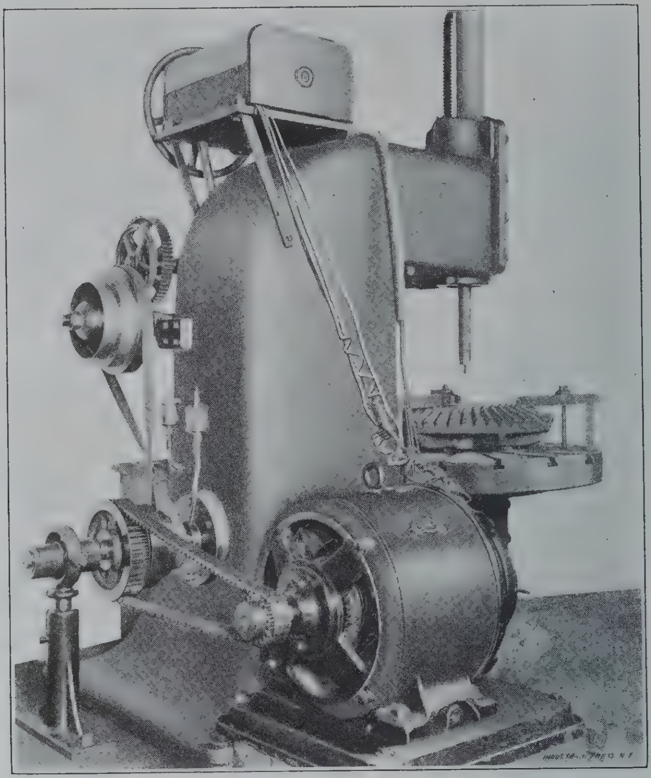

Fig. 7. Betts Car-wheel Mill, Motor-driven, Renold Chain Drive.

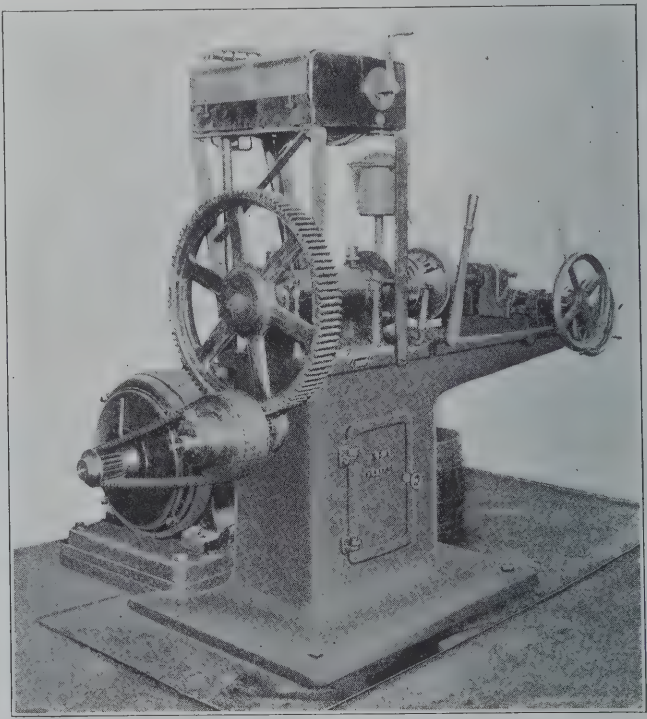

Fig. 8. Acme Bolt Cutter, Motor Driven, Renold Chain Drive.

At about the same time when the application of motors to the various tools was being studied out, this company began the manufacture of the Renold silent chain gear in this country. While a great deal of it is used in the shops, still nowhere is a foot used where it is not the best thing for

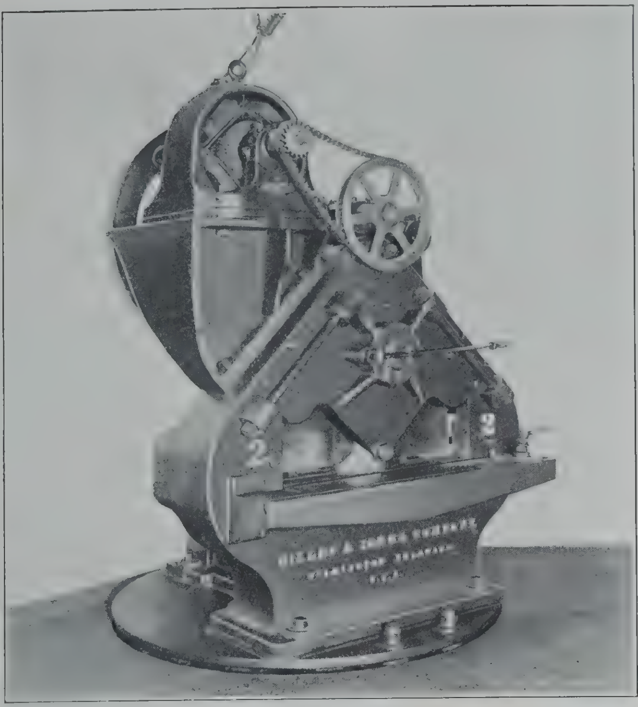

Fig. 9. Hilles & Jones Angle-iron Shear 10 H.P. Motor, 750 r. p. m. Renold Chain Speed 1190 feet per minute.

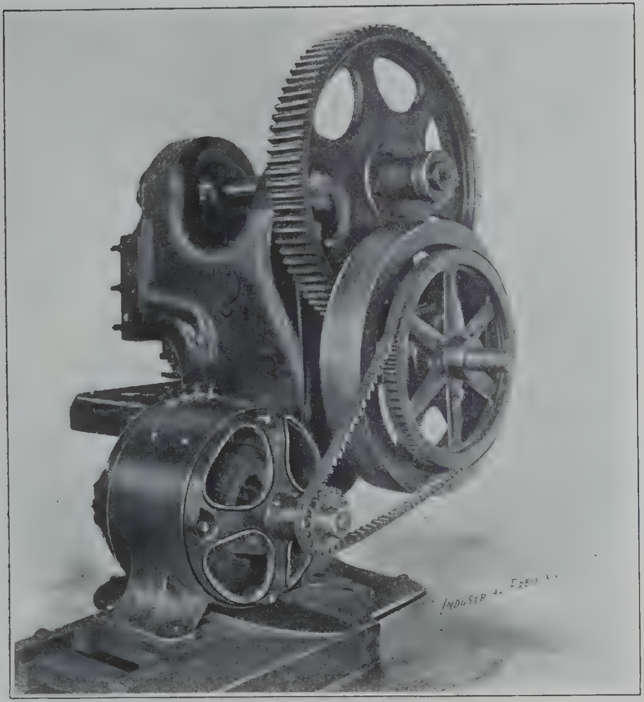

Fig. 10. Ferracute Punch, Motor Driven, Renold Chain.

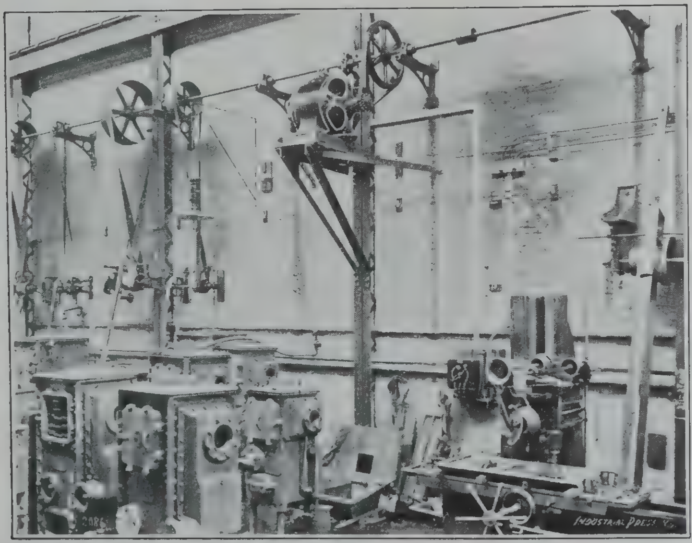

Fig. 11. Line Shaft Driven by 15 H.P. Motor and Renold Silent Chain.

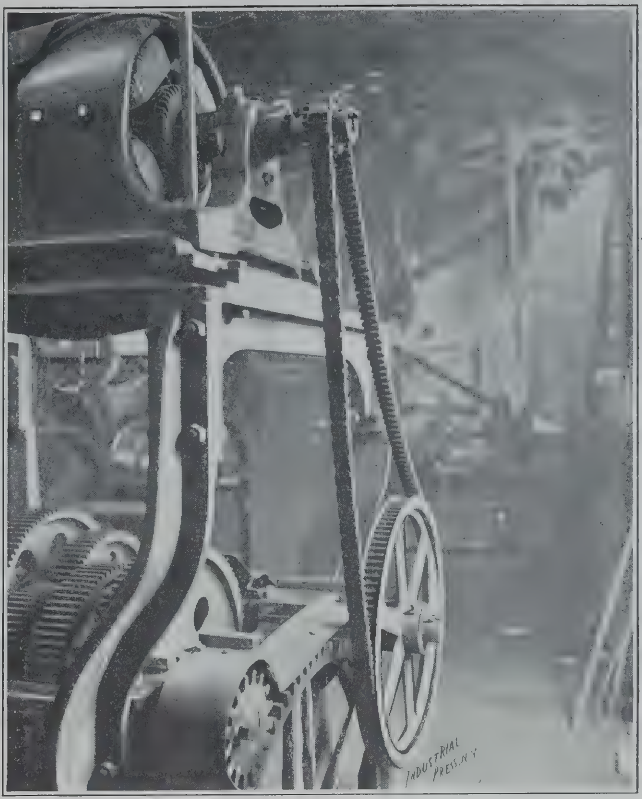

Fig. 12. Old Roll Lathe Driven by Westinghouse Motor, Renold Chain.

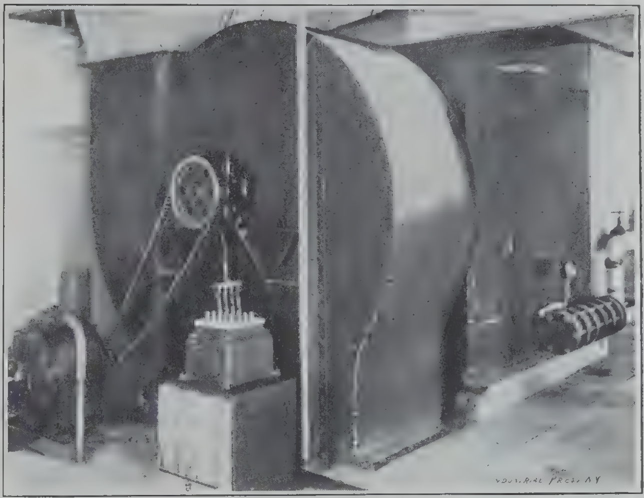

Fig. 14. Sturtevant Heating Fan, Motor Driven, using Renold Chain.

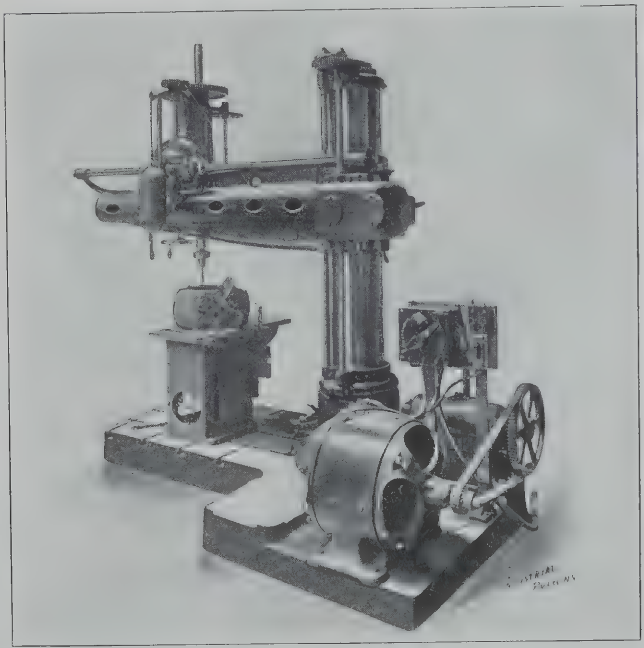

Fig. 16. Bickford Radial Drill, with Motor on Extension Base. Constant Speed Motor, Renold Chain Drive.

the place. There are belt drives and spur-geared drives, and while their number is small compared to the number of chain drives, it represents very fairly about the proportion that such drives should bear to chain drives in the ordinary shop.

Concisely stated, the advantages of the Renold chain are, that it may be run on shorter center distances than a belt and on longer centers than spur gearing. The center distances are dictated only by convenience and may be fixed, or the motor may be mounted on rails. The chain is silent; it is efficient; it is compact; the drive is absolutely positive and the calculated output is a certainty.

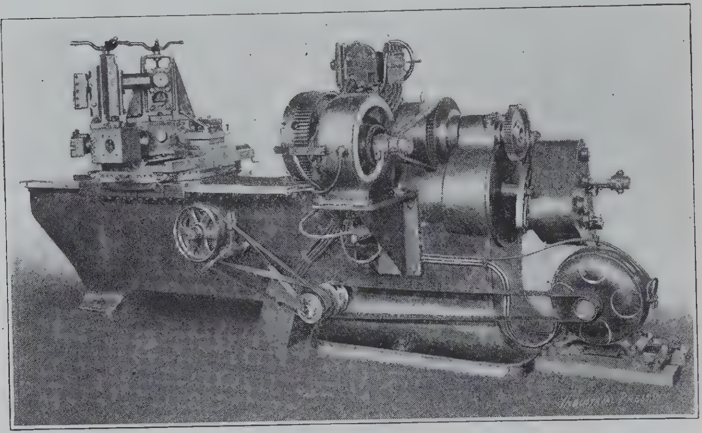

Fig. 13. Renold Chain Drive from Crocker-Wheeler Motor to American Turret Lathe.

The majority of the accompanying cuts are from photographs taken in the Link-Belt Engineering Co.'s works at Nicetown, Philadelphia. They are intended to show as large a variety of tools and motor applications as possible. In nearly every case the tools were originally belt-driven. In at least five cases the method shown for attaching the motor has been adopted by the builder of the tool as his standard. In the main, the photographs speak for themselves, but a few comments on some of them will not be out of place:

Figs. 1 to 10 inclusive show drives in these works. Most of those shown are on structural tools, which arises from the fact that many of the motors in the machine shop are below the floor and are therefore difficult to photograph satisfactorily.

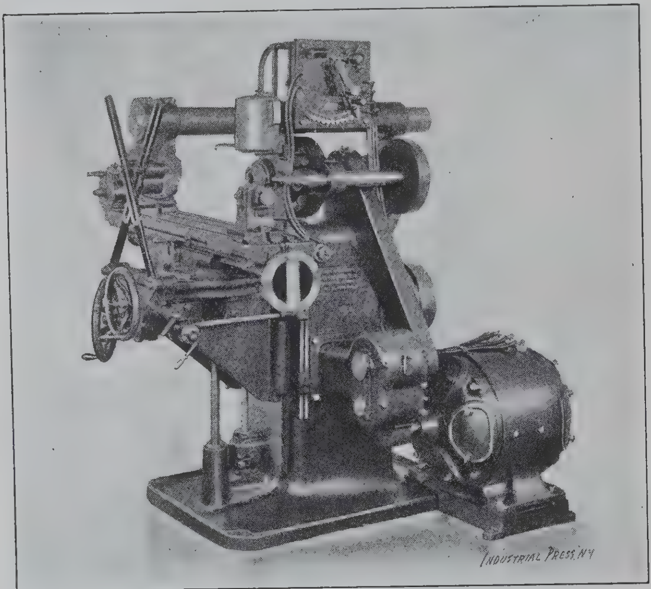

Fig. 15. Brown & Sharpe Universal Milling Machine, Renold Chain Drive Incased.

Fig. 1 shows a General Electric motor mounted on a bracket on a gate shear. The motor is out of the way and the drive is compact and simple.

Fig. 2 shows one of three punches similarly arranged. The General Electric motor is mounted on a cast bracket secured to the machine, making an absolutely self-contained outfit. The work of the chain on this intermittent service has been most excellent.

Fig. 3 shows a set of bending rolls. These were formerly driven by two belts and double clutches. The present arrangement, while thoroughly serviceable and much more easily handled than the old rig, is, at the same time, sightly, compact and efficient. This tool illustrates, perhaps, as well as any other, the possibilities of the Renold chain in converting old tools to the motor drive.

Fig. 4 shows a drill press, a type of several, all of which show increased output, because the chain does not slip.

Figs. 5 and 6 show tools as now supplied by the builders. The arrangement on the Newton cold saw (Fig. 5) was designed by the Link-Belt Co. and is now used by the Newton Machine Tool Works on motor-driven saws supplied by them. The method of attaching the motor to the Bullard 37-inch mill, shown in Fig. 6, was developed by the Bullard Machine Tool Co. It brings out in no less a degree than Fig. 5 the fact that a minimum change in the tool itself is necessary to attach the motor, where the Renold chain is used. It will be noted that the tool is standard in every way except for the addition of the motor base, which is held by the top bolts shown. This feature of building motor-driven and belt-driven tools from the same patterns is one much appreciated by the tool builders.

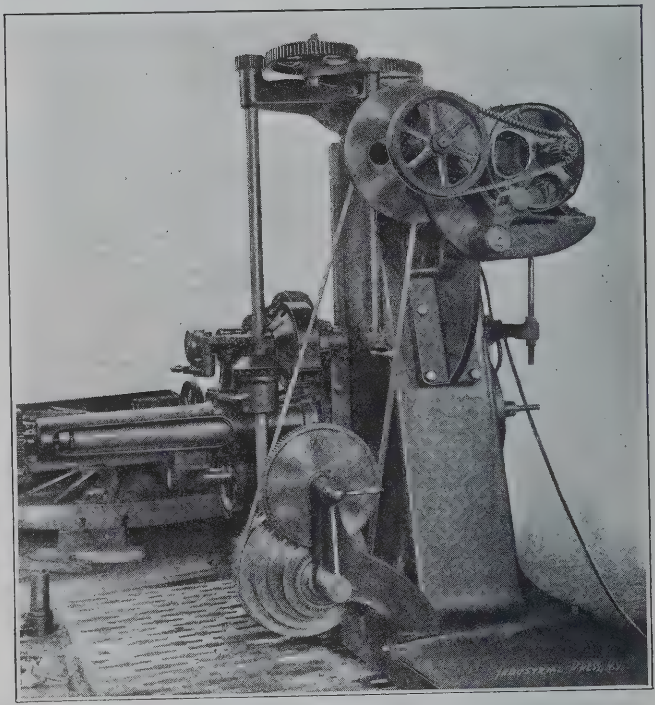

Fig. 17. Floor Boring Machine, Electrically Driven, Renold Chain.

Fig. 7 shows a Betts car-wheel mill with Bullock variable speed motor.

Fig. 8 shows an Acme threading machine with variable speed reversing motor. The superiority of this arrangement over the usual one, with two belts and two shifters, is obvious.

Fig. 9 shows an angle-iron shear driven by a Westinghouse motor. This was supplied with a spur-gear connection by the makers, there being one idle gear. Silent chain was substituted as an experiment and a saving of 15 per cent. in current was found. This was not altogether unexpected, because the efficiency of the silent chain gear is about 96 per cent.

Fig. 10 shows a Ferracute punch; motor on wood base.

The rest of the photographs were taken elsewhere, but show typical machine-shop practice.

Fig. 11 is a line-shaft drive.

SHOP CONSTRUCTION.—3.

THE CHIMNEY OR STACK—ITS DESIGN AND CONSTRUCTION.

OSCAR E. PERRIGO.

Thus far our methods of construction, and the necessary materials for them have been such as are encountered daily by the architect and the builder. We now come to the erection of the chimney or stack, which has many peculiarities and restrictions on its design and construction, resulting from its narrow foundation, great height, and the necessity of its resisting not only the high wind pressures and great changes in temperature at different seasons but also the great difference of temperature on the inside and on the outside. It seems to us necessary, therefore, to treat this subject of chimney construction in a separate article, wherein we will consider the respective merits of and the objections to chimneys of the more common forms and materials.

Regarding the chimney built of brick, the principal objections would appear to be its first cost, which is considerable, and the fact that owing to its narrow base and great height very firm and solid foundations must be prepared. This, of course, becomes more difficult and expensive where the ground is soft and excavations must be made at great depth, or where piles have to be driven to build the foundation upon. At the present time many sheet-iron or steel chimneys are erected, and it is the prevailing idea that they are the more economical. About the only advantage they seem to possess, however, is that owing to their comparatively light weight they may be erected on superstructures upon which a brick chimney could not. Then too, their first cost is much less than for a brick chimney of equal capacity. Some of their disadvantages are, that they are very liable to rust at the seams and rivets, owing to the impossibility of keeping these points properly protected from water. Therefore they are comparatively short-lived. Again, in the effort to protect the metal they must be frequently painted, or coated with some of the numerous "cure-all" paints, "warranted to protect them perfectly inside and out;" and the use of *any* protective covering is a continual expense for maintenance to which the brick chimney is not subject.

The conclusion, therefore, must be that, if the life of the chimney is of less consideration than its first cost, we would adopt that constructed of sheet-iron or steel; but if we regard permanency and the ultimate outlay, both for construction and maintenance and all the advantages derived, brick is evidently the material to be chosen.

The height of the chimney will depend somewhat upon surrounding hills, high buildings and similar obstructions to the free course of the wind, but should never be less than the diameter of the internal flue multiplied by twenty. The diameter of the internal flue will depend on the aggregate areas of the smoke flues or "up-takes" leading from the boilers, and these necessarily depend upon the grate surface, allowing about 4.5 square feet per horse power. There are many methods of calculating the diameter of chimney flues, some of which are very complex and depend upon many assumed conditions at each step, which ofttimes have hardly more practical value than guesses. Others assume to calculate the volume of gases, the speed of their flow, the area of grate openings, etc., all of which might be changed with each sample of coal, or according to the condition of the weather. Practical engineers will probably favor the following simple method, even with its arbitrary assumptions, and will be quite successful in the practical application of it as it is the result of much actual experience. The horse power being given—say, in this case 470—and allowing 4.5 square feet of grate surface per horse power, we have 104.4. At 5 pounds of coal per horse power, which is quite liberal, we will burn 2,350 pounds of coal per hour. Our chimney is 100 feet high. We divide the pounds of coal burned per hour by the square root of the height multiplied by 12 ($10 \times 12 = 120$) and we have 19.58 as the area of the chimney flue, in square feet. Divide this by .7854 and extract the square root and we have the diameter, slightly less than 5 feet. Having the diameter of flue and height given we may by inverse methods obtain the horse power, grate surface, etc. In making these calculations we should be sure to get capacity enough; for if the chimney is a little too large no harm is done, while if a little too small a serious expense is incurred for a supplementary one.

All chimneys over 75 feet high should be built with a central "core," or flue, preferably of circular form, surrounded by an outside casing sufficiently strong to properly support the inner core and to resist the pressure of the strongest winds. The thickness of the walls of both the outer portion and the inner core should be sufficient to be very rigid near the ground and gradually thinner as the walls rise, the "breaks" being, of course, on the inside of the outer portion and the outside of the inner core. These breaks are usually four inches, or the width of a brick at each step. The "batter," or inclination of the outside face of the main structure should be a quarter of an inch per foot. In our case we are supposed to require a chimney 100 feet high, with a circular flue five feet in diameter.

In the sketches, Fig. 1 illustrates a vertical section through the center of the chimney and its foundation. It shows the thickness of walls, special form of central flue, retaining caps at the top, and special arrangements for increasing the draft. Fig. 2 is an elevation of the exterior, showing its general form and appearance when completed. Fig. 3 shows a horizontal section through the octagonal portion on the line *AA*, Fig 1. Fig. 4 shows a horizontal section through the square base, on the line *BB*, Fig. 1. Fig. 5 illustrates, on an enlarged scale, the number of bricks necessary for a course, if the square form were to be continued to the top. Fig. 6 shows the economy of adopting the octagonal form, as saving material and labor, and offering considerably less surface to wind pressure from certain directions.

In the Figs. 5 and 6 the upper half shows the laying of a "header" course and the lower half the laying of a "straight" course. In these two sketches it will be seen that in a header course, the octagonal form contains 52 bricks less than the square form; and in a straight course 32 bricks are saved. Assuming five courses per foot in height, and that in each foot we have one header course, we save by the octagonal form 180 bricks. This, of course, is less as we approach the top, but the average saving will be considerably over 100 bricks per foot, or over 8,000 for the whole work. Actual experience shows that the extra labor cost of making the many corners is more than balanced by the smaller number of bricks laid in the octagonal form than in the square form. The appearance is much enhanced and the wind pressure is considerably diminished by getting rid of the projecting corners.

The base of the chimney is of square form, this being more convenient for the introduction of the smoke flues or "uptakes" from the boilers, the placing of the ash doors and the general appearance. The ash door is shown in Fig. 2. The opening should be arched, preferably of semi-circular design, as affording the most strength to sustain the great weight of brick-work over it. It should be closed with a sheet-iron door. The openings for smoke flues should also be strongly arched, similar to the ash doorways. From the square portion at the base, the main shaft of the chimney is of octagonal form, as indicated in Fig. 4.

For foundations the earth should be excavated to perfectly hard ground, making a pit 28 feet square; that is, twice the depth of the foundation, assuming that in consequence of the condition of the ground it is necessary to excavate to a depth of 14 feet. In this pit should be a bed, 4 feet thick of large stones laid in strong cement mortar. Upon this should be courses about 18 inches thick and gradually drawn in at the top to 16 feet square. By strong cement mortar we mean that containing two parts cement, one part of lime, and about three parts of clean, sharp sand. The amount of sand will vary considerably with its fineness, sharpness and its freedom from dirt; the finer the sand the greater the quantity that must be used.

In erecting the central core and the outward supporting structure great care should be used to make all joints of uniform thickness, and to see that as the courses are laid on, they are frequently leveled. "Batter plumbs" should be used

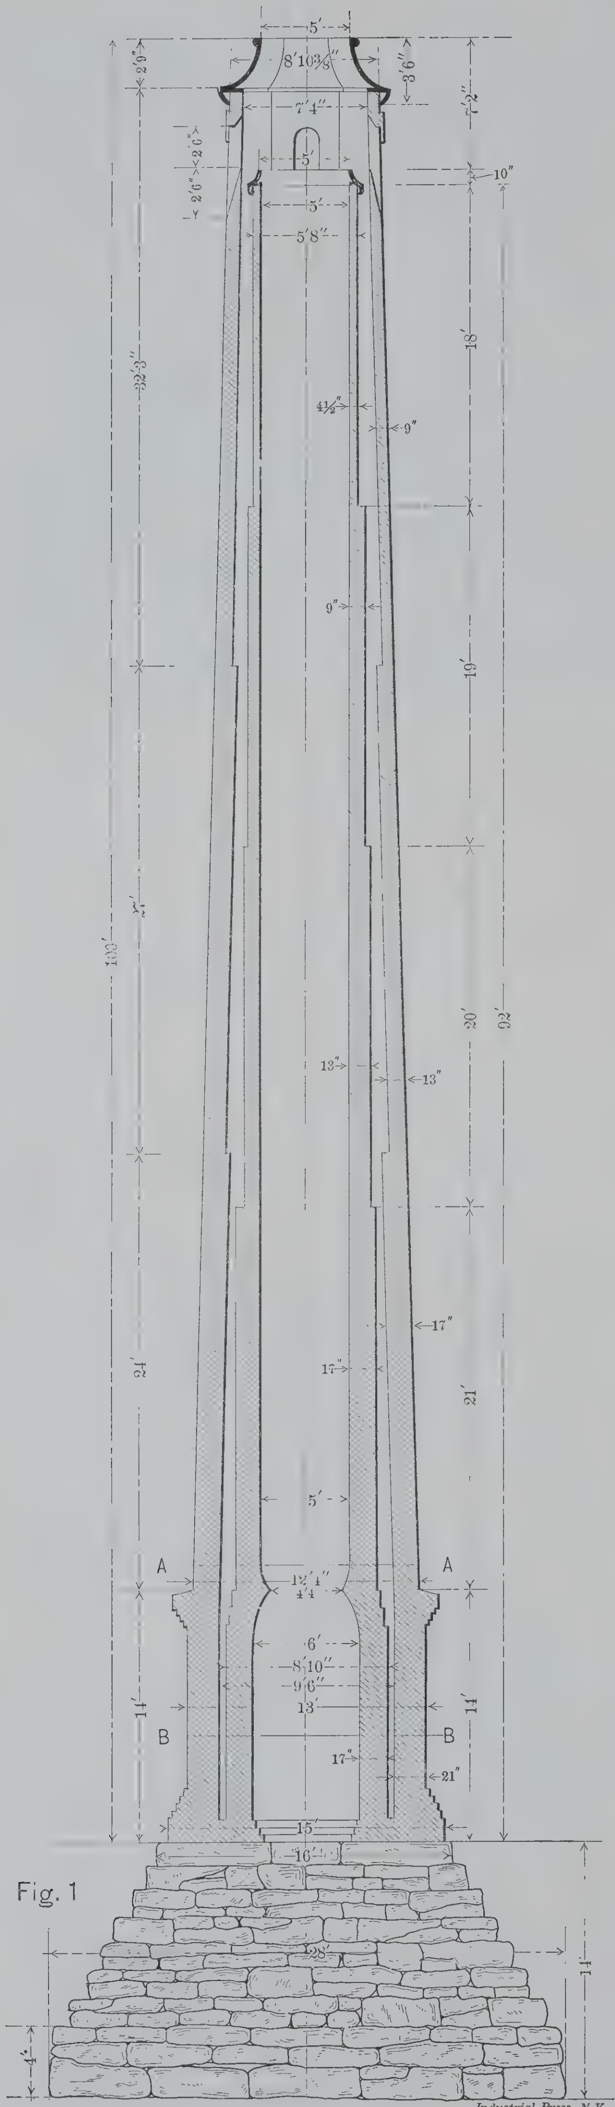

Fig. 1

Industrial Press, N.Y.

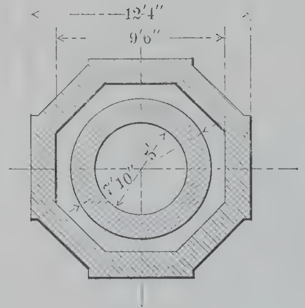

Fig. 3

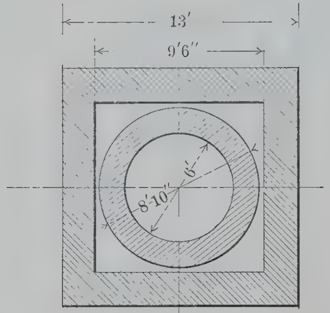

Fig. 4

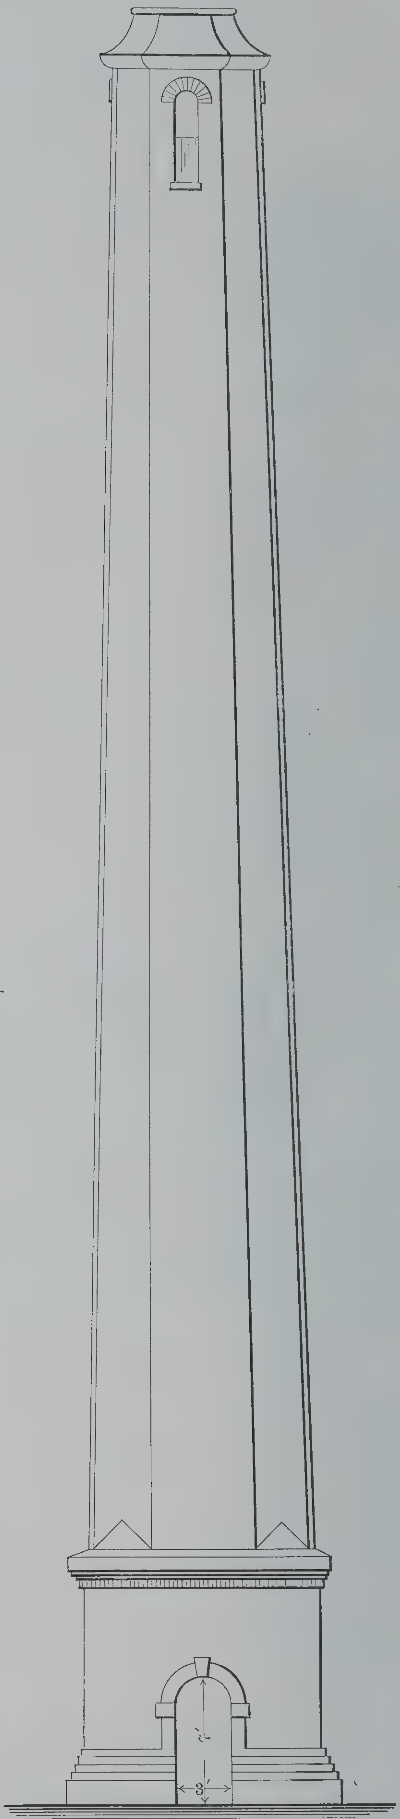

Fig. 2

Figs. 1 and 2. Sectional and Exterior Elevation of Chimney. Figs. 3 and 4. Horizontal Sections through A A and B B.

for the outside; that is, the board on which the plumb line is attached should have the batter or inclination by being made narrower at the bottom. For instance, a plumb board four feet long should be six inches wide at the top and four inches at the bottom (the batter being equal on both edges).

Another matter that must be scrupulously attended to is that of properly supporting the inner core. It will not do to lay bricks from wall to wall so as to tie them together, as the expansion and contraction of the inner core would soon ruin the structure. The support is given by building up into the outer wall inwardly projecting bricks reaching half way across the space, and against these, others projecting outwardly from the inner core. These should be placed on all eight sides, in the same course, and at intervals of not over eight feet through the entire height.

The form and thickness of walls and the heights of the "breaks" are shown in Fig. 2. The central flue is formed after the model of the well-known student lamp and forms a very effective combustion chamber for escaping smoke. It is the form adopted by a prominent engineer who built a large number of chimneys of this design which have been in successful use for many years.

The smoke flues enter the chimney below the constricted portion of the inner flue. The top caps are of cast-iron and may be made in sections and bolted together, as well for convenience in erecting as for economy of pattern making. That on the inner core terminates 7 feet 2 inches below the top of the main cap. At four sides of the outer structure are openings, as shown in Fig. 1, the bottom of each opening being on a level with the top of the inner cap. By this means the current of air which always rises along any high wall is taken advantage of, as it passes up the side of the chimney, into these openings, and out the top of the chimney, and creates a partial vacuum over the top of the central flue, thus considerably increasing the draft. Means should be provided for reaching the top of the chimney, as the iron caps will need painting, or lightning rods may have to be placed or repaired. Iron ladders up the side may be fastened to the wall, or a permanent block may be attached to the main cap and provided with a wire rope, for this purpose.

As a matter of safety from lightning it is well to provide lightning conductors. A round copper rod of not less than ⅝-inch diameter, or one of equal area of cross section, may be run up outside of the chimney, through heavy glass insulators, and terminate four feet above the main cap in four points, 5-16-inch diameter or equivalent area. The lower end of the rod should go into *moist* earth and be attached to a cast-iron plate 30 inches square and ¾-inch thick.

STEEL AND ITS TREATMENT.—4.

HARDENING BATHS.

E. R. Markham.

When steel is heated to the proper hardening heat it is plunged into some cooling bath to harden; the rapidity with which the heat is absorbed by the bath determines the hardness of the steel. Knowing this, it is possible by the use of baths of various kinds to give steel different degrees of hardness and toughness. A bath that will absorb the heat contained in a piece of steel the quickest, will make it the hardest, everything being equal.

A bath of mercury will cause a piece of steel plunged into it to be harder than if the steel were plunged in any of the liquids commonly used for this purpose. But as a bath of mercury would be extremely expensive it is but little used.

Clear cold water is the bath more commonly used than any other, and for most cutting and similar tools gives good satisfaction; although many old hardeners claim better success with water that has been boiled, or that has been used for some time, provided it is not dirty or greasy.

A very excellent bath that is used almost universally is made by dissolving all the salt possible in a tank of water. Salt water, or brine as it is commonly termed, is used in most shops on certain classes of work and in some shops it is used altogether when a bath of water is desired.

Various kinds of oil are used to accomplish various results. When small or thin cutting tools requiring a hard cutting edge are to be hardened, a bath of raw linseed or neatsfoot oil is used. When toughness is the desired quality, as in hardening a spring, a bath of tallow, sperm oil or lard oil is used.

But the nature of steel of different makes varies so much that no one bath answers best for all purposes, or for the same purpose when applied to steels of different makes.

Sometimes it becomes necessary to use a bath containing two or more ingredients in order to accomplish the desired result.

I have in mind a manufacturing concern who made a great many heavy springs. Until they changed the make of steel they had been using for years they had excellent results from hardening in lard oil; but after changing they could do nothing with this bath. After considerable experimenting, they were advised to use the following mixture:

Spermaceti oil	48	parts
Neatsfoot oil	45	"
Rendered beef suet	4	"
Resin	3	"

They had very good results with their bath until a drummer came along with good cigars, and a steel 2 cents a pound cheaper, and then trouble was the result.

By the way, I have visited and known of several shops where a few good cigars, or an occasional wine supper, which some glib-tongued salesman was willing to put up for the man who did the buying, caused more trouble in the hardening department than a little.

But, to return to the hardening of the springs, when the *new* steel came, the springs would not harden satisfactorily in the mixture mentioned. They were finally advised to try a bath of boiling water and this worked very nicely.

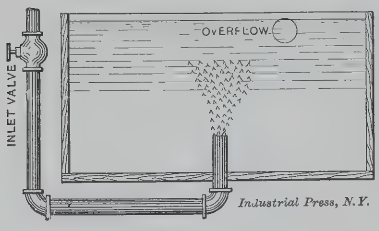

Fig. 1.

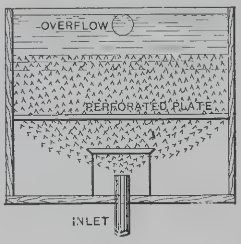

Fig. 2.

Very small cutting tools such as taps, reamers, counterbores, etc., harden very nicely in a bath made by dissolving 1 pound of citric acid crystals in 1 gallon of water.

The following bath is recommended where it is desirable to have the tool *hard* and *tough*:

Salt ½ teacupful; saltpeter ½ oz.; pulverized alum 1 teaspoonful; soft water 1 gallon.

The following bath gives excellent results, but care must be exercised in its use as it is deadly poison.

To 6 quarts of soft water add 1 oz. corrosive sublimate and 2 handfuls common table salt. When dissolved it is ready for use.

Sulphuric acid is added to water in various proportions from one part acid to ten parts water, to equal parts of acid and water—some even using clear acid. But although excellent results, so far as the hardened surface is concerned, may be obtained by employing this acid, steel makers do not advocate its use, claiming that the after effects are injurious to the steel. And the writer's experience substantiates the claims of the steel makers. I do not advocate the use of any of the acids which act on steel, provided any other form of bath will give satisfactory results.

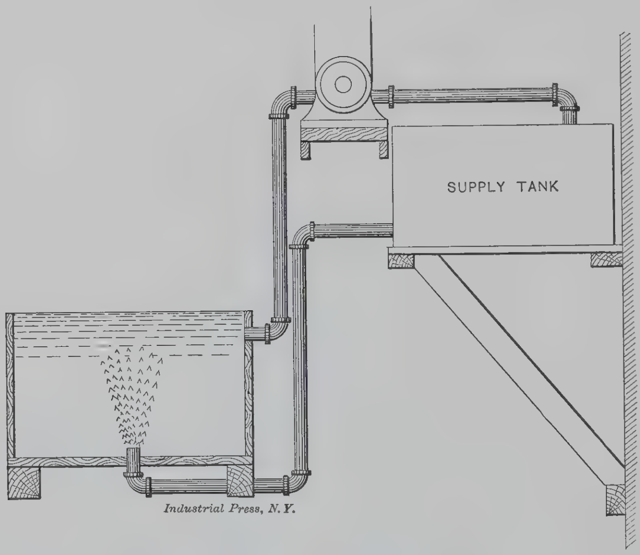

Fig. 3. Hardening Bath with Circulating Pump.

There are many other compounds used with success in various shops, but their number is legion, and if I were to give all the different baths I have used, and seen used, it would be necessary to devote several articles to this subject.

As a rule a tool steel fit to use for cutting tools will harden in a satisfactory manner in clear water. If the outline is irregular, or it is desirable that it should be *extra* hard, a bath of brine answers admirably.

Articles of an irregular shape, made of steel liable to crack when hardened, should be dipped in warm water or brine, the temperature of the bath depending on the liability of the piece to crack.

Such tools as milling cutters, made from high carbon steels, are oftentimes hardened to advantage in a bath of water having one or two inches of oil on the surface.The article is brought to the proper temperature in the fire and immersed in the bath, passing down through the oil into the water. Enough oil adheres to the red hot steel, especially in the corners of the teeth or projections, to prevent the water acting as suddenly as it otherwise would, thus doing away in a great measure with the tendency to crack.

It is a good plan when hardening large pieces of almost any shape, if they are first dipped in water or brine, to allow them to remain in this liquid until the surface is hard, then remove and instantly plunge in a tank of oil, allowing them them to remain in the oil until cold. This works especially well in case of such tools as cutters, punching press dies, etc., where it is not necessary that the hardened surface be very deep; the depth to which the piece is hardened depending on the length of time it is left in the water. For most purposes old hardeners allow the article to remain in the water until it ceases to "sing;" this is the peculiar noise occasioned by putting a piece of red hot steel in water. When the piece stops singing it is removed from the water, plunged into oil and left until cold.

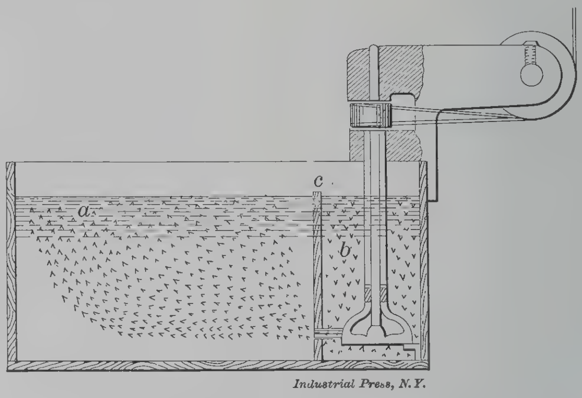

Fig. 4. Hardening Bath with Mechanical Agitator.

When pieces are to be hardened, and it is necessary to harden the inside walls of a hole or some depression, as the face of an embossing or forming die, or any similar piece, it is necessary, if good results are desired, to have a bath which has a stream or jet of water coming up from the bottom as shown in Fig. 1. If clear water is used in the bath, the inlet pipe may be connected with some constant supply, but if brine or some solution is used it becomes necessary to have a supply tank and use a pump, as shown in Fig. 3. The contents of the bath are pumped into the supply tank and run down the supply pipe by the force of gravity.

At times it is desirable to have a bath in which there is no gush or jet of fluid, but where the contents of the bath are kept in motion in order to force the steam away from the surface to be hardened. There are a number of ways of accomplishing this. Fig. 2 shows a bath having a pipe coming up from the bottom. The jet strikes a plate which spreads the fluid, after which it comes to the surface through the perforated plate.

Fig. 4 shows a bath in which the contents are kept in motion by some mechanical means contained in the tank. Such a bath may be made by following the instructions given in reference to Fig. 4. A tank of any convenient size may be made having a partition as shown at *c;* the portion of the tank marked *a* is intended to be used for the immersion of the articles being hardened, while *b* contains a pump, Archimedian screw, or some similar device for forcing the water into the side *a*. If a pump is used the water is forced through the pipe shown; if an Archimedian screw, the partition *c*, does not extend way to the bottom and the water is forced under it. In either case it returns to *b* over the top of partition *c*, as shown, thus insuring a rapid circulation of fluid. This form of bath is especially to be desired where brine or some favorite hardening solution is used. It is also possible to heat the contents of the bath when it is considered advisable, as is the case where articles are to be hardened that are liable to crack from contact with extremely cold liquids. Much more uniform results may be obtained, especially when small, thin pieces are hardened, if a uniform temperature can be maintained in the bath. As the surface of the bath is coated with ice in winter, the fluid is luke-warm in summer, and the temperature is anywhere between warm and extreme cold, depending on the condition of the atmosphere; it will readily be seen that uneven results must be the consequence. In order to be able to keep the contents of the bath at somewhere near a uniform temperature a small coil of steam pipe may be placed in the tank, and a thermometer may be used so as to readily show the condition of the bath.

While it may seem unnecessary to be so particular about the temperature of the bath—and it is unnecessary on most work, as an experienced hardener can determine the temperature near enough by the sense of feeling—yet there are jobs where it is essential that a certain uniform temperature be maintained in order to get uniform results. I do not mean by this that it is practical to attempt to keep the temperature within a few degrees of a given point but it can be kept somewhere near in order to get the best results possible.

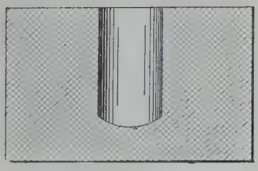

Fig. 5.

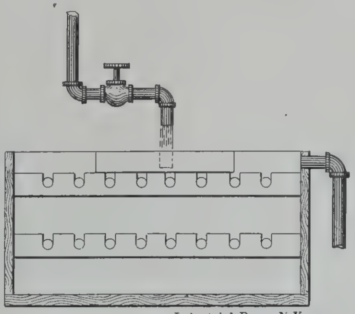

Industrial Press, N.Y.

Fig. 6.

At times it is necessary to harden the walls of a hole that does not go way through the piece, such as a die used for compression work, or some forms of dies for striking up cylindrical pieces. Fig. 5 shows a sectional view of a die having a hole running part way through it, as described. Now, if a piece of work of this description were hardened in a bath whose contents were not agitated it is doubtful if the walls of the hole would be hardened in the least, as the steam generated would blow the liquid out of the hole and none could enter until the steel was cooled to a point where it could not harden. Better success would follow if it were dipped in a bath having a jet of water coming up from the bottom of the tank; but in this case it would be necessary to invert the piece in order to get the liquid to enter the hole, and if it were deep it is probable that enough steam would rise in the hole to keep the contents of the bath from affecting the walls near the bottom. Now, in order to get satisfactory results when hardening work of this character, it will be found best to have a bath so constructed that the liquid can be run into the hole by means of a faucet or pipe, as shown in Fig. 6. If the hole is deep and there is danger of the steam preventing the liquid effectually working at the bottom, a pipe may be run nearly to the bottom, as shown in sectional view, Fig. 7. The pipe must not be nearly as large as the hole or the results will not be satisfactory.

Sometimes it is necessary to harden several pieces of a nature whose outline betokens trouble if they are dipped in a cold bath, and yet it seems necessary to use a cold bath in order to get the desired result. Take for instance, a shank mill of the shape shown in Fig. 8. If this mill is heated to the proper degree of heat and plunged in a dish containing just enough water or other liquid to harden the teeth before the water gets hot, the teeth will harden in a satisfactory manner and the water will heat so as to do away with any danger of cracking from internal strains. The size of the dish will determine the depth of the hardening. When one piece is hardened the dish may be emptied and filled with cold water for the next. I have seen this method used with excellent results, not only on milling cutters, but on broaches, dies, etc., that showed a tendency to crack when dipped in a *large* bath of *cold* fluid. Of course, it must be borne in mind that the dish selected for the bath must be large enough to hold a sufficient quantity of liquid to harden the piece the necessary amount, before it becomes too hot; but it is essential that it should not be too large for the contents to heat, because then there is no difference in its action from that of a large bath.

Baths for Case-hardening.

The design of the bath used for cooling work being case-hardened must be such as will adapt it to the work being hardened.

Where work is case-hardened in large quantities it is customary in most shops to heat the work in iron boxes; when the work is in the proper condition the box is inverted over a tank of water or other fluid, and the contents dumped into the bath. If the pieces of work are large or bulky and the tank is shallow they reach the bottom of the bath while red hot and as a consequence the side of the piece that lies on the bottom will be soft. In order to overcome this trouble the tank must be made deep enough so the pieces will be chilled before reaching the bottom. If it is not considered advisable to have an extremely deep tank, and the pieces are large, various ways are taken to insure the pieces hardening. One method which the writer has used with excellent results is to have a series of rows of wire rods reaching across the tank, no two consecutive rows being in the same vertical plane. The work as it descends into the bath strikes these wires, thus turning over and over and bringing all portions in contact with the contents of the bath. These wires also separate the pieces from each other and from any packing material which may have adhered to them.

The wires also retard the progress of the articles, thus giving them more time to cool before reaching the bottom of the bath. In order to insure good results it is necessary to have a jet of water coming up from the bottom of the tank and an outlet provided near the top for an overflow. The overflow pipe should of course be larger than the inlet pipe, and should be located far enough below the top edge of the tank so that the contents of the tank will not overflow when a box of work is dumped into it.

In order to be able to get the hardened pieces out of the bath readily it is necessary to provide a catch pan as shown in Fig. 9. The bottom of this pan should be made of strong wire netting or a piece of perforated sheet metal, preferably the former. The holes in the pan allow the packing material to fall through to the bottom of the tank and will also allow the water from the supply pipe to circulate around the work and to the top of the bath. This catch pan should be provided with strong wire handles, as shown, in order to raise the pan.

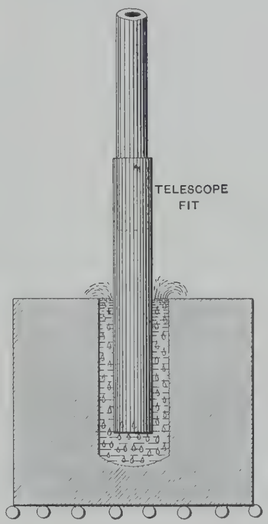

Fig. 7.

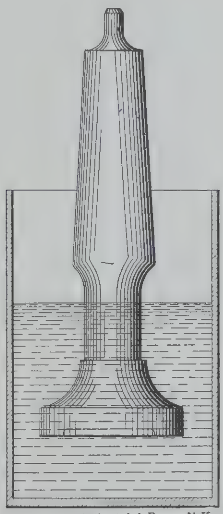
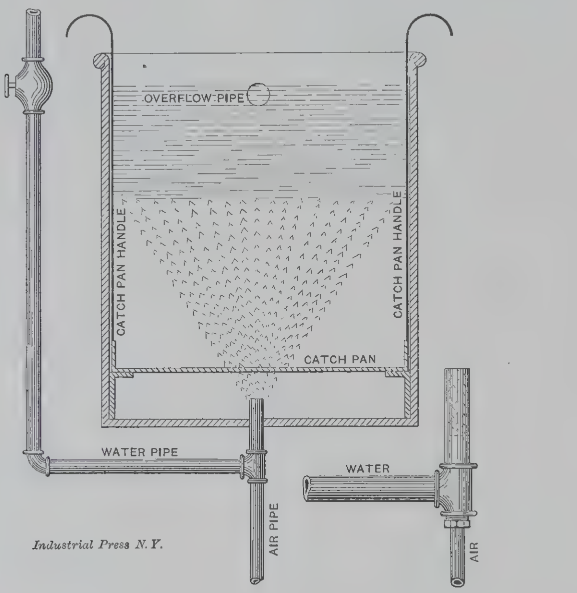


Industrial Press, N.Y.

Fig. 8.

I was at one time requested to call at a shop where they were having very unsatisfactory results with their case-hardening. An examination showed they were dumping their product into a barrel of water to harden. The box containing the work was inverted over this barrel and the work and packing material went into the water in a lump. Some of the pieces that happened to get out of this mass were cooled sufficiently to harden somewhat but the majority of the pieces were soft, or else they were hard on one side and soft on the other. An examination of the bottom of the barrel showed it to be considerably charred; in places the outline of the pieces was plainly visible, where the pieces had reached the bottom while red hot and had burned their way into the wood. It is needless to say that the side of the piece of work which was down did not harden. As the concern did not think it advisable, considering the limited amount which they had to case-harden, to get a tank of the description shown in Fig. 9, we made a catch pan as described, blocked it up about 6 inches from the bottom of the barrel by means of four bricks. We then bored a hole through the bottom of the barrel, screwed in a piece of pipe and by this means we were able to connect an ordinary garden hose so as to get a jet of water coming up from the bottom. As the barrel was out of doors we simply bored a 2-inch hole about 4 inches from the top of the barrel for an overflow and let the water run onto the ground.



Industrial Press N. Y.

Fig. 9. Case-hardening Bath having a Catch Pan to facilitate removal of the Work.

When the work was ready to dump we sifted it out of the box into the water gradually, instead of dumping it in a body. As soon as the box was emptied we grasped the wire connected with the catch pan and raised and lowered the pan in a violent manner in order to separate any pieces that might have lodged together. The result was very satisfactory and I think they are using a barrel to this day.

Where large quantities of work are hardened, baths are made with some means of keeping the work in motion after it reaches the bottom of the bath. Sometimes this is done by mechanically raising and lowering the catch pan and at the same time turning it around. Then again it is done by means of several sweeps which are attached to the lower end of a vertical shaft, the shaft resting in a bearing in the center of the catch pan. These sweeps or arms revolve and keep the pieces in motion, turning them constantly, but unless arranged properly they have a tendency to gather the work in batches thereby *undoing* what they are intended to do. Then again they have a tendency to scratch the surface of the work, which is a serious objection if color work is wanted.

When it is desired to get nice colors on case-hardened work, an air pipe may be connected with the bath as shown in Fig. 9, the water and air entering the bath together.

While it is not advisable to let air come in contact with pieces to be hardened for colors, while passing from the box to the water, yet the presence of air in the bath will have the effect of coloring the work nicely.

The air should enter in such a manner as to insure its reaching all parts of the bath. The pipe should be considerably smaller than the inlet water pipe and should extend a short distance up into it in order to prevent the air and water working against each other. A connection should be made as shown in detail. The writer does not suppose it will ever be necessary for many readers of MACHINERY to construct *all* the different bath tanks mentioned or find it necessary to construct these precisely like those shown. But some form or a modification of it will be found to fill almost any requirement in the ordinary shop.

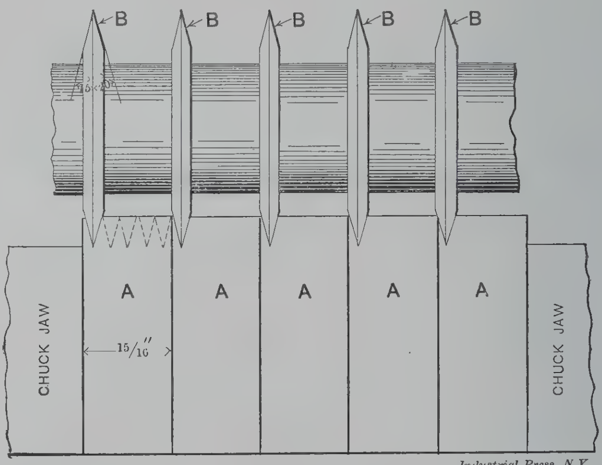
* * *

ANGULAR MILLING AND PLANING JOBS.

At the shop of the Falkenau-Sinclair Machine Co., Philadelphia (formerly A. Falkenau), an angular milling job was done recently that was somewhat difficult and out of the ordinary class of milling operations. More properly, in regard to the difficulty of the job, it was found practically impossible in one jobbing machine shop where it was tried, presumably because of inadequate fixtures; but it was comparatively easy when done with good tools and fixtures and in accordance with sound machine shop practice.

The job was milling five narrow angular grooves in one edge of a number of steel pieces 28 inches long, 2½ inches wide and 15-16 inch thick. The grooves were 3-16 inch wide and 5-16 inch deep and were carried to a sharp angle at the bottom. The steel pieces were for work of a special character the nature of which makes no difference in this connection except that it required the grooves to be quite exact and smooth, with no ragged edges at the tops. As indicated in the accompanying cut the sides of the grooves were sharply inclined, the included angle being 35 degrees. One side of the grooves made an angle of 20 degrees with the medial line and the other, 15 degrees.

In the shop referred to, that failed on the job, an attempt was made to mill the grooves successively with a single cutter while the piece was held in a milling machine chuck having narrow jaws. As a consequence the piece, of course, overhung the jaws a considerable amount on each side, which condition produced a peculiar result, but one that would have been predicted by anyone familiar with the characteristics of the stock used—cold-rolled steel. Cold-rolled steel has a surface under considerably more compression than the interior. In fact the interior is in a state of tension which causes the state of compression in the surface. If one side of a cold-rolled bar is planed off, the ends will curve toward that side when the clamping bolts are loosened. The first groove was cut along one side and the second one next to it and so on until the last one, when it was found that the piece had assumed a rainbow shape and that the last groove cut was the only one that was straight, the others all having a curvature increasing up to the first one milled, which had the most. The explanation is simple, of course. The first cut reduced the amount of stock on that side and as the chuck jaws offered but little restraint the stock curved toward that side slightly, the curvature increasing with each cut. The remedy for this action was simply to use a heavy milling machine chuck having extra long jaws which embraced nearly the full length of the pieces and held them perfectly straight until all the grooves were milled. Then there was little or no tendency of the pieces to curve in either direction; and if they did slightly, the grooves would remain parallel, which was the principal consideration.



Industrial Press, N.Y.

A Job of Angular Milling.

After it had been demonstrated that the grooves could be successfully milled, it was decided to mill a number at once, using gang cutters. Strange to say an eminent tool-making firm which furnished the cutters, recommended that the cutters be ranged side and side so that, say, the five grooves in one piece would be milled at one pass. This was found to be impracticable on account of the chips wedging between the cutters and causing rough, ragged edges at the junctures of the grooves; and the plan of mounting as illustrated, was adopted, the cutters *B*, *B*, *B*, *B*, *B*, being spaced apart the width of the pieces *A*, *A*, *A*, *A*, *A*, so that the successive cuts of each cutter were taken in each piece in the same relative position. This plan worked quite successfully.

In connection with the same contract a planer job of unusual character was done. It was grooving the top of a steel casting 16 feet long, 44 inches wide and perhaps 10 inches thick, with V-grooves of the same shape as those milled by the milling machine. The grooves were smaller, however, being about 20 to the inch. These grooves were planed with a gang tool, the cutters being spaced apart on the same principle as the milling cutters, that is, so that the chips of adjacent tools would not interfere. After the grooves were planed they were rolled, to produce a smooth surface, with a gang of steel rollers held by a holder in the tool-post. After rolling, the whole surface was polished with oil and emery, the workmen using pine sticks endways of the grain, for rubbers. A remarkable feature of this job was the freedom from blowholes, sand pits and flaws in the steel casting, the surface being perfect in this respect. It showed that steel founding has reached a high state of art in America when large steel castings of this shape can be made with a surface as free from flaws as rolled plates.

* * *

An Illinois Central Railroad freight car, fitted with ball-bearing axles, has been subjected to a test trip of 2,600 miles, carrying a load of 80,000 pounds. The results are reported to be eminently satisfactory, the balls and bearings showing no appreciable wear, and the car being ready for service without any repairs after the long trip.

NEW POLISHING ROOM OF THE BROWN & SHARPE MANUFACTURING CO.

Visitors at the plant of the Brown & Sharpe Mfg. Co., Providence, R. I., before the "new building" (building No. 4) was erected, have often been shown the grinding and polishing room in the basement of the main or No. 1 building. This, we think, was always considered a model of neatness and much superior in its appointments to the general grinding rooms. Since the erection of the new building, however, a new room has been equipped on the upper floor which is much superior to the old room and much more comfortable and convenient for the workmen. It is the lightest and cleanest polishing room we have ever seen, which fact will be appreciated by examining the accompanying illustration, Fig. 1.

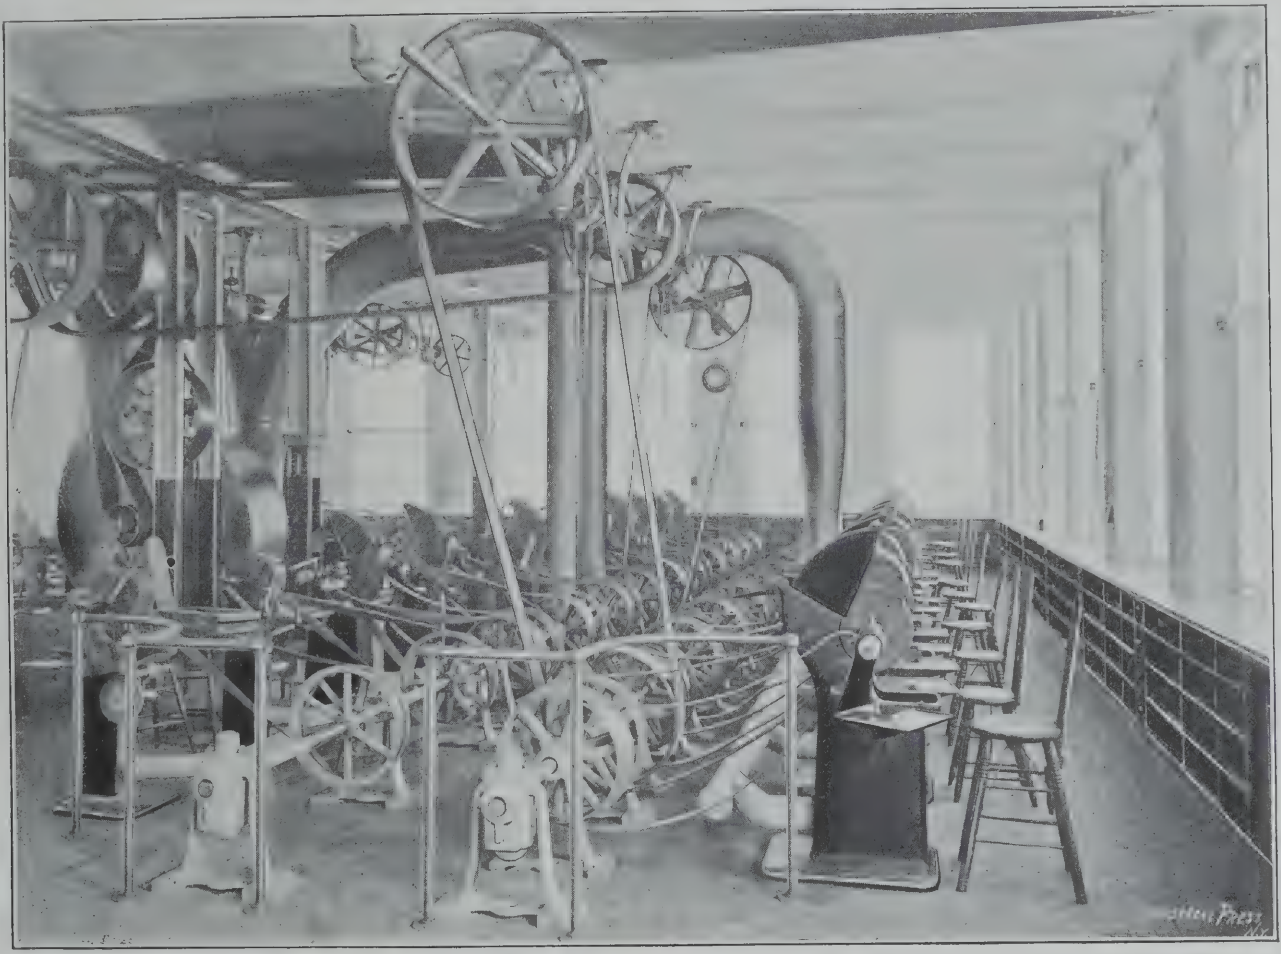


Fig. 1. New Polishing Rooms of the Brown & Sharpe Mfg. Co.

The piping and general arrangement of the machines and shafting are indicated in Fig. 2. The polishing machines are of the same design as those illustrated in the Brown & Sharpe catalogues some years ago, but which they do not now manufacture except for their own use, the machines now being handled by the Builders Iron Foundry, Providence.

The larger polishing machines shown in the foreground of the half-tone were especially designed with a view to economizing as much space as practicable. Ordinarily two machines are required, one running with an open belt and one with a cross belt, to enable the top of the wheel in one case, and the bottom in the other, to be used for polishing. In the machine mentioned, however, the horns for carrying the wheel spindle are located a sufficient distance apart to enable the spindle to be reversed. Each machine is provided with two sets of tight and loose pulleys, one set on each side, that carry open and cross belts, thus enabling the operator to use the same machine for polishing different classes of work that may require the use of the top or bottom of the wheel. The belt not in use is hung upon a hook provided for that purpose.

By this arrangement one machine answers for all kinds of work within its capacity, and does away with the necessity of the operator moving from one machine to another, thus keeping his work always in one place, and economizing, because practically only half as many machines are required as ordinarily.

Another important feature is that the loose pulleys are not mounted upon the driving shaft but upon especially arranged bearings that are either upon an extension of the shaft bearing concentric with the shaft or (where the bearing does not come into proper position) upon especially arranged supports. It is obvious that this arrangement reduces the wear of the pulley bearings to a great extent, as they remain stationary and do not revolve upon the shaft. The machine columns are hollow and have hoods partially encasing the wheels, while the bases of the columns connect with exhaust piping leading to the large fan shown at the center in Fig. 2. The draft from the rapidly revolving wheels forces the dust around under the hoods where it drops to the bottom of the column and is then taken care of by the exhaust piping and fan exhauster. The dust is delivered by the fan to a separator on the roof, which finally discharges to a can or dust collector enclosed within a closet on the floor of the polishing room.

The separator and collector are of the well-known cyclone type. There are now 36 buffing wheels of the type described, in the room, the smaller ones being shown in the illustration, besides several belting machines which also have dust guards. Ample provision is made for wheel storage around the sides of the room and the equipment includes washing machine, sink, glue stove, an emery chest divided into compartments, etc. The exhaust pipes are made in sections of different diameters, starting at 4 inches at the extreme end of each row of smaller polishers and at 5 inches at the ends of the row of larger machines; increasing to 10 and 12 inches, respectively at the center. It will be noted that a binder pulley is used for the belt driving the fan—a system quite generally followed throughout the works. The speeds of the different lines of shafting are indicated in Fig. 2.

* * *

Thomas C. Lace proposes that a color scale be adopted by the National Blacksmiths' Association for forging, hardening, tempering, and annealing carbon tool steel which for tempering shall consist of ten pieces of tool steel of convenient size, tempered from light straw down to the greenish blue of the color when the temper has run out. Nine of these pieces should be divided into three divisions, the first three for shades of straw color to brown, the next purple to blue, and the third, blue. He says that the lithographic color scales in existence are generally a bad imitation of tempering colors. The scale referred to would be a *fac simile* of what would be required for the guidance of the smith in every particular. The printed scales lack the metallic luster of tempered steel and there is no pigment known that will imitate it exactly. The forging, hardening and annealing heats could be imitated to a certain extent by paint or colored glass, but either is subject to the same fault of the printed tempering scale, that is, the translucent color of hot steel, is lacking.

PISTONS AND PACKING RINGS.—2.

SOME DEVICES FOR FLOATING THE PISTON ON STEAM PRESSURE—EFFECTS OF WEAR.

J. H. Dunbar.

Since writing the first article under this heading (July, 1902 issue), I have secured copies of several patents, showing plans for floating the pistons of horizontal engines on steam, instead of letting them ride on the bottom of the cylinder. There is no question but that a practical scheme to support the pistons is needed, nor that it will not be welcomed alike by engine builders and engine users. Just now the tail-rod is growing in popularity, but it is objectionable, owing to its taking up room and adding to the weight of the reciprocating parts, etc. These and other faults make it so far from being satisfactory, that there is plenty of room for something else, if the device is practical.

Before discussing these patented inventions, to be referred to later, it is well to remember that pistons are not steam-tight, in the sense of a safety valve. If there are such, the writer has not seen them. There are plenty of pistons, which if the cylinder head is taken off, and steam admitted behind the piston, will not immediately begin to leak, but after the pressure has been on, say five minutes, a little lake of water will be formed on the bottom of the cylinder, and as soon as the piston and cylinder get hot, steam will begin to sizzle around the piston at some part of its circumference. The actual leakage, when the engine is running, will be much more than when standing with the pressure on, for the friction of a film of water between metal surfaces is greater than that of a gas, between like surfaces. When the engine is standing with the pressure on, most of the leakage changes to water, owing to the thin space, and comparatively cold surfaces between which it must pass, while if the engine was running, it would to a greater extent, be steam. As illustrating the difference in leakage, between water and a gas, take a gas engine, turn it on the compression stroke to the center, or rather to the end of its stroke, and if the compression does not all leak out in less than thirty seconds, the piston is tighter than any that the writer has met with. Gas engines, as a rule, are very easy to turn, when the lead is off, and if the fly-wheel is "tramped" around leisurely, but very little resistance will be encountered, on account of compression. I think that for tightness, gas engine pistons will compare favorably with those made for any general purpose. If any engineer thinks his valves and piston absolutely tight, let him take a gasfitters' test pump and try to jam the cylinder full of wind, through the indicator pipe. Or let him clean the indicator piston and cylinder, then connect the indicator to a hand bicycle pump, and see how much pressure he can churn up against a hundred and twenty pound spring on the piston, using air as a pressure-producing medium. Then turn the indicator upside down fill the cylinder full of oil or water, then pump in air, and note the difference. Of course, in this, as in everything else, different experimenters will get widely differing results. There is one thing, however that they will all agree on, viz: That the volume of leakage, under like conditions, is much greater with a gas than when a liquid is employed to produce motion in a machine, by pressure, or when acted upon by a machine to produce pressure. It is not much trouble to accurately determine the air leakage of a piston but it is different when it comes to steam. The writer knows of no satisfactory method of measuring the steam leakage of a piston when it is in service. Pistons that apparently leak only a little steam, do so enormously when used against air.

The first patent that the reader's attention is called to, in which the inventor's object was to make the piston swim in the cylinder, is shown, substantially as in the patent, in Fig. 1, of the piston. The packing rings are set obliquely in the head, are loose in the groove and so shaped as to act as check valves, i. e., when ring *A* is forced to the side of its groove marked *B*, steam can flow under and around it to the space between the rings, but not past ring *C*. On the return stroke, the rings change to the opposite sides of their grooves, and steam enters the space past packing ring check valve *C*. It will be noticed that there is more area on the bottom of the piston, between the rings, than on top, hence its tendency to lift when steam is admitted to it. The trouble and expense to make pistons and rings by this method, and the serious question as to whether the rings would act according to the inventor's dictation, will stand between the invention and its popular use. Better results would no doubt be had, if the piston was run bottom side up, and as much steam as possible be kept from between the packing rings. The patentee is Mr. William J. Thomas, Sausalito, California.

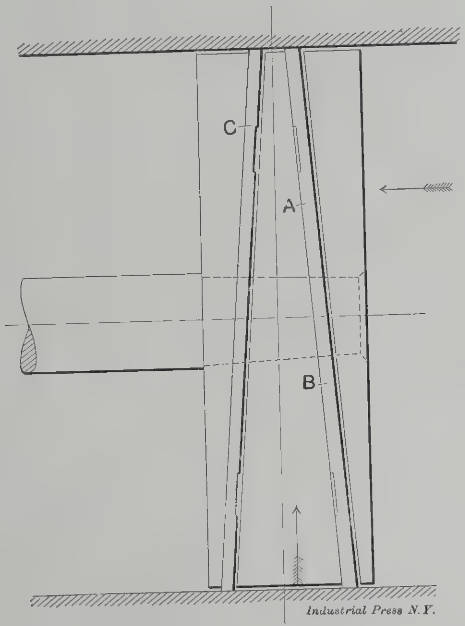

Fig. 1. Packing Rings set Obliquely to "Float" the Piston.

Mr. Henry M. Hunt, Indianapolis, Ind., has patented an invention for counterbalancing the weight of the piston and rod of horizontal engines, by making the bull-ring with a cavity in the bottom and surrounding it with packing strips, and then keeping a constant pressure there, just sufficient to lift the piston. To do this he has a pressure-regulating device, inside of the piston, consisting of three helical springs, three valves and a diaphragm, with joints and ports to correspond. To make Mr. Hunt's invention more easily understood, and also to provide some means by which the steam may get on top of the bull-ring, and go down through it to the top of the diaphragm I have made several changes in his design.

Fig. 2 shows this invention. The cavity in the bull-ring is *t*, and *s* is the diaphragm, connected by toggle joint to the ball valves. This view shows the port holes *a* through the followers closed. When the pressure in *t* gets too low, the diaphragm drops and opens one of the ports, and steam flows in from the steam side of the piston, the hole in the opposite follower being closed. I show holes drilled through the bull-ring, near the top, marked *c*, in order to allow any steam that may get between the rings, to press the diaphragm down, and maintain a pressure in the cavity sufficient to carry the weight of the piston, and also the steam load on top of it. I do not see why, for horizontal stationary engines, an arrangement of this kind could not be made to just float a piston. On locomotives such pistons would do a lot of vertical hammering if they had any play at all in that direction. In general, they will likely be regarded as costly, unreliable and not adapted to piston heads made in one piece, the latter being the most important consideration.

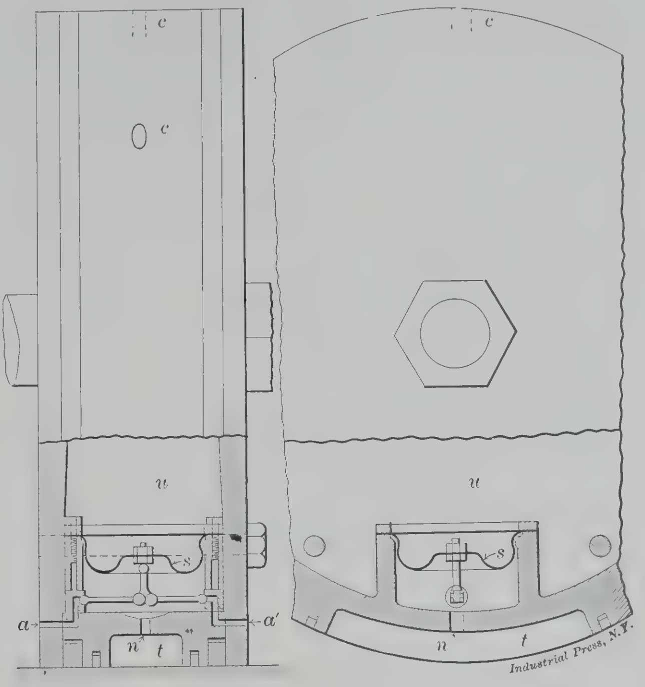

Fig. 2. Another Device for "Floating" a Steam Engine Piston.

In Fig. 3 we have what the inventor, Mr. James Thierry, Laramie, Wyoming, calls a "self-poising" piston. I have taken some liberty with this design too, by putting the counterbalancing cavities on the bottom of the piston, instead of on top where they are shown in the patent. I think that this inventor has made some mistake in his design, for with the cavities on top of the piston, there don't seem to be anything for the steam to do but to help hold the piston down. There are several patents, similar to this one as I have shown it, and all of them would be improved by some kind of a compensating device that would take care of the steam load and varying steam pressure on the piston.

As a parting shot at this part of the subject, I suggest making a piston as shown in Figs. 4, 5, 6 and 7. Fig. 4 shows an end view of it in section at the face of the rings. Fig. 5 is a vertical section through the center of the piston. Fig. 6 is an enlarged plan view of the joint, or cut in the outside ring *a*, and shows how the inside ring, *b*, stops any leak that would otherwise take place there, by the steam going in at one end of the lap, down under the ring and out at the other end. The flanges of the piston do not touch the cylinder at any part of their circumference, and are turned semi-eccentric, so that as the ring *a* wears down they will still clear the cylinder; for it is intended to make the piston a steel casting of one piece, it being understood that steel and cast-iron do not wear well together, hence the flanges are relieved on the bottom. The outside ring, *a*, is cast iron, and made eccentric, and its thick side put at the bottom so the flanges can be cut away, and still leave about the same depth of bearing on the edge of the ring at all parts of its circumference. Ring *b* is made eccentric to give it a uniform groove contact.

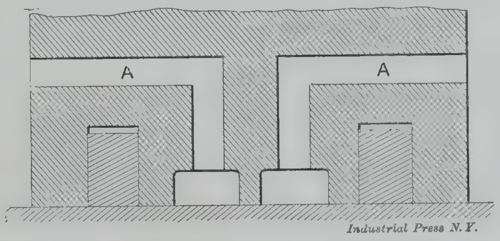

Fig. 3. Thierry's "Self-poising" Steam Engine Piston.

Its thick side is up, and both rings are dowelled in their respective positions by pin *c* in the piston.

To equalize, or rather to get an average pressure between the ring and cylinder on all parts of their circumference, the bottom half of ring *a* is reduced in breadth an equal amount on each side as shown at *xx*, and in depth an amount equal to the eccentricity of the ring. The amount of side reduction depends on the weight of the piston, and the average steam pressure upon it. If the head weighs 500 pounds, is 20 inches in diameter and the pressure 100 pounds, then the width of the ring should be reduced on each side; would be $500 \div 100 \times 20 = \frac{1}{4}$-inch, making a 20-inch ring 2 inches wide. on top, and the bottom half 1½ inch wide. Now the steam pressure on the outside of the ring where it has been cut away at *xx*, tends to collapse it, and not to lift the piston bodily. The tendency to collapse the ring under such circumstances would be about as great as though the ring traveled over the counterbore ¼ inch. Were it not that some steam gets under the rings to hold them out to the cylinder, it would not do to let them travel past the counterbore, as is generally done. Suppose with our 20-inch piston, the pressure at the beginning of the stroke is 200 inches, then its tendency to collapse the ring vertically is $\frac{1}{4} \times 20 \times 200 = 1{,}000$ pounds, but if there is four times the area on the inside of the ring, and one-fourth the pressure, the collapsing tendency is just balanced, but the total pressure between the ring and cylinder is 500 pounds more on the top half than on the bottom, and consequently, the top half of the ring and cylinder will be worn the most. Suppose further, that the engine takes steam full stroke, and that the 200 pounds are maintained and also that the wear is proportional to the load, making the top half of the ring wear twice as much as the bottom, say ¼-inch and ⅛-inch respectively. The piston, as a whole, has gone down just as much as the bottom of the ring and cylinder, has worn, but never had a tendency to lift, nor can it unless the ring collapses.

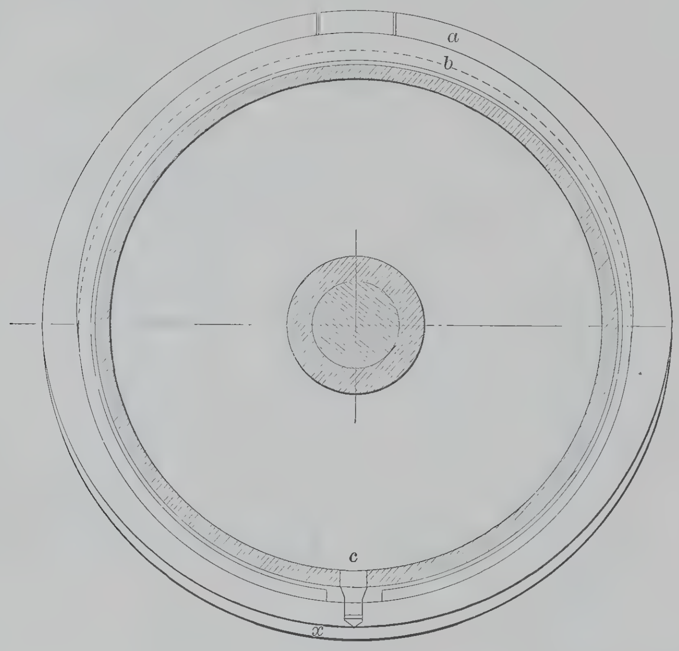

Fig. 4.

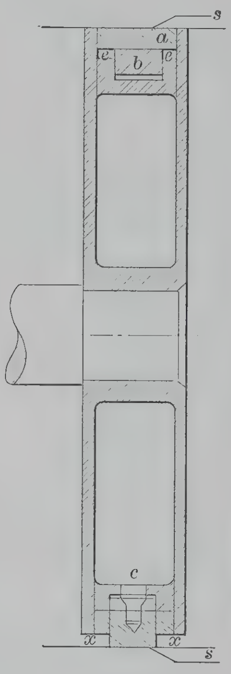

Fig. 5.

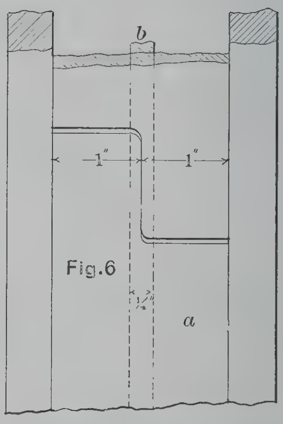

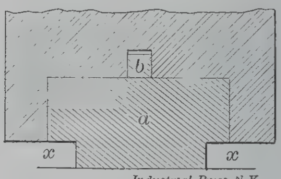

Industrial Press N.Y.

Fig. 7.

I feel safe in saying that unless a ring is so tight in its groove that it is liable to stick, more steam will get under it than is necessary to prevent collapsing. Of course, rings can be run so far over the counterbore that the external pressure might exceed the internal pressure, but there is no necessity for it. A 1-16-inch over-travel is enough, and in general there does not seem to be any use for more. The dotted lines *ss*, in Fig. 5, represent the counterbore, and show the proportionate distance the rings should travel over it.

Ring *b* in addition to covering the joint in *a*, confines to a great extent, the steam to one end of ring *a*, holding it in space *e*, thereby lessening ring and cylinder wear, and consequent friction. Its width (ring *b*) will depend on circumstances, but as a rule one-half the breadth of *a* will be best. It is shown in Fig. 5 so wide that possibly not enough steam will get under it from space *e* to keep both rings from collapsing. In Fig. 6 it is only wide enough to cover the cut in *a*, which of course limits its breadth in that direction.

It seems, too, that the weight of a 20-inch piston, say 500 pounds, having a bull-ring surface of 2½ inches wide and 15 inches chord length, in contact with the bottom of the cylinder, ought not to cause any appreciable wear, due to its weight only; for when spread out, it is less than 14 pounds to the square inch, certainly not enough to pay to put on a tail-rod. If however, in addition it has to carry a steam load on one flange, and whatever may get on top of the bull-ring, it is different. If the flanges and bull-ring are cut away so that they are balanced, so far as steam pressure is concerned, then a tail-rod may be of some use, provided it is stiff enough to carry the piston without too much deflection. If the flanges and bull-ring are not relieved, the bottom of the cylinder is worn to a circle, whose radius is determined by the amount the piston and tail-rod will deflect. Without a tail-rod, it does not make much difference to the piston if the crosshead does lift a little at each end of the stroke, as a locomotive does in running ahead, but if a tail-rod is used the piston gets an unnecessary amount of shaking up and down.

Near the close of the first article on this subject, I implied that one ring to the piston was enough, and so far as ring and cylinder wear is concerned, the piston I have shown in Figs. 5 to 7 may be called a single-ring piston. There are some advantages that a piston of this type has over those with a ring at each end of the piston as shown in Fig. 8. To make it clear, the "deformity" has been somewhat overdrawn, for stationary practice, but locomotive men will recognize it as "true to life." In the sketch, the flanges are reduced in diameter so the weight of the piston is borne by the bull-ring, the packing rings having a liberal amount of vertical play in their grooves. It is evident that if one ring wears the cylinder any at all, one more will wear it a like amount, and the bull-ring will probably wear the bottom of the cylinder as much as both packing rings. So it is easy to see that that part of the cylinder which is traversed by all the rings, must suffer more wear than at the ends of the stroke, where only one of the end, or outside rings touches it, making the shoulders as shown at each end of the cylinder. If wear is proportional to pressure, and only one ring at a time has pressure under it, a single ring would wear the cylinder as much as both those in Fig. 8. But that is questionable, and in the high-pressure cylinders of multiple-expansion engines, there is pressure on each side of the pistons, but the most unnecessary wear in two-ring pistons would be due to a trifling leak of one ring that would let enough steam through and get under the other. There is often but a few cubic inches of space between the rings in pistons, and when that gets full of water, an insignificant amount of leakage from the live steam side of the head may keep the pressure between the rings, equal to that on the piston. It was shown in the first part of this article that steam may leak considerably, where water will not, hence if this theory holds good, an objectionably high pressure will be constantly between and under the rings. It seems clear to me that the better the rings fit in a two-ring piston, the more pressure will be maintained under them, and the more wear and consequent friction will be produced. If both rings leak plentifully, the pressure under each of them will be less. Water has no trouble in getting out if the hole is big enough.

It will occur to the reader that the wider a packing ring is, after some economical width is exceeded, the greater frictional resistance it will produce. Were it not for the steam pressure that gets under it, making the load to carry proportional to its area, the width of rings would be in the same class as journals, crossheads and other bearings. As it is, ¾-inch is believed to be as good a breadth as any, for diameters of 20 inches and over. Under that diameter, ½-inch, ⅜-inch, ¼-inch, etc., will be found to be satisfactory. Rings should always be made wide enough so the piston will strike the cylinder heads, before the rings can get into the counterbore. For a single-ring piston, where the weight of the head is carried on the ring, it ought of course be made wider than the regular two-inch width. For the piston shown in Fig. 5, ring *a* should be 1 inch wide at the bottom, 1½ inch wide at the top, and ring *b* ½-inch wide, and edges parallel. Steam will of course get under the outside ring at the cut, if at no other place, and probably under the inside one too, but there will be no pressure higher than that of the exhaust in space *e* on that side, for any pressure that gets in from the live steam side can get out easily by the same route when the exhaust takes place. Taking the weight of the piston into consideration, this combination of ring widths, would wear a cylinder about as much as one ¾-inch ring in a piston of like diameter supported on a tail-rod. It will be noted that the flanges of the head in Fig. 5 are considerably smaller than the cylinder, and that the pressure on the edge of the ring will keep it against the exhaust. The rings ought, of course, to be as close a fit in their grooves as practical, and also have smooth, accurate surfaces. Then the only time they will have an excuse for leaking will be when they are shifting in the grooves, which they will do when the pressure is about equal on both sides of the piston. If there is any difference in the amount of play, the outside one should have the most, to make sure that the edges of the inside ring make joints in its grooves. As regards leakage, the edges of ring *a* are not important, but its circumferential surfaces are.

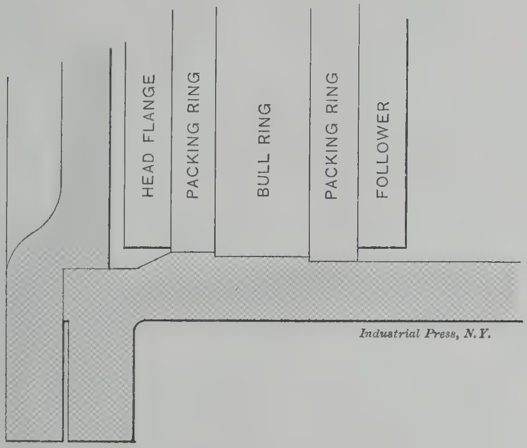

Fig. 8. Showing the "Step" Effect of Packing Ring Wear.

The question of lubrication is always closely allied to any moving part of a machine, and while there are other parts of an engine that may be of more importance, there are none that are oiled in such a bungling manner. It is stationary practice to turn a drop of cylinder oil loose in five or six barrels of steam, somewhere between the boiler and the engine, and then it is a case of "go as you please" until it is filtered out of the exhaust, when it is cooked over again. When the supply is liberal, as it usually is, enough of the oil finds the parts to be lubricated, and excessive wear is seldom found. When it comes to lubricating locomotive cylinders it is different. There they allow a drop of oil to every few miles the engine runs, or a few drops to the round trip, I have forgotten which. The oil and steam are mixed the same way as in stationary engines, but the homeopathic doses of oil administered to the steam used in the locomotive, are too often rushed through to the smokestack, without having time to get sidetracked on the cylinder. Now if there is any law of friction that is not befrilled and festooned with strings, it is the one that wear and frictional resistance are greater between dry, than between lubricated surfaces. I believe that this law is as true as it is that two trains cannot pass on a single track, and yet some railway managers offer their engineers a premium on the oil that they save. This puts me in mind of a picture the Jones & Lamson people have in their catalogue, of an old party with a microscope, looking for a leak in the head of a barrel, while the bung-hole at the bottom is wide open.

THE VALUABLE MAN OF THE FUTURE.

In a handbook recently issued by the New England Association of Teachers of Metal Work, containing addresses given before that association, in a paper on Hand Work in Modern Shop Practice, by our contributor, Mr. Edward R. Markham. He comments on the modern tendency to manufacture as cheaply as possible by means of machinery, and to abolish hand work, and closes with a bit of personal reminiscence. He says:

> Young men learning the trade are not, as a rule, taught to become skilled filers, or scrapers, and less is taught them about the use of the cold chisel and hammer. Any work of this nature is left to the "old fogies" who are considered oftentimes as being good for nothing else.
>
> In time these older men will have finished their shop work, and as machines are built that require in some of their details very accurate hand work, who is to do it? Not the average young journeyman, or the apprentice learning his trade in most of our machine shops. There are exceptions to the conditions I have cited; there are employers who realize the conditions that must face them in a few years, and are educating their young men in lines that will allow them to fill that gap that must come. But these employers are the exception rather than the rule. I predict that in less than twenty years the machinist or tool maker capable of doing good hand work will be at a premium. He will not have to depend on any organization to keep up the standard of wages for him. He will be able to demand any reasonable compensation. The law of supply and demand will attend to his case.
>
> I learned my trade under my father. He is one who believes in teaching a boy as *much* of a trade as possible. Many days, weeks and months have I stood at the vise with file or hammer and chisel in my hands, and worked and growled because I was made to do things that boys in other shops knew nothing about. But many, many times have I been thankful that my father knew more than I thought he did.
>
> There have been times when I doubted the advantage of having been able to command the confidence of the boss to the extent that he would trust me to go down into the wheel pit, and, with chisel and hammer as weapons, and a tallow candle for my light, chip a keyway in a jack shaft; or, tell me if he would like to have me stay a little while in the evening and cut another in the main line. It isn't all fun, sitting straddle a line of shafting and chipping a slot one-half inch wide and six or eight inches long, especially when you haven't room to swing the hammer, and must give the force of the blow by main strength rather than by the haft of the hammer head. But it had to be done and the man that can do the unusual things about the shop is the valuable man.

* * *

Rock blasting extraordinary has recently been done in Wales. One blast in the Trever quarries, Carnarvon, brought down 60,000 tons of rock, and 12,500 pounds of powder were exploded. The other blast was still larger, it being estimated that 100,000 tons of rock were dislodged. This blast was made to secure material for the building of a breakwater at Goodwick, Pembrokeshire. Only 10,500 pounds of powder were fired, yet the amount of rock is greater than in the other case, probably being the largest ever brought down by one blast.

Election day has come and gone and the usefulness of the voting machine has again been demonstrated in no uncertain manner. The first voting machine tried in New Jersey was used in Paterson the last election and with very gratifying results. The result was known ten minutes after the polls closed. In other districts the poll clerks worked hours, in some cases until five o'clock the next morning before the last ballot was counted. The voting machine is the one "machine" in politics that all good citizens may unhesitatingly indorse. It saves time in voting and counting, and insures the secrecy of the ballot. The cost of paper and printing for tickets used and unused in every election, is alone an item of considerable importance. The voting machine has come to stay.

GRAPHITE VS. FRICTION.

We have occasionally had inquiries about the use of graphite as a lubricant and points have been brought out through correspondence that may be of interest to the general reader. The action of graphite is somewhat different from that of fluid lubricants and there are differences of opinions as to the part it is capable of playing in alleviating friction, some contending that graphite is not properly called a lubricant, and even that it has abrasive properties, unfitting it for use between bearing surfaces. This latter opinion was recently expressed to us by a person who had been engaged in testing lubricants, but who, possibly, may have been somewhat prejudiced in the matter.

According to the strict definition of the term, graphite is rightly called a lubricant. The term is derived from the Latin *lubrico*, meaning to make slippery, a result certainly accomplished by graphite. While we have not had opportunity to verify the statement that graphite has abrasive qualities, it is very evident that the results from this action are so slight as to be negligible in practical work. We are inclined to the opinion that, if abrasion has actually been observed, it is due to the presence of foreign substances rather than to the graphite itself.

The crystalline, or more commonly called flake graphite, is the kind most suitable for bearings. It is composed of flakes of irregular circular shape, about 1-40 inch in diameter and varying from .002 to perhaps .0002 inch in thickness. The formation is very similar to that found on a large scale in slate quarries, where the slate breaks up readily into thin slabs, entirely similar to the minute flakes into which graphite separates.

The function of graphite is not so much to take the place of lubricating oil or grease as to make the surfaces of the wearing parts smooth and polished so they will slide over one another with as little friction as possible. For this reason it is perhaps misleading to call graphite a lubricant. The result accomplished by it is analogous to the result obtained by the use of the modern grinding machine when finishing journals or bearings. If the journal of a rotating piece is finished by turning or filing, simply, and is soft, it will take more power to rotate it in its bearings than if the parts are hardened and ground, and accurately cylindrical. Friction is caused by the slight irregularities of surfaces fitting into one another, and so requiring force to make one slide upon the other. Grinding reduces these irregularities and when we come to a surface as smooth as ice the friction is very little indeed. Graphite accomplishes practically this result. It fills up the pores and produces a smooth surface, in just the right condition for a bearing, and as the coefficient of friction of graphite is only about half that for iron or steel, its value in a bearing is very manifest.

While graphite is seldom used as a lubricant without oil, its low coefficient of friction makes it a fairly efficient lubricant when employed without oil, or when for any reason the oil has become dissipated, leaving a graphite coating on the wearing surfaces. Such a condition might exist in a gas engine or superheated steam engine cylinder, or a heated bearing, if the temperatures were high enough to vaporize the oil. It is well known that graphite will "cool off" a hot bearing, for the reason, of course, that it makes smooth surfaces out of the roughed-up ones; and in a similar way, and on the plan that prevention is better than cure, its previous use will tend to prevent a bearing from roughing up and heating. It is more effective on rough than on hardened and ground surfaces and is generally considered very efficient for heavy work, where it is not liable to be squeezed out from between the surfaces by the great pressure. But there are cases where it is decidedly better for light work than oil; for example, in the runways in the Mergenthaler linotype machines. In these the matrices from which the letters are cast are of brass or composition, and upon the depression of the keys on the keyboard they slide down inclined grooves to their proper positions for the casting of the line of type. Were oil used to lubricate the grooves, it would gather dust and the matrices would stick, a difficulty not experienced with graphite.

Graphite is almost indestructible. It is pure carbon and is not attacked by acids and will protect metallic surfaces from corrosion. It is used by many machinists when putting together machinery that must be exposed to the weather, such as locomotives or hoisting machinery. In these cases, if the screw threads and surfaces in contact be coated with a film of graphite and oil, the parts will not rust together and can be easily taken apart when occasion requires. In steam and gas engine cylinders graphite is not as generally employed as would be the case if it were easier to automatically feed it into the cylinders, as is done with oil by the use of the sight-feed lubricator. Many devices have been invented for the purpose, however, and some of them are proving quite successful.

Graphite is efficient in reducing friction and its use is increasing as its merits become better known and the way in which it operates is better understood. No more striking illustration of its qualities can be given than by mentioning a peculiar incident related by Mr. Malcolm McNaughton, of the Joseph Dixon Crucible Co. In India, where graphite is mined, many houses have tiled roofs. These are of the simplest kind, having no locking devices for holding the tiles, which are laid loosely on the roofs. The angle of the roofs is less than the angle of repose for the tiles. The winds carry the dust from the plumbago compounds and drive it into the crevices of the roofs; and in some cases the angle of the roofs has proved too great under these conditions and the tiles have slid to the ground, whereas, were it not for the graphite they might have remained on the roofs for years.

THE ROTARY PUMP.

The first steam engine was undoubtedly of the rotary reaction type, but the first practical steam engine was of the reciprocating piston type, converting rectilinear motion into rotary motion by means of the connecting-rod and crank. Now the signs of the times seem to point to the displacement of the reciprocating piston steam engine by the steam turbine, and who would dare to assert that the same fate may not befall the present type of gas engine? There seems to be no theoretical reason why the gas turbine cannot be brought to a successful issue although the practical difficulties appear at present to be formidable enough. In the matter of pumping, the reciprocating piston pump has held the field, both for moving liquids and gases. It is true that we have had the centrifugal pump for liquids and the fan blower for gases, but until comparatively recently these have been regarded as being strictly limited to low heads and light pressures. But there is no good reason for such a condition except the difficulty of getting the proper designs. All good rules work both ways, and the reversible cycle is a well-established principle of mechanics as well as of thermodynamics. The water turbine utilizes the energy of water falling from great heights and does so with good efficiency. Why should it not in reverse order act as a pump working against high heads? Again in the case of the fan blower: If a pressure of a few ounces per square inch may be readily obtained with an ordinary fan, two blowers connected tandem fashion should double the pressure of delivery, three triple it, and so on.

A paper was recently read on rotative pumping by Mr. John Richards before the Technical Society of the Pacific Coast, in which it was pointed out that the engineering world has recently entered on an anti-reciprocating machinery epoch and that pumps as well as steam engines would eventually be re-formed on these lines. The first centrifugal pump is believed to have been invented about two hundred years ago by a Frenchman, Denis Papin, in Hesse, Germany, where it was known as the "Hessian suck." Centrifugal pumps are cheaply manufactured and work very well where the heads are low, but as ordinarily constructed they are not adapted to high heads, say more than forty feet, as the vanes encounter frictional resistance that seriously reduces the efficiency. The kinetic energy of water leaving the vanes of a centrifugal pump cannot be efficiently converted into pressure without using water spaces, as is done in the Sulzer high-lift centrifugal pumps. The ordinary centrifugal pump, may, however, be compounded for higher heads. The first attempt made in England in this direction was that of Prof. Osborne Reynolds, who designed a triple compound centrifugal pump which worked efficiently, but it was not a commercial success. One great difficulty met in centrifugal pumps is getting a motor adapted to the pump, the tendency always being to adapt the pump to the motor. Prof. Unwin says that the friction of vanes increases as the fifth power of the diameter; so there must be a great waste of power when the wheel is made too large, in the effort to accommodate it to the motor.

The centrifugal pumps made by Sulzer Bros., Mannheim, Germany, are remarkably efficient and in consequence have acquired a world-wide celebrity. The following table is made up of the actual results obtained from four Sulzer pumps:

Gallons raised per minute ..	285	444	634	870	1,400	2,060	3,170	4,120	5,706
Head in feet, one-stage	78	111	164	246	262	262	262	262	262
Head in feet, two-stage.....	157	223	328	492	524	524	524	524	524
Head in feet, four-stage....	315	446	656	984	1,050	1,050	1,050	1,050	1,050
Efficiency, per cent	67	70	72	74	75	76	76.5	77	77.6

An installation of Sulzer pumps is working in the Horcajo mines in Spain against a head of 1,550 feet (672 pounds per square inch) and at an efficiency of 70 per cent. The operation of rotary mine pumps from one level to another is eminently the field of the electric motor. Great masses of pump rods and moving machinery are replaced by apparatus that can be conveniently located and connected by insulated wires, the whole making a combination not easily excelled in the matters of simplicity and elasticity. A cut is given in the paper illustrating the construction of a four-stage Sulzer pump to operate against a head of 800 feet or 347 pounds per square inch. The construction shown does not, however, represent their present practice.

The De Laval Steam Turbine Co. are using rotary pumps successfully against high heads. In their machine the turbine shaft makes several thousand revolutions per minute, say, perhaps 30,000, while the driving shaft which is geared to it rotates much slower, say, at 1,500 revolutions. They use two pumps, one for suction and one for forcing. The suction pump is placed on the low-speed shaft, and the forcing pump on the high-speed shaft, with the result that the water obtains so high a kinetic energy that it easily discharges against a head of 250 pounds or even more.

In regard to rotative compression of gases Mr. Charles Parsons has furnished fans driven by steam turbines that deliver air under a pressure of 25 pounds per square inch in what is believed to be a one-stage machine. A two-stage machine on the same principle would double the pressure, and so on. From experiments recently made it is believed to be quite practical to compress gases to high pressures by the direct-acting rotary process, and we may before long look for some interesting developments along these lines.

* * *

LIQUID FUEL FOR THE UNITED STATES NAVY.

In the November issue appeared an editorial of some length on the possibilities of liquid fuel, which gave some of the recent developments in the use of petroleum fuel as applied to stationary, locomotive and marine engineering. As mentioned in the editorial the United States Navy Department have been making quite extensive experiments with liquid fuel with the view of using it to a greater or less extent on naval vessels. As might be expected these tests are of an exhaustive nature and broad in their scope, the object being to find the best form of apparatus, how well it is adapted to naval use, and the nature of the practical difficulties to be overcome. Rear-Admiral Melville's report to the Secretary of the Navy has now been made public, but of course it is not conclusive on all points, the findings of the board published being of a preliminary nature. The report indicates, however, that the use of liquid fuel for military purposes is desirable, but that there are a number of practical problems yet to be solved before it can be regarded as being fully adapted to such use.

As regards the matters of cost and supply of petroleum, it is pointed out that the cost will always be greater than that of coal except where unusual conditions prevail. The expense of transportation alone will be sufficient to make oil cost more than coal except perhaps at some Gulf and California ports; and while the matter of cost is secondary in military matters, it must be considered. As to the limited supply of petroleum, it is mentioned that probably not more than one per cent. of the total amount of oil used as fuel would be consumed by the navy.

The installation of fuel oil apparatus on board ship is fraught with many difficulties. Great care must be taken to prevent fires and explosions. Not only must sparks from the furnaces be guarded against, but also the dangers arising from the electric wires and apparatus. It is thought probable that the great bulk of such fuel used on warships will be stored in the double bottoms. But wherever stored there is the difficulty of preventing the accumulation of explosive gases in tanks that are partially full. In the merchant service the oil is often stored in expansion tanks or trunks that rise to the height of the deck. On some of these vessels the oil tanks are surrounded by a cofferdam so that any leakage of oil will be quickly discovered. It is said to be comparatively easy to free such tanks from the dangerous gases that tend to accumulate therein.

The special board composed of Lieutenant-Commanders Edwards, Parks and Bailey sought to determine: 1. The relative advantage of air and steam as an atomizing agent. Air compressors are not desirable on shipboard as they are heavy and take up considerable room. If steam is to be used instead it is important to know to what degree to superheat it in order to make it a satisfactory atomizing agent. The use of air making necessary an air compressor, is not a vital objection, however, since air compressors are already in use on shipboard for other purposes. 2. The pressures at which oil, steam and air should be delivered at the burners. 3.

The best design of steam boiler for liquid fuel. 4. The simplest and most economical method of heating the air and oil. 5. Whether or not an air receiver is necessary between the compressor and the burner to reduce the air pulsations. 6. The relative value of the leading types of oil burners. The Bureau have over 2,000 drawings and specifications on file and about 30 patents are being issued a week on oil-burning apparatus. 7. The non-production of smoke. This is most important from a military standpoint.

The board also sought to find: 1. The evaporative efficiency of oil as compared to coal under like conditions. 2. The degree to which combustion could be forced with both steam and air as the atomizing agents under forced and natural draft. 3. The ability of the oil burner to work under forced draft. 4. The liability of the boiler to injury under forced draft. 5. The amount of steam necessary for atomizing the oil. 6. The effect of pre-heating the air necessary for combustion. 7. The time required to properly train firemen to care for oil burners. 8. The best means of reducing the roar caused by the minute and incessant explosions within an oil-burning furnace.

With the Hayes oil burner it was not at any time found possible to get an evaporative efficiency (corrected) of 11 pounds of water per pound of oil. Steam was furnished from an independent boiler at a pressure of 90 pounds. The oil was fed to the burners at a pressure of 80 pounds. During the trials the pressure for atomizing purposes as well as the pressure at which the oil was forced to the burners, was increased each day. It was found that the higher the pressure the greater the amount of water evaporated. The efficiency was also slightly increased with the higher pressure, but the percentage of steam required for atomizing also slightly increased with the pressure. It was also found that the thermal efficiency of the oil burned was not increased by the use of steam. The popular idea that the steam is disassociated at the high firebox temperature and that the hydrogen and oxygen are afterwards united, is regarded as a misconception. All steam that enters the furnace will escape as steam and carry with it considerable waste heat. The amount of waste heat carried off in this manner will depend on the temperature of the furnace and the amount of steam introduced. The quantity of available heat for evaporative purposes is undoubtedly reduced by the use of steam as an atomizing agent. The information that has already been secured on the subject of liquid fuel and made public, is summarized as follows:

1. That oil can be burned in a very uniform manner. 2. That the evaporative efficiency of nearly every kind of oil per pound of combustible is probably the same. 3. That marine steam boilers can be forced to as high a degree with oil as with coal. 4. That the firemen favor oil. 5. That the air supply necessary for combustion should be heated before entering the furnace. 6. That the oil also should be heated. 7. That when using steam as the atomizing agent higher pressures are undoubtedly more efficient in atomizing the oil than low pressures. 8. That under forced draft conditions no means have yet been found for preventing the escape of black smoke from the funnels. This condition is very undesirable from a military point of view. 9. That the consumption of oil cannot be forced to so great an extent with steam as with compressed air as the atomizing agent. This is probably because the air for atomizing also supplies oxygen, while the steam displaces the air entering to support combustion, and thereby hinders it somewhat.

The boiler used in the experimental tests was of the Hohenstein straight water tube type. This boiler, in the opinion of the Board, is one that can be put on the very limited list of American straight tube boilers that have been found suitable for naval purposes. Careful examination of the boiler after the tests showed no distortion of the tubes nor any damage to it whatever, although it had been subjected to an unusually severe work. The tubes remained free of mud, showing a good circulation. Some recommendations were made which it was believed would improve it for naval purposes, one being the use of a 42-inch drum in front instead of a 24-inch drum. This would tend to make the water level more uniform in a seaway.

NOTES AND COMMENT.

REVIEW OF CURRENT EVENTS, TECHNICAL AND MECHANICAL.

When the Hudson River tunnel, track elevations and general abolishment of grade crossings, and other improvements now in progress on the Pennsylvania Railroad between New York and Philadelphia are completed, it is predicted by President Cassatt that the distance between the two terminals (more than 90 miles) will be made regularly by the through trains in one and one-half hour. The time will be correspondingly reduced, on account of similar extensive improvements, between New York and Baltimore, Washington and other points.

We have previously commented on the extensive use now being made of concrete construction in place of stone for all kinds of building purposes. Concrete is successfully used for foundations, retaining walls, culverts, arches, walls of buildings, chimneys, etc. A concrete dam is nearing completion near Ithaca, N. Y., which is being built to impound a water supply for that city. The dam is across a narrow gorge and will be 100 feet long and 90 feet high. The concrete wall will be 8 feet thick at the bottom and 2½ feet at the top. Expanded sheet steel plates are imbedded in the wall to bind together as one solid mass and to give the necessary tensile strength. The dam will be faced on both sides with vitrified brick.

A press dispatch to the *New York Times* says that after making a thorough test of oil as fuel on its passenger locomotives for ten months, the Southern Pacific Railroad has decided to return to the use of bituminous coal. Its mines at Carbonado recently received orders to begin shipping 25,000 tons a month to San Francisco. Those mines have been operated by the Southern Pacific for twenty years, but were partially shut down after the road began using oil. During that time the product of the mines has been used for coke making. It is reported that oil was not a success on the passenger locomotives for two reasons. One was that it deposited a coating on the flues, which had to be removed every day, otherwise it kept the heat from the water, causing a great waste of fuel. The other was that the intense heat produced by the oil also cracked and split the boiler sheets.

The following table taken from a paper on the world's coal supply, issued by the Treasury Bureau of Statistics, shows the coal production of the world in the latest available year, the figures for the United States, United Kingdom, Germany and France being for 1901, the others for 1900:

Countries.	Short tons.	Per cent of total.
United States	293,298,516	33.86
United Kingdom	245,332,578	28.32
Germany	168,217,082	19.42
Austria-Hungary	43,010,761	4.96
France	35,596,536	4.11
Belgium	25,856,024	3.00
Russia	17,799,016	2.00
Japan	8,187,262	1.00
Other Countries	28,867,765	3.33
Total	866,165,540	100.00

Lightning does not strike water, Professor J. Trowbridge of Harvard declares. This discovery he has made in his experiments with the highest electromotive force ever used. By means of his battery of 20,000 cells he obtained a voltage of 6,000,000, which force, he says, is at least comparable to lightning, and enabled him to deduce his conclusions. "I found that lightning does not strike water, if there is anything else within reach," says Professor Trowbridge, "in the course of my experiments on the effect of high tension or high electromotive force. With my large battery I was able to obtain an electric spark about seven feet long, and found that instead of striking the water a spark of six or seven feet in length invariably jumped to some adjacent object in preference to striking the liquid surface. A spark of only a few inches in length, however, invariably will strike the water, but such a spark is not, of course, compared to lightning."

The glaciers and snow fields of the upper Alps in Switzerland have been aptly named "white coal" since the mountain torrents having them for their sources, are generally being utilized for power purposes, which means that coal is not required where water power is available. The recent coal strike in this country has been an unpleasant demonstration of the necessity of coal for almost all industries and of the paralyzing effects on business, when it cannot be obtained. We have almost unlimited water power in many parts of the country, but unfortunately it is usually so located as to be unavailable except for such industries as need not be close to the principal markets. The development of the electro-chemical industries as exemplified at Niagara Falls promises that many of these remote water powers may be made useful. The great water power of the streams and rivers in the Rocky Mountains, has often been referred to, but it is doubtful if its vastness is generally appreciated. A project is on foot to harness the Colorado River, near Williams, Arizona. A fall of 5,000 feet can be secured in a distance of about one mile by tunneling. A very small volume of water falling such an immense distance will generate great power, so what will it be for a great river!

A COSTLY TEST.

A few years ago the British Admiralty, in order to carry out certain investigations regarding naval construction and gunnery, had an old battleship turned out to sea where it was sunk and destroyed by a heavy fire from the large guns on the several ships participating in the experiment.

It is now stated that it has been decided to break up the torpedo-boat destroyer *Wolf*, at Portsmouth, with the object of discovering wherein lies the weakness which has led to so many mishaps and disasters in the case of these craft during the present year. The *Wolf*, which was launched in 1897, at a cost of $1,250,000, has been placed in a specially fitted dry dock while awaiting the costly operation. The steel cradles will first be removed from amidships and the vessel will be left hanging by her ends, in order to ascertain if the sagging strain thus imposed is sufficient to break her back. If she survives this ordeal the *Wolf* will be hung see-saw fashion across the cable, both ends being left unsupported, so as to show how she would fare if lifted amidships on the crest of a wave. Other tests will be applied. Great interest centers in the outcome of the experiment, from which the naval architects anticipate obtaining most valuable data for designing future torpedo boat destroyers.

FIRE IN NEW WILLIAMSBURG BRIDGE TOWER.

On the night of November 10 a serious fire broke out in the New York tower of the new Williamsburg Bridge across the East River, which was with great difficulty extinguished. The fire raged fiercest at the top of the tower 330 feet from the ground. The tower construction is entirely of steel, but the fire was fed by the wooden scaffolds, ladders, footbridges, oil, waste, and other inflammable materials used in the construction work. The wires composing the four huge cables had all been laid and were being covered with a waterproofed canvas covering, over which will be placed steel casings. This work had been partially done and it was feared that the cables had been severely damaged over the tower where the flames were the hottest, it even being predicted that they would have to be renewed at a cost of perhaps $1,250,000 which would, in consequence, delay the completion of the bridge more than one year. It was found, however that the cables had been well protected from the direct effect of the flames by the saddles that carry the cables over the top of the tower. A conservative estimate of the damage made by an engineer connected with the Roebling Co. puts the damage at $50,000. Each of the four cables is 18½ inches in diameter, and is composed of 7,696 wires laid in 37 strands of 208 wires each. The wires have a tensile strength of about 200,000 pounds per square inch of cross section. The total width of the new bridge will be 118 feet and the lowest part of the roadway will be 135 feet from the water at high tide. Its total length is 7,200 feet which is about 660 feet greater than that of the Brooklyn Bridge. The center span is 1,600 feet long.

DEVELOPMENT OF WATER POWER AT NIAGARA FALLS.

According to an account recently published in a Buffalo newspaper, the amount of capital now invested in the development of the power of Niagara Falls is $32,500,000. There are at present five companies exploiting the power resources of this famous and wonderful waterfall: Niagara Falls Power Co., Niagara Falls Hydraulic Power & Manufacturing Co., Canadian Niagara Falls Power Co., Ontario Power Co., and Lower Niagara River Power Co. The Niagara Falls Power Co. are now supplying 50,000 electrical horse power from their No. 1 power house and will soon be in position to supply 55,000 horse power from their No. 2 power house, which is nearing completion. The Niagara Falls Hydraulic Power & Manufacturing Co. are enlarging their canal so as to add 100,000 horse power to their present output. The Canadian Niagara Falls Power Co. are working night and day on a 100,000 horse power plant, the output of which will be mostly used on the American side. This company also have a franchise for an additional 100,000 horse power which will probably be developed as soon as the present installation is completed. The Ontario Power Co. have plans for the development of 400,000 horse power and the work is being hurried with all possible speed. The contract for the first 50,000 horse power has been let. The Lower Niagara River Power Co. have secured a franchise for 200,000 horse power which will soon be developed. The total power development possible by these five companies, is about 1,000,000 horse power. The effect of such vast resources of cheap power will undoubtedly be that Niagara Falls and vicinity will eventually become one of the greatest manufacturing centers in the world.

FOR PREVENTING ELECTROLYSIS.

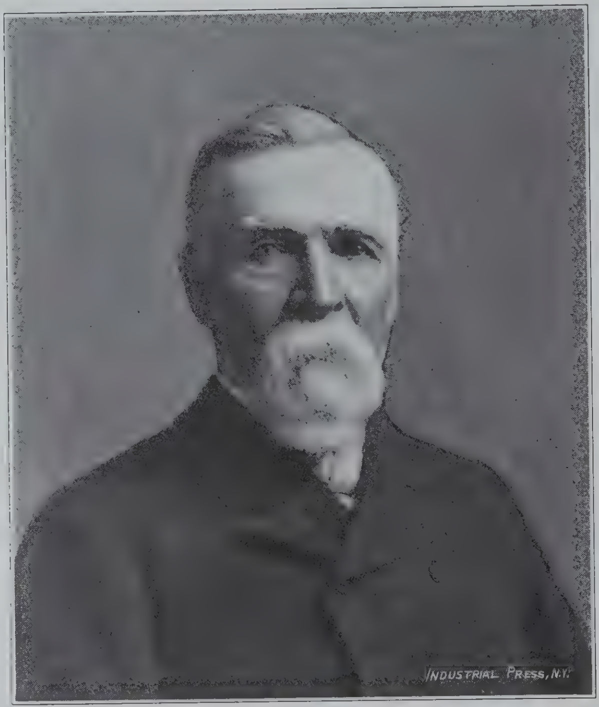
Bearing on the subject of electrolysis, which has become so important in our great cities, are several bits of experience given at a convention of fire engineers in New York City the latter part of September. These were by Capt. Brophy, who read a paper on "Electrolysis." As reported in the *Electrical World and Engineer* he recommends breaking the continuity of metal in pipes by the insertion of insulating joints at suitable intervals. In that case the poorly bonded track would have to receive immediate attention, and its carrying capacity be increased either by proper bonding, increasing the size of the rails, or the addition of return feeders. If neither plan was adopted an increased coal bill would be the result. This plan of placing insulators or circuit breakers was not adopted at first, because none had been devised. But within a quite recent period such breakers have been devised, manufactured and used. Capt. Brophy added:

"In one of our large cities a natural gas system of piping had been connected by a large cable to the dynamos of the street railway system in order to drain them of current, but electrolytic corrosion took place very rapidly at the joints. In this case 'necessity was the mother of invention,' and an insulating joint was devised and inserted at suitable points in the pipe system, and the connection to the dynamos discontinued, since which time no corrosion has taken place.

"I have quite recently taken measurements between the natural gas pipes and the rails of the street railway in Wheeling, W. Va., to ascertain the flow of current from pipes to rails, also to ascertain the flow of current in the different lines of pipes. I will not give here a list of these measurements, but as a result of one made near the power house I found 300 amperes flowing from pipe to rail, the pressure being 10 volts, or representing a little over 3 horse power. The gas company has decided to place insulating joints in their pipe system. I have just returned from Wheeling, where the work has progressed far enough to show that the lines wherein these joints have been placed have no current flowing over them, and when the work is completed these pipes will not act as return feeders for the railroad, and electrolytic corrosion will cease. It will be a matter of indifference to the owners of these pipes what the condition of the street railway tracks may be. Not so with the city of Wheeling, however. Up to the present time the return or stray currents were conducted jointly by the gas and water pipes, but from this time on, the entire load must be borne by the water pipe."

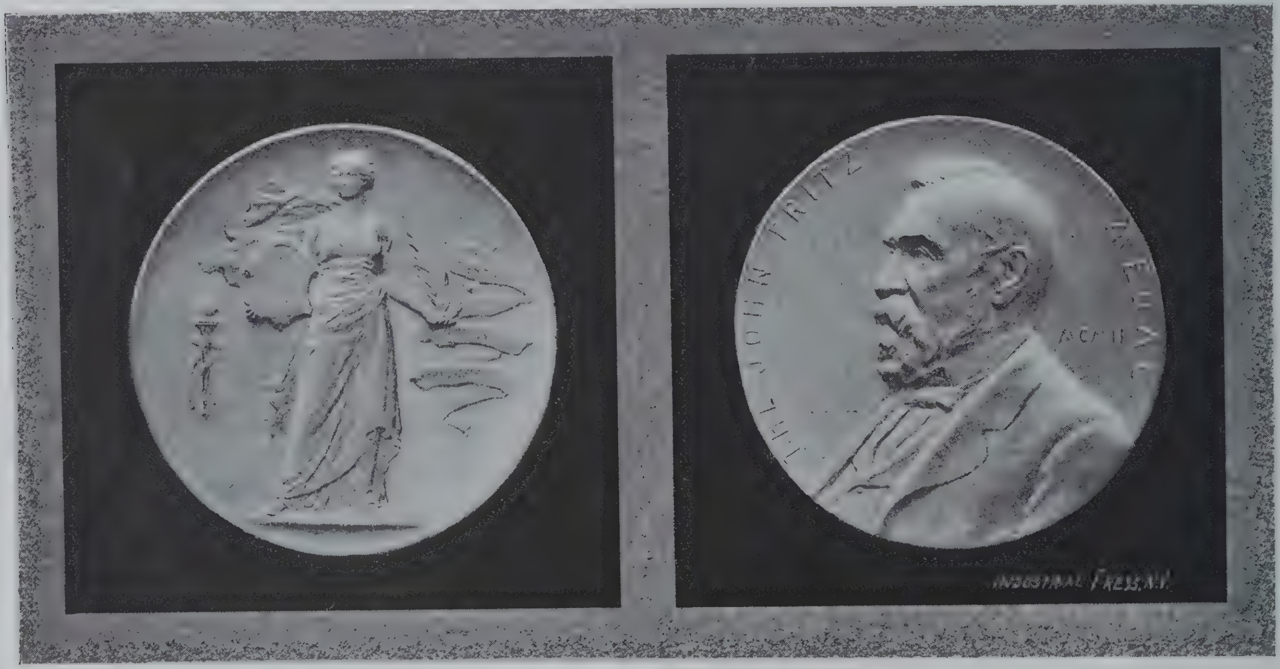
THE JOHN FRITZ MEDAL.

A banquet was given at the Waldorf-Astoria Hotel, New York, on Friday evening, October 31, in honor of the eightieth birthday (August 21, 1902) of John Fritz, the well-known veteran of the iron and steel industry of the United States; and a gold medal was given him in recognition of his scientific and industrial achievements. The banquet was attended by nearly five hundred guests, many of whom are among the foremost in the metallurgical industry in this country, and many others equally prominent in other industries and in the professions. Mr. H. C. Prout, editor of the *Railroad Gazette*, was toastmaster on the occasion and Mr. John Thompson made the speech of presentation. Speeches were made by or letters read from Abram S. Hewitt, Rear-Admiral Geo. W. Melville, Brig.-Gen. Eugene Griffin, Andrew Carnegie, Irving M. Scott and many others. Mr. Prout announced the establishment of a John Fritz gold medal to be presented yearly for notable scientific and industrial achievement, without restriction as to sex or nationality. A permanent fund of $4,000 has been raised by the friends of Mr. Fritz, the interest of which will be ample for the annual purchase of the medal. The annual awards of the medal are to be made by a board of sixteen members chosen equally from the membership of the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers and the American Institute of Electrical Engineers.



INDUSTRIAL PRESS, N.Y.

John Fritz, Engineer. Born August 21, 1822.



Reverse and Obverse of John Fritz Medal.

John Fritz was born August 21, 1822, on a farm in Chester County, Pa., which he left at the age of sixteen to work in a machine shop to learn the machinists' trade. In 1846 he became connected with a bar mill. The tools provided for the building and repair of rolling mill machinery were of the crudest description and were seemingly totally inadequate for such work. The bar mill referred to had practically only one machine tool, a roll lathe. After much persuasion he succeeded in getting the firm to purchase some small lathes, a planer and a drill press. Mr. Fritz's influence was always in the direction of improved tools and appliances, believing that they could always be made a most profitable investment. In 1854 he became connected with the Cambria Iron Works, and about 1860 he erected a puddle and rolling mill and later a blast furnace at South Bethlehem, this being the origin of the great Bethlehem Steel Works. The subsequent development of these works in the manufacture of armor plate for battleships and of hollow steel forgings for industrial purposes by the Joseph Whitworth fluid compression process, are matters of general knowledge.

Mr. Fritz invented and built the first three-high rolling mill in America while superintendent of the Cambria Iron Works. The great difficulties he encountered in its development would have discouraged a man of lesser courage and determination. Before the invention of the three-high mill the two-high rolling mill was in common use. With this the hot plates were returned on top of the upper roll, which of course made an idle pass for each working pass. This not only caused a loss of time, but allowed the plates to cool on the idle pass and made the rolling of large thin plates extremely difficult, if not impossible. The three-high train not only does away with the idle pass and saves time, but keeping the plates continually between the rolls is a distinct advantage, as heat is added mechanically. There is also the tendency to weld up any incipient cracks that may have started in the edges of a plate during the previous pass, because of the reverse action of the rolls. So obvious were the great advantages of the three-high rolling train, after it had once been worked out to a successful issue, that its most strenuous opponents were almost at once won over, and it was not long before it was generally adopted for other rolling mills. To-day it is practically the only form of train known for general work. Probably no other invention has made such a change in the methods or possibilities of the art of forming metal into shapes by the rolling process, or has had a greater influence on the production of iron and steel.

WORM GEARING.

NOTES ON THE DESIGN OF SELF-LOCKING WORM GEARS.

C. F. BLAKE.

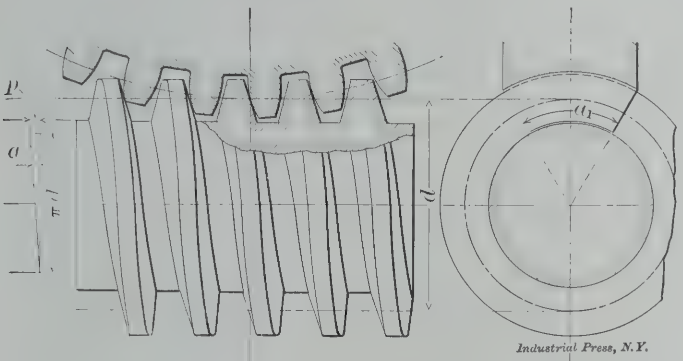
The fact that, among all the valuable matter on gears to be found in the volumes of our technical press, so little rewards the searcher after information on worm gearing, has led to the presentation of the following notes from the writer's note book, being matter obtained from various sources when designing occasional worm gears.

The old opinion that the friction and wear of worm gears are necessarily very great, and that the efficiency is necessarily very low, making worm gearing an unmechanical contrivance, is no longer met with. In Unwin's Machine Design it is stated that in well fitted worm gearing, of speed ratios not exceeding 60 or 80 to 1, motion will be transmitted backwards from the wheel to the worm.

In the *American Machinist* of Jan. 13th and 20th, 1898, Mr. F. A. Halsey, writing on modern practice with worm gearing, shows from many examples of practice that worm gearing may be designed to have a very satisfactory degree of efficiency. In Prof. Forrest R. Jones's work on machine design may be found tabulated the results of many examples from practice, some of which show an efficiency as high as 74 per cent. before abrasion began, the most notable example being that of a worm running at a surface speed of 306 feet per minute under a load of 5,558 pounds, and showing an efficiency of 67 per cent., with no abrasion. The tables in Prof. Jones' work show that under light loads very high surface or rubbing speeds are allowable, running as high as 800 feet per minute, while Mr. Halsey gives diagrams showing the relations of the rubbing speeds, thread angles and efficiency, showing in general that an increase in the thread angle increases the efficiency.

There is, however, an important function of worm gearing which is not brought out in these articles, and which in certain classes of machinery is of the first importance; often, indeed, becoming the determining factor in deciding upon the choice of a worm gear as the power transmitter. It is the property a worm gear possesses, under certain conditions as to its design, of being self-locking, and preventing motion backwards.

An instance where this property becomes of prime importance and accounts for the use of the worm gear, is in crane work, where the winding drum is driven by a worm gear so designed that when the power is shut off the gear will not run down or backwards under the impulse of the load, but will be self-locking, holding the load at any point.



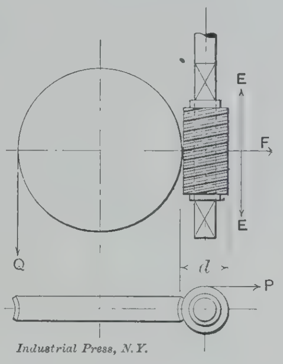
Industrial Press, N.Y.

Fig. 1. Single Thread Worm in Mesh with Wormwheel.

Fig. 1 shows a single thread worm in mesh with the worm wheel, a being the angle of the worm thread with the axis of the worm wheel, and in order that the system may be self-locking, that is that the worm wheel may be unable to run the worm, the tangent of the angle a, must be less than the coefficient of friction between the teeth of the worm and wheel, or as

$$\tan. a = \frac{p}{\pi d}, \text{ so } \frac{p}{\pi d} < f \quad \ldots\ldots\ldots\ldots (1)$$

in which p = the pitch, d = the pitch diameter of the worm, and f = the coefficient of friction between the worm and wheel. It is necessary to assume a value for f, which, if the condition determining the use of the worm gear is its self-locking property, should be assumed conservatively low. Unwin states under the authority of Prof. Briggs, that a well-fitted worm gear will exhibit a lower coefficient of friction than any other description of running machinery. Prof. Jones gives a series of values for the coefficient of friction of screw gears, one of which is a pinion of 4 inches pitch diameter, the average value being f = .05 corresponding to a rubbing velocity of 250 feet per minute. Mr. Halsey in his articles assumes f = .05, and Mr. Wilfred Lewis says that when the worm gear is worked up to the limit of its safe strength, a rubbing velocity greater than 200 to 300 feet per minute will prove bad practice. It is in heavy machinery where worm gears are mostly used as self-locking transmission elements, and here they are usually worked up to the safe strength of the wheel, hence it is fair to assume f = .05 when designing a self-locking worm gear, and to limit the rubbing velocity to 200 feet per minute, and we have for the limiting value of p at which the system will be self-locking.



Industrial Press, N.Y.

Fig. 2.

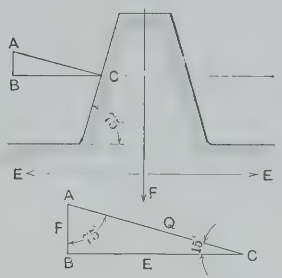


Fig. 3.

$$p = .05\,\pi\,d = 0.157\,d \quad \ldots\ldots\ldots\ldots\ldots (2)$$

The sliding velocity in feet per minute at the pitch line is expressed by

$$V = \frac{\pi\,d\,n}{12} = 0.261\,d\,n \ldots\ldots \quad \ldots\ldots\ldots (3)$$

where d = the pitch diameter of the worm, and n = the number of revolutions per minute of the worm.

Under the above assumption, that for continuous service and heavy pressures, the sliding velocity should not be more than 200 feet per minute, we have as the limiting value of d to avoid all cutting,

$$d = \frac{200}{0.261\,n}$$

The exact nature of the surface of contact between a worm and wheel is involved in doubt; many claim it is only a point; it certainly is not large, and consequently a wide face for the wheel is not needed. If the angle a_1 is made 60 degrees, it will make the face right for any ordinary worm of 4 to 6 inches diameter.

There is in all worm gearing a very heavy end thrust on the worm shaft, and also an outward force normal to the worm axis, each of which must be suitably provided for in the design of the shaft and bearings. The end thrust may be taken by bronze washers slipped into the bearings at the end of the shaft, which may be removed when worn and replaced with new ones. Shoulders may be provided on the shaft, between which and the bearings bronze collars may be placed, these being split to enable new ones to be easily and quickly placed in position when the old ones become worn. Roller thrust bearings are very often applied to worms, and these as well as the bronze washers may be supplied with adjusting setscrews to take up the wear instead of renewing the washers.

In Fig. 2 let P = the tangential force at the pitch line of the worm, d = the pitch diameter of the worm, Q = the tangential force at the pitch line of the worm wheel, E = the end thrust of the worm shaft, F = the force on the worm shaft normal to the worm axis, then, friction being neglected,

$$Q = \frac{P\,\pi\,d}{p} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

In Fig. 3 let the force Q be represented by the line A C normal to the tooth side of the worm at the pitch line; draw A B normal to the axis of the worm, and B C parallel to the axis or coincident with the pitch line of the worm; then when measured to the same scale to which A C was drawn, A B = F, and B C = E. As the angle C A B is 75 deg. (for the 15 deg. involute system) we have,

$$\frac{F}{Q} = \text{sin. } 15°, \text{ and } F = 0.258\ Q \ \ldots\ldots\ldots\ (5)$$

$$\frac{E}{Q} = \text{cos } 15°, \text{ and } E = 0.966\ Q \ \ldots\ldots\ldots\ (6)$$

Taking friction into consideration, the force P_1 tangential to the pitch line of the worm, which it is necessary to employ

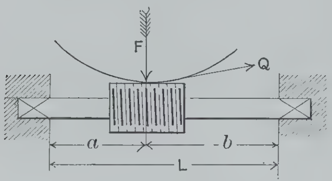

Fig. 4.

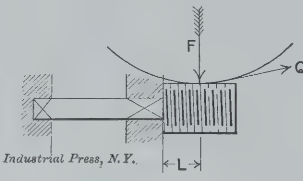

Fig. 5.

in order to produce a force Q tangential to the pitch line of the wheel, is given in Weisbach as

$$P_1 = Q\,\frac{h + f}{1 - h f} \ \ldots\ldots\ldots\ \ldots\ldots\ (7)$$

in which

$$h = \frac{p}{\pi\, d}$$

The efficiency of the worm and wheel is then,

$$\frac{P}{P_1} = e \ \ldots\ldots\ldots\ldots\ldots\ldots\ (8)$$

Example: A single thread worm of 1 inch pitch running 80 rev. per min. is to transmit to a worm wheel a tangential force Q = 5,000 pounds, and is to be self-locking.

Here from (3)

$$d < \frac{200}{.261 \times 80},$$

or d may be as large as 9.6 inches before abrasion need be feared.

From (2)

$$p < 0.157\ d, \text{ assume } p = .125\ d,$$

then as p = 1 inch, d = 8 inches, or the worm will require to be 8 inches pitch diameter in order that the angularity of the thread may be small enough to make the system self-locking. It will be seen that the required diameter will be increased as the value of f is decreased, and in case the required diameter of the worm proves too great for practice, and the pitch cannot be reduced on account of considerations of strength, some outside aid, such as a brake or friction disk applied to the worm shaft, will have to be adopted.

From (7),

$$\text{as } h = \frac{p}{\pi\, d} = \frac{1}{3.14 \times 8} = .039, \text{ we have}$$

$$P_1 = 5000\,\frac{.039 + .05}{1 - (.039 \times .05)} = 445 \text{ pounds.}$$

From (4),

$$5000 = \frac{3.14 \times 8 \times P}{1}, \text{ or } P = 199 \text{ pounds.}$$

From (8),

$$\frac{P}{P_1} = \frac{199}{445} = 44\% \text{ for the efficiency of the worm gear.}$$

The formulas may, by starting with those for the efficiency, be used to determine the pitch diameter which will give the proper thread angle for any given pitch and degree of efficiency.

It is clear from the foregoing, that a worm gear of large pitch will require a pitch diameter of the worm altogether too large for practice if it is to be self-locking, and that the system as usually designed may be expected to run backwards. To prevent this, a friction disk may be placed in the bearing which receives the thrust of the worm shaft when the system is running backwards, and the diameter of the disk so proportioned as to just hold the worm shaft stationary under the impulse of the worm wheel.

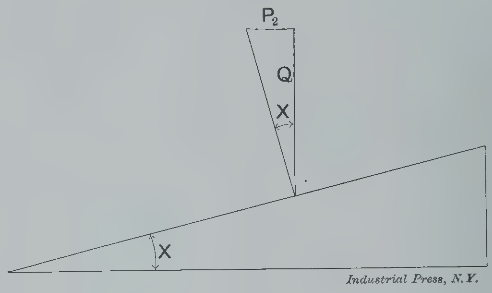

Fig. 6.

The foregoing discussion neglects the effect of the thrust of the worm shaft in its bearings, the frictional resistance of which must be added to that of the teeth to obtain the actual conditions of a self-locking system. This frictional resistance depends upon the values of the end thrust E and the normal force F already found, and the diameter and form of the bearing. In nearly all cases of worm gearing the mounting of the worm upon the shaft will be covered by one of three cases, either unsymetrically between the bearings, symetrically between the bearings, or over-hung.

Case 1, Fig. 4, the bending moment upon the worm shaft is,

$$M = \frac{F\,a\,b}{L} = \frac{.258\ Q\,a\,b}{L} \ \ldots\ldots\ldots\ldots\ (9)$$

Case 2, the same as Case 1, except that the worm is central between the bearings, and

$$a = b = \frac{L}{2}$$

the bending moment upon the worm shaft is,

$$M = \frac{.258\ Q\,L}{4} = .0645\ Q\,L \ \ldots\ldots\ldots\ (10)$$

Case 3, Fig. 5, the bending moment upon the worm shaft is,

$$M = F\,L = .258\ Q\,L \ \ldots\ldots\ldots\ldots\ (11)$$

In each of the above cases the shaft is subjected to a combined twisting and bending strain, the twisting moment being the same in each case, T = P R, which is, however, so small as to be negligible in what follows.

In the following table the first column shows the several styles of journals most commonly used for worm shafts, the second column gives the moment of friction for each under a load in the direction of the arrow, the third column gives the coefficient of friction assumed, and the fourth column gives the tangential force P_2 at the pitch line of the worm resulting from the resistance of friction in the journals, and found by dividing the moment of friction in column 2 by the pitch radius of the worm.

TABLE GIVING MOMENT OF FRICTION WITH VARIOUS TYPES OF BEARINGS

Style of Journal.	Moment of Friction.	f	$\frac{\text{Moment of Friction}}{R}$
A 	$\frac{f\,F\,d_2}{2}$	.05	$\frac{.04\ P\,d_2}{p}$
B 	$\frac{2\,f\,E\,r}{3}$	.05	$\frac{.2\ P\,r}{p} = \frac{.1\ P\,d_2}{p}$
C 	$\frac{2\,f\,E\,(r^3 - r_1^3)}{3\,r\ \text{sin. } y}$	.05	$\frac{.2\ P\,(r^3 - r_1^3)}{p\,r\ \text{sin. } y}$
D 	$\frac{2\,f\,E\,(r_1^3 - r^3)}{3\,(r_1^2 - r^2)}$	.05	$\frac{.2\ P\,(r_1^3 - r^3)}{r_1^2 - r^2}$

There are always acting upon the worm shaft the two forces F and E; consequently to get the resultant retarding force tangential to the pitch line of the worm, we must take the sum of the resultants due to the frictional resistance of each force separately. Referring to the table we will, for each worm shaft, find the conditions shown at A, in addition to the conditions shown either at B, C or D, as the case may be, and the total resultant force P_2 at the worm pitch line, will be the sum of the quantities given in column 4 opposite the particular cases.

These frictional resistances developed by the journals act in a direction helpful to the self-locking property of the worm, and enable the designer to use a larger thread angle for a given diameter of worm, or a smaller diameter of worm for a given thread angle, thus getting within the limits of good practice, and increasing the efficiency of the system for the forward movement.

Having determined the force P_2 tangential to the worm pitch line, resulting from the frictional moment at the journals, the angle of repose for this force acting with the force Q, as shown in Fig. 6, is given by the equation,

$$\tan.\ x = \frac{P_2}{Q}$$

The thread angle found previously to the consideration of the effect of the journal friction may now be increased by the angle x, making the thread angle a+x. This may be accomplished either by increasing the thread angle, increasing the pitch, or decreasing the pitch diameter.

Consider, now, that in the foregoing example, the worm shaft is of the form of Case 2, the worm being central between the bearings, and the distance between bearings being 36″.

Then from (5) we have,

$$F = .258 \times 5{,}000 = 1{,}290 \text{ pounds,}$$

and from (6)

$$E = .966 \times 5{,}000 = 4{,}830 \text{ pounds.}$$

From (10)

$$M = \frac{.258 \times 5000 \times 36}{4} = 11610 \text{ inch pounds.}$$

Assuming $f = 10{,}000$ pounds per square inch for the allowable fiber strain in the worm shaft, we have

$$M = \frac{\pi}{32} d_1^3 f \text{ or } d_1 = 2.28''$$

From the table, Case A.

$$P_1 = \frac{.04 \times 199 \times 2.28}{1} = 17.21 \text{ pounds.}$$

From the table, case B.

$$P_1 = \frac{.1 \times 199 \times 2.28}{1} = 45.37 \text{ pounds.}$$

Then

$$P_2 = 17.21 + 45.37 = 62.58 \text{ pounds.}$$

$$\tan.\ x = \frac{62.58}{5000} = .0125$$

$$x = .7^\circ$$

From (1).

$$\tan.\ a = \frac{1}{3.14 \times 8} = .039$$

$$a = 2.25^\circ$$

Then

$$a + x = 2.95^\circ$$

$$\tan.\ 2.95^\circ = .052$$

$$\frac{p}{\pi d} = .052 = h, \text{ and } d = 6''.$$

If now we substitute these new values of h and d in equations (7) and (4) we shall have,

From (7),

$$P_1 = 5000 \frac{.052 + .05}{1 - (.052 \times .05)} = 500 \text{ pounds-}$$

From (4),

$$5000 = \frac{P \times 3.14 \times 6}{1} \text{ or } P = 270.7 \text{ pounds.}$$

From (8),

$$\frac{P}{P_1} = \frac{270.7}{500} = 54\% \text{ efficiency for the worm gear.}$$

The total efficiency of the system, taking account of the journal friction will be

$$\frac{P}{P_1 + P_2} = \frac{270.7}{500 + 62.58} = 48\%$$

It thus becomes clear that while the efficiency of the worm threads and wheel teeth has been increased above 50 per cent, the efficiency of the whole system including the journals is below 50 per cent. and the system retains its self-locking property. It is evident that when running forward the end thrust E upon the worm shaft will be upon the opposite end from that when running backwards, and on this account a system may be designed to have a high efficiency on the forward movement and still preserve its self-locking property.

If both the journals be made roller bearings, and the end taking the thrust on the forward movement be made ball bearing, while the opposite end be made like Case C or D in the table properly proportioned, the worm may be designed to show a very high efficiency on the forward movement, while the frictional resistance of the step bearing on the opposite end will cause the system to be self-locking by reason of the energy absorbed at the step bearing.

The formulas may be put into more convenient form for this purpose, as follows:

The designer will have, to start with, a knowledge of the force Q required at the worm wheel, the force P_1 at the pitch line of the worm developed from the source of power, the pitch required for the worm wheel, and the efficiency e for which he wishes to design the system. We then have,

$$\frac{P}{P_1} = e, \text{ and } P = P_1\, e$$

Substituting this value for P in equation (4) and solving for d we have,

$$d = \frac{p\, Q}{3.14\, P_1\, e}$$

for the worm neglecting the journals, when the journals and thrust are roller and ball bearings respectively, and

$$d = \frac{p\, Q}{3.14\, (P_1 - P_2)\, e}$$

when the journals and thrust bearings are considered.

The worm being thus designed for the given efficiency on the forward movement, it remains to determine such proportions of the step bearing for the backward movement as will present enough frictional resistance to render the system self-locking. Let e_1 = the efficiency when the journals and thrust are considered, then

$$\frac{P}{P_1 + P_2} = e_1 \text{ or } P = e_1\, (P_1 + P_2)$$

and substituting the value of P found above

$$e\, P_1 = e_1\, P_1 + e_1\, P_2$$

and

$$P_2 = \frac{P_1\, (e - e_1)}{e_1}$$

By equating this force P_2 to the proper quantity from column 4 in the table of journal resistances the proportions required of the journal or step bearing may be determined.

* * *

The British cable-laying ships have completed the laying of the Pacific cable from Vancouver to Sydney, Australia. This is the first cable across the Pacific, but others will probably follow soon. No serious trouble appears to have been encountered laying the cable over the submarine valley six miles deep that must be crossed, and which has been the chasm feared by cable companies.

TESTING INDICATOR SPRINGS.

NEW APPARATUS AT THE NEW YORK NAVY YARD FOR THIS PURPOSE.

As far as we have been able to determine, the first indicator testing apparatus in which the attempt was made to approach the conditions of practice, was built at the Brooklyn Navy Yard, now the New York Navy Yard, in 1888. This apparatus was for testing springs under static steam pressure and has served as a model for other testing devices in various engineering laboratories. At the time of the Navy Yard fire three years ago (Feb. 15, 1899) the building containing the testing room was destroyed and when the new Navy Yard buildings were put up, a larger and more complete testing room was equipped—one of the many improvements under the direction of Commander J. A. B. Smith. A new indicator testing apparatus was built, embodying novel features, many of which had been worked out by Mr. Chas. A. Webb, the instrument maker in charge of the room. This apparatus is designed for both static and dynamic tests of springs. Under the latter arrangement the scale of a spring is determined while both the pencil and the drum of the indicator are in motion and a diagram is being traced. By this method the inertia effects of piston, spring and pencil levers are the same as when the indicator is used on a steam engine. The dynamic method of testing springs is original with Prof. C. H. Peabody, of the Massachusetts Institute of Technology, Boston, who designed the first machine for this purpose. Those who have copies of the February '99 issue of MACHINERY will find therein a description, both of the original Brooklyn Navy Yard apparatus and of Prof. Peabody's machine.

When testing a spring it is placed in its proper position in the indicator and the instrument is attached to a steam cylinder corresponding to the cylinder of a steam engine. The indicator drum receives an oscillating motion similar to the motion that it would receive from an indicator reducing motion on a steam engine. Steam is admitted to and exhausted from the steam cylinder, thus giving motion to the indicator pencil in substantially the same manner as when the admission and exhaust take place in an engine cylinder. Mercury gages are used for showing the admission and exhaust pressures in the cylinder so that they may be compared with the corresponding pressures indicated by the pencil lines of the diagram.

In Fig. 3 are typical diagrams reproduced full size and taken with a 100-pound spring. The figures on the diagrams indicate the admission and exhaust pressure in each case. The three upper diagrams were taken at pressures above the atmosphere and the three lower diagrams at pressures below the atmosphere, or in a vacuum. Further reference will be made to these below.

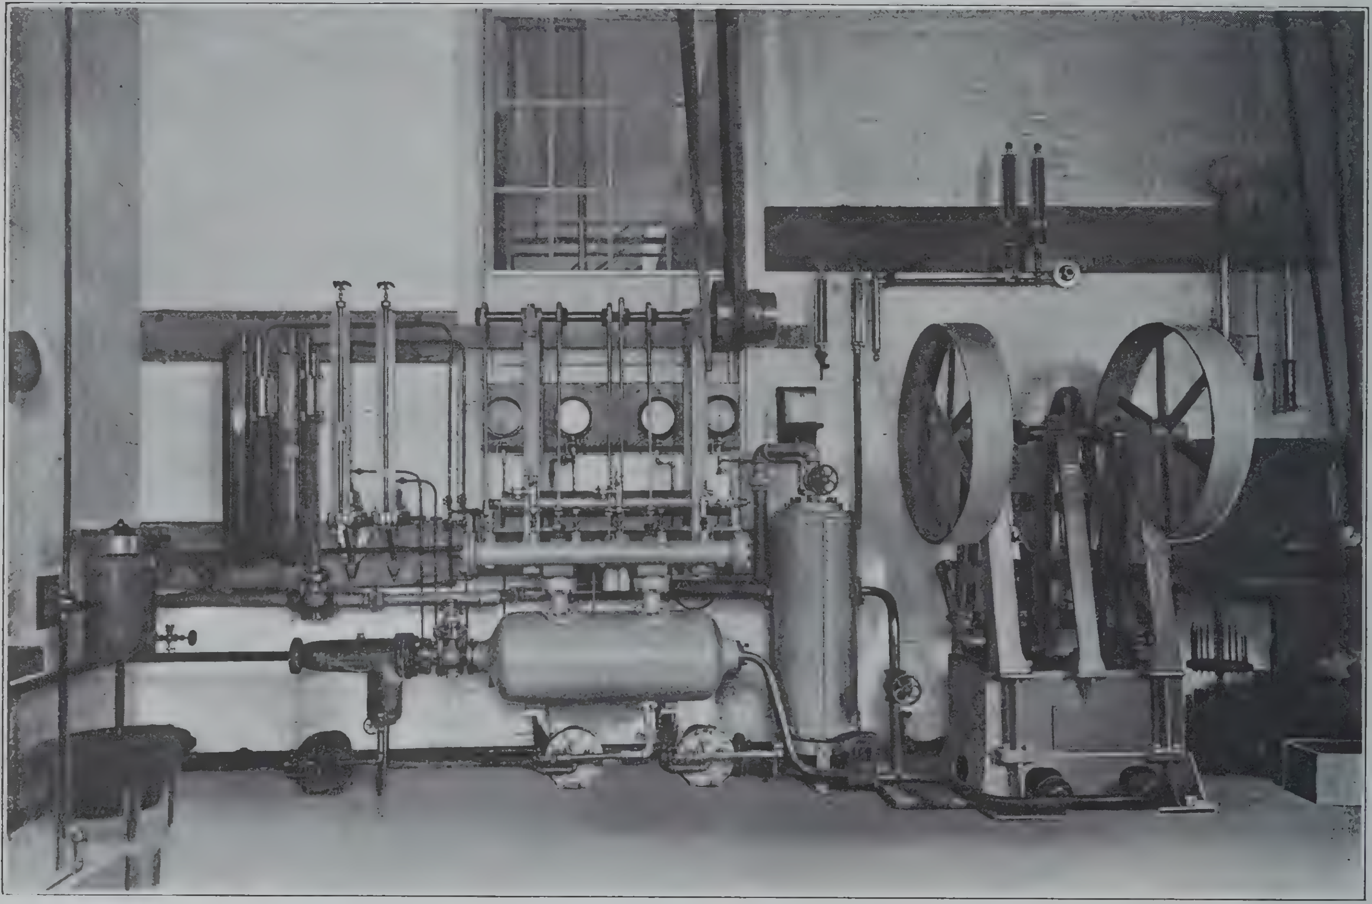

Fig. 1. New Apparatus at the New York Navy Yard for Testing Indicator Springs.

The New York Navy Yard Apparatus.

A general view of the new Navy Yard apparatus is shown in Fig. 1, and details appear in the succeeding illustrations. While it embodies the same principle as Prof. Peabody's dynamic tester, it is modified to permit a number of indicators to be tested at the same time, and the general arrangement of the various parts is quite different from that in the original machine.

An essential element of the apparatus is the cylinder *AA*, Fig. 2, to or from which steam can be admitted or exhausted, as mentioned above, and having the bosses *ggg* for the reception of the indicators to be tested. The shaft *BB* at the top of the machine is driven by an electric motor and has five eccentrics, the left one of which connects with a crank on the end of the drum *EE* to which the indicator strings are attached by thumb screws, thus giving motion to the indicator drums. Two other eccentrics operate piston valves, entirely similar to the ordinary slide valve, in the valve chambers *bb*. These serve first to admit steam from the reservoir *C* to the manifold cylinder *AA* and secondly to exhaust the steam from the latter cylinder to the exhaust reservoir *D*. Finally two middle eccentrics operate small piston valves in the casting *cc*, one of which momentarily admits steam at the admission pressure to the base of one of the mercury gages at *M;* and the other valve momentarily admits steam to the other mercury gage at the exhaust pressure.

To explain the formation of the diagrams of Fig. 3, a typical diagram has been drawn, Fig. 4, upon an enlarged scale, with reference letters. The line *ab* is the admission line, admission being for a very brief duration, as when an engine is running with an extremely short cut-off. The inertia of the pencil carries the admission line too high at first and so connection with the mercury gage is not made until it has settled to its normal level at *c*. The connection is only for an instant and steam at admission pressure is bottled up, as it were, in the base of the mercury gage. When the machine is running at its usual speed the height of the mercury remains at an almost constant level and can be easily read, a vernier attachment being used to determine tenths of pounds. From *d* to *e* is exhaust, and when the normal exhaust level is reached, at *f*, connection with the other mercury gage is made, for registering the exhaust pressure. This in brief is a general description of the machine, but there are numerous interesting features that should be treated more in detail and which receive attention below.

Regulating the Steam and Exhaust Pressures.

Continuing with Fig. 2, the steam enters the reservoir *C* through a De Rycke separator and the reducing valve *d*. It is manifestly necessary to have different pressures of steam in the reservoir in order to test the springs under different degrees of compression. With a static apparatus, where but little or no steam escapes from the reservoir, this can be easily accomplished by means of a globe valve. In this case steam is being drawn from the reservoir in greater or less amounts and a reducing valve is essential. A great deal of difficulty was experienced in securing a valve that would keep the pressure absolutely constant when operating between wide limits, and the one finally adopted after severe tests was the Leslie reducing valve, made by J. S. Leslie, Paterson, N. J. The exhaust reservoir *D* has an outlet to the atmosphere through an exhaust pipe in which is placed the reducing valve *e*, so that any degree of back-pressure can be secured. If desired to run a test under vacuum corresponding to conditions when indicating a condensing steam engine, connection is to be had to an air pump through the pipe shown at the right of the exhaust reservoir. All of these various parts drain into Kieley traps, as indicated.

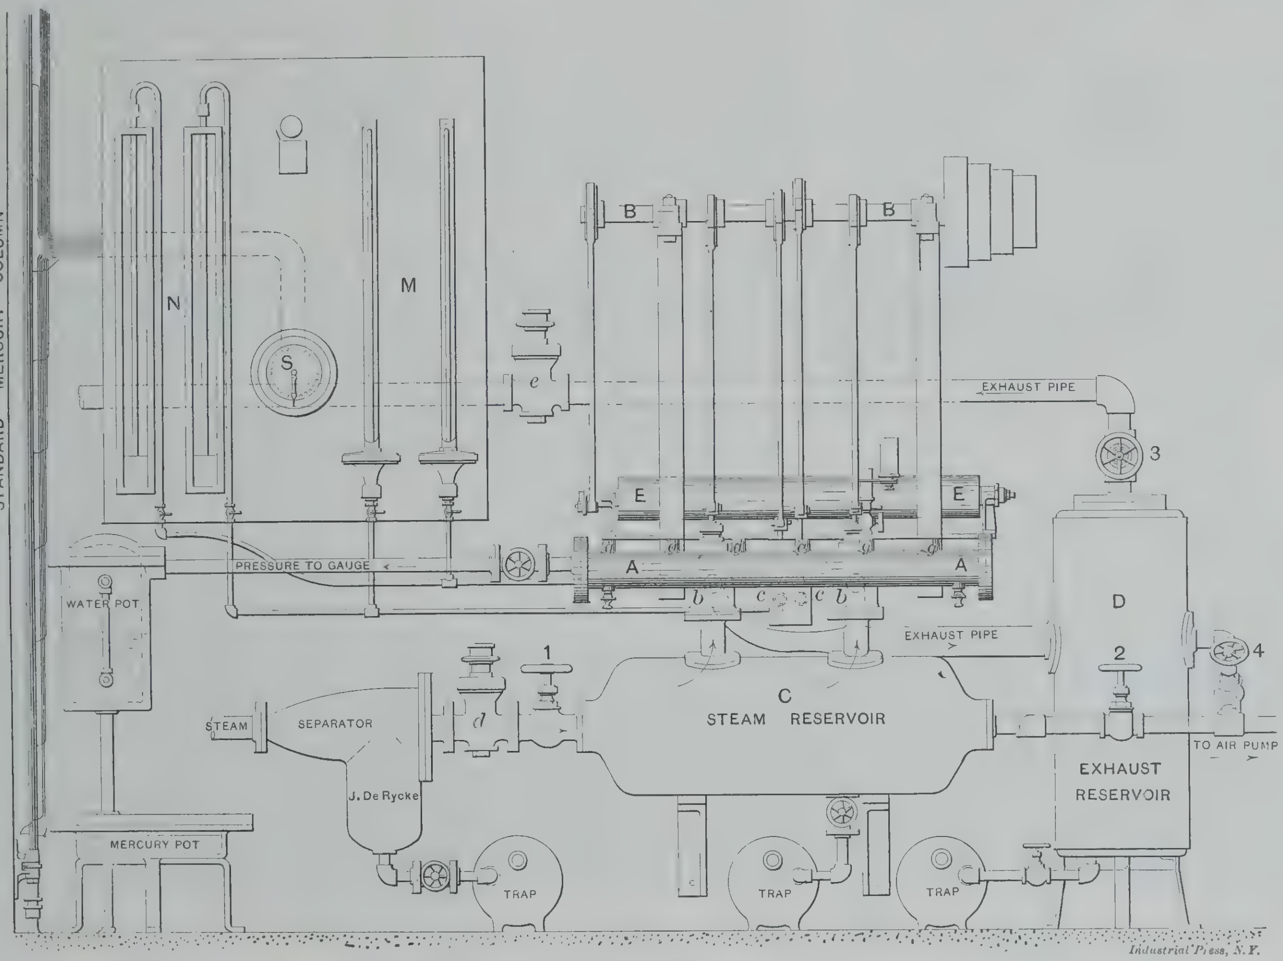

Fig. 2. Diagram of New York Navy Yard Indicator Spring Testing Apparatus.

Vacuum Tests.

Should it be desired to test a spring at pressures below atmospheric pressure only, the steam line being below the atmospheric line, it is possible to do so by two different methods. It will be noted that the steam reservoir can be connected directly to the air pump by valve 2 and can be opened to steam pressure by valve 1. The exhaust reservoir can be connected to the air pump by valve 4 and can be opened to atmospheric pressure by valve 3. When making vacuum tests, therefore, the pressure can be so regulated that either the steam or the exhaust reservoir can be used for the higher pressure, the other one serving for the lower pressure. Thus by opening valve 1 slightly and throttling at valve 2, the pressure can be maintained in the steam reservoir at any desired amount below atmospheric pressure, this being used when tracing the upper line of the diagram. The exhaust reservoir would then be opened to the air pump, valve 3 being closed.

The other method would be to open valve 3 and throttle at valve 4, giving a pressure in the exhaust reservoir slightly less than atmospheric pressure; and to close valve 1 and open wide valve 2, which would give the air pump pressure, or the complete vacuum in the steam reservoir. By either of these methods diagrams similar to the three lower ones in Fig. 3 would be traced.

When making vacuum tests the vacuum gages at *N* are used, instead of the mercury columns at *M*. The vacuum gages were made by the Hohmann & Mauer Co., Rochester, N. Y. The mercury columns *M* were made by the Quimby Steam Engineering Co., Philadelphia, and are of novel design. While they are capable of measuring pressures up to 300 pounds the total rise of the mercury is only 36 inches for 300 pounds pressure, this short rise being accomplished by means of an arrangement for compounding pressures, in the base of the column.

Details of Construction.

In Figs. 5 and 6 are shown sections through the valves and valve chambers, which admit steam to and exhaust it from the manifold cylinder and which connect the latter with the pressure and vacuum gages. Fig. 5 shows the valve for admitting steam to the gages. It is a hollow piston valve having holes at *a* and *b* which, when they come opposite holes *A* and *B* in the casing, allow steam to flow through. It will be understood that the manifold cylinder is represented in section at *C*. In Fig. 6 the manifold cylinder is also shown at *C* and the piston valve indicated allows steam to enter from the bottom in the direction of the arrow and to pass out from the cylinder through the upper port into the exhaust passage *E*. It will be noted that the valve is balanced.

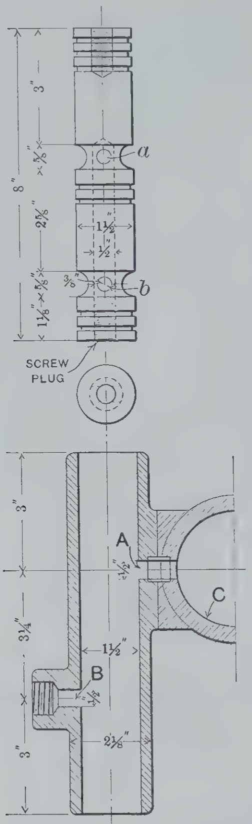

Fig. 5.

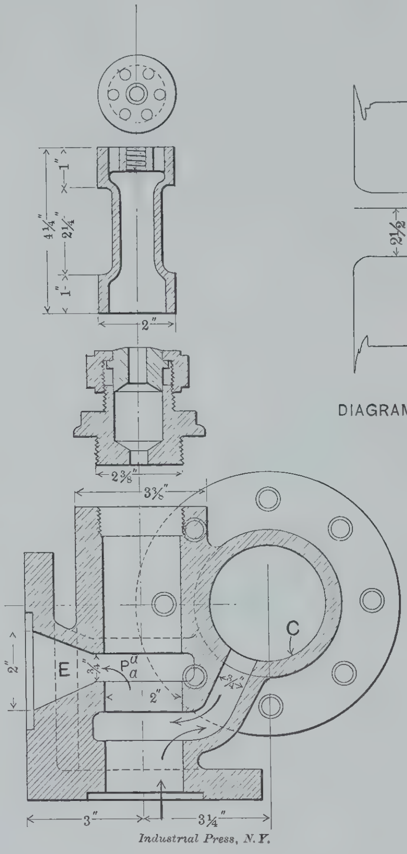

Industrial Press, N.Y.

Fig. 6

Details of the drum to which the indicator strings are attached for giving motion to the indicator drums are shown in Fig. 7. It will be evident that for the purpose of testing springs it is not necessary to trace a long diagram, one an inch long serving every purpose that would be accomplished by having a card four or five inches long. It was a matter of convenience, therefore, to provide for adjusting the positions of the indicator drums when taking cards, so that two or three diagrams can be traced side by side on the same piece of paper, as in Fig. 3. To accomplish this the drum is made so that it can be rotated a slight amount by hand, independently of its connection with the eccentric, the effect of this adjustment being the same that would be accomplished by lengthening or shortening the strings of the indicators. The mechanism for making this adjustment is shown in Fig. 7. The hub *H* of the drum is hollow and in making this angular adjustment it rotates upon tube *B*. When the drum is oscillated by the eccentric, however, the tube and drum turn as one piece, being locked together by the pin *P*. To accommodate the pin there are two diagonally opposite spiral slots in the hub of the drum and two straight axial slots in the tube. The pin is carried by a cylindrical piece *C* which can be moved endwise by a crank or handwheel on the end of screw *S* in the lower view, Fig. 7. Inasmuch as the pin is constrained to move in a straight line longitudinally with the drum by means of the straight slots in the tube *B*, the drum must turn one way or the other through the influence of its spiral slots. A complete sectional view of the drum appears in Fig. 8, showing the lever attached to the tube or hollow shaft at the left, through which the drum is oscillated by means of its eccentric.

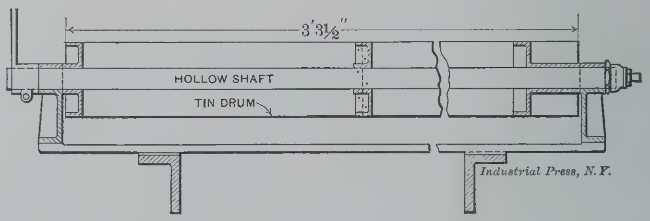
Static Tests.

The original Navy Yard apparatus was for testing springs under static pressure only. This is the method that is still used, pending more complete tests with the dynamic apparatus above described, provision being made for this. The standard mercury column is shown at the extreme left in Fig. 2 and is used not only for testing springs but for standardizing gages and the smaller columns used with the dynamic tester. When testing under static pressure the connection between drum *E* and its eccentric is broken. The indicator strings are attached to the drum and the latter is turned and set by hand in such a position that the different indicator drums will have been rotated slightly. An electrical device is shortly to be added whereby the main drum *EE* can be released, allowing the indicator drums to fly back to their original positions through the action of their own



Industrial Press, N.Y.

Fig. 8. Sectional View of Drum.

springs, and the indicator pencils to be applied to the paper simultaneously, which will trace a mark about $\frac{3}{8}$ inch long. This part of the apparatus has not yet been completed.

This electrical connection will be made automatically through the mercury column at 5-pound intervals, the switch *S*, Fig. 2, being used for the purpose. The column is connected by wires with the switch, and as the mercury rises, contact will be made when it reaches the point corresponding to that at which the switch is set. By moving the switch point by point, and increasing the pressure under the mercury column, a spring may be tested at 5-pound intervals throughout its whole range. The method of varying the height of the column of mercury will be evident from Fig. 2. Steam is admitted from the manifold cylinder *A* to the water pot, forcing water down into the mercury pot and in turn forcing mercury into the column. When testing springs under vacuum by the static method the vacuum gages *M* are used, the same as when making the dynamic tests.

* * *

RE THE METRIC SYSTEM.

A recent news item states that a printing ink factory of mammoth proportions will soon be built near Paris, France, by Cincinnati, Ohio, capitalists. The building is to be of peculiar fireproof construction. Fireproof brick will encase the steel frame, and the doors and outside window shutters will be constructed of steel with layers of asbestos in the center. Then follows a remarkable statement by the president of the company to the effect that although the plans have been drawn in Cincinnati, they will have to be redrawn by a French draftsman as the drawings in France must be made to metric measurements. While we are not prepared to dispute that the drawings may have to be redrawn in France to conform to certain requirements of the French building laws, we certainly shall challenge the implication that the Cincinnati draftsmen cannot make them on account of the metric measurements. In fact, the chief contention of the advocates of the metric system is that it is particularly well adapted for drafting room use. While it is generally admitted that it is not as convenient for constructive work in the shop as a system divisible by four, it is assumed that for draftsmen and designers, who have calculations to make, the decimal system is much to be preferred.

THE "HERCULES" FLOATING CRANE AT THE NEW YORK NAVY YARD.

A floating crane of gigantic proportions has been completed by the Brown Hoisting Machinery Co., Cleveland, O., for the New York Navy Yard, which will be used in the construction of the battleship Connecticut as well as in the repair work that is being constantly done. The illustration shows the crane moored at a dock in the Navy Yard, just as it was lifting a test weight of 115 tons, consisting of heavy engine shafts, etc. The crane is supported upon a steel pontoon 100 feet long, 60 feet wide and 11 feet deep. The runway on which the trolley travels is over 200 feet long, projecting at either end about 50 feet. The cables are of sufficient length to enable the crane hooks to be lowered to a depth of 20 feet below the water level, and the structure is tall enough so that they can be raised to a height of 65 feet above the water.

The pontoon is divided into three main longitudinal compartments. On one side are the boilers, on the other side the steam capstans and in the center is a counterweight weighing 250 tons. In floating cranes it has generally been customary to keep the pontoon level and the crane in an upright position by filling or emptying large water tanks placed at either end when heavy weights were to be lifted. In this crane, however, the very novel plan is adopted of a moving counterweight, shown in Fig. 2, which travels on four tracks. The counterweight is moved backwards and forwards by a cable under the control of a steam engine, which operates automatically through the action of a float in a water tank in which the level of the water is governed by the inclination or depression of the pontoon. Assuming a heavy weight to be hoisted at one end of the runway, that end of the pontoon will depress, causing the water to flow into the tank, raise the float—which opens the throttle valve—and start the engine connected with the counterweight. The latter travels towards the other end of the pontoon until the balance is restored, when the position of the float changes and the engine stops. Should the weight being lifted be racked along the runway, the counterweight would move continuously, keeping the pontoon in balance.

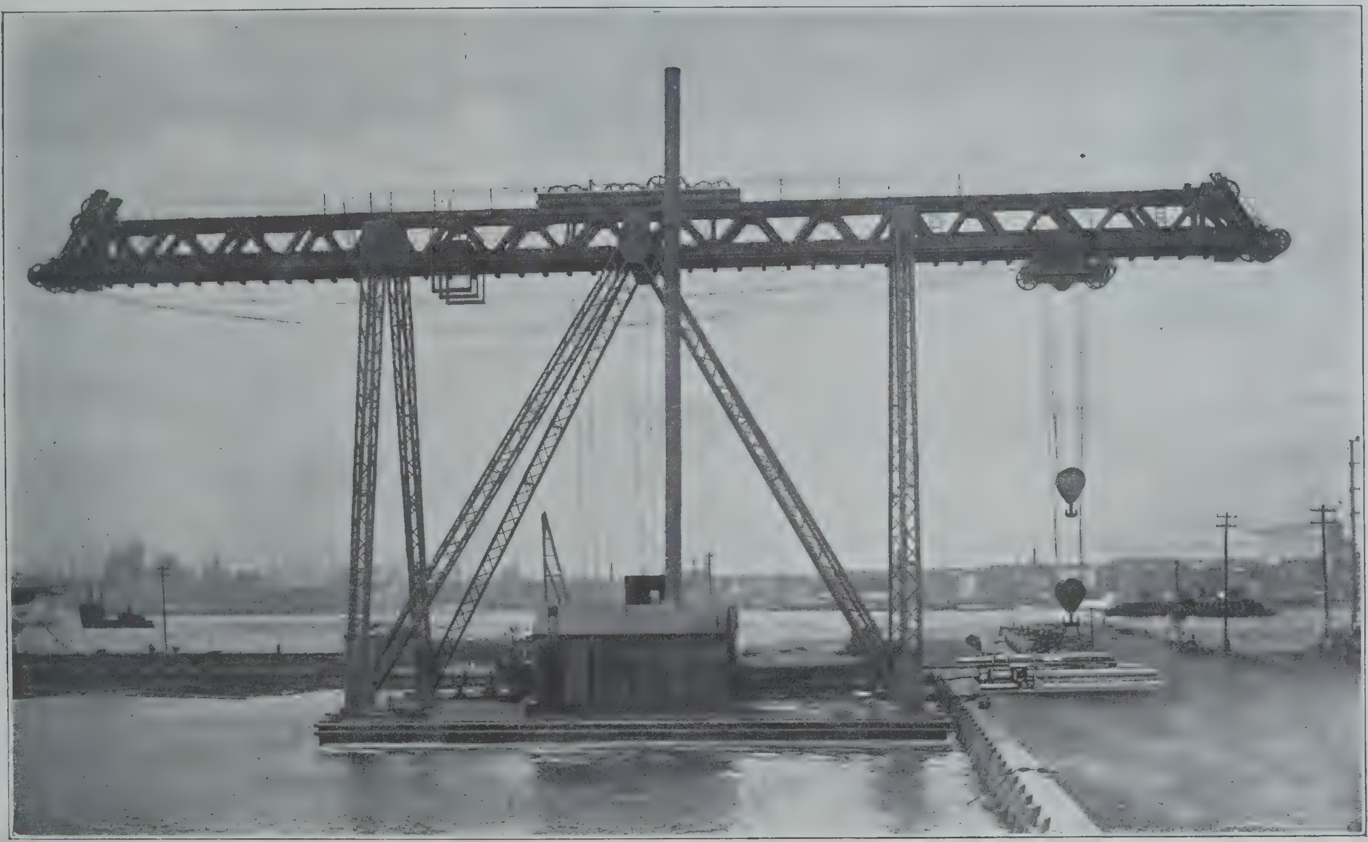


Fig. 1. "Hercules" Floating Crane at the New York Navy Yard, Lifting a Weight of 115 Tons.

As a matter of safety, should its cable break, it is necessary to have some device to keep the counterweight from going too far in either direction. The effect of turning a 250-ton weight loose in the hold of a pontoon can better be imagined than described. In Fig. 2 there is a shaft *S*, having an upper arm at *A* to which one end of the cable is attached. Should the cable break, arm *A* would be released, allowing the shaft to rotate and the shoes *B B* to drop upon the tracks, blocking the wheels against further motion. As a final precaution however, there are several spring buffers at each end of the pontoon, to assist in absorbing the shock, in case the counterweight should break away.

The hoisting apparatus is operated by four steam capstans, one for hoisting each crane hook and two for racking the trolley along the runway. The engines are geared to an intermediate driving shaft which in turn drives the different capstans through steam-operated friction clutches. These place the powerful mechanism within easy control of the operator and make quick handling possible. A pair of cables is used for each crane hook; that is, the tackle blocks and sheaves are all double, with two complete sets. The rated capacity of the crane is 100 gross tons, but it can easily handle a larger weight at the extreme ends of the arms, while at or near the center of the pontoon it can hoist a still greater weight.

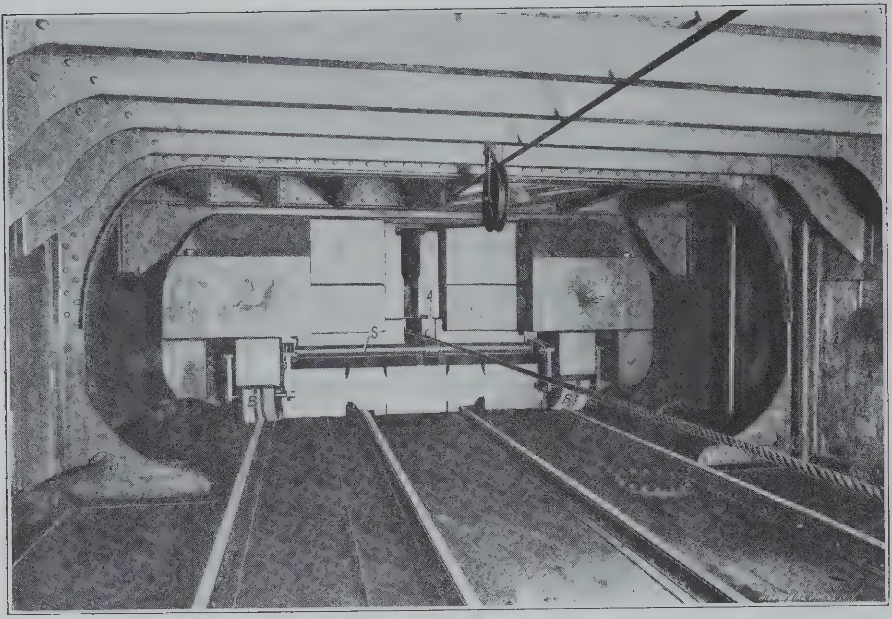

Fig. 2. Counterweight in Hull of Crane, weighing 250 Tons.

* * *

The pitting of discharge nozzles working under high heads, also the tips of cast iron propeller blades, is attributed by W. S. Smith in the *Journal of Electricity, Power and Gas* to the liberation of oxygen in a semi-nascent state because of reduced pressure. When air is absorbed by water the air and water become a solution instead of a mechanical mixture. When the pressure on the water is reduced the air separates in a condition to readily attack cast iron surfaces. Now it is well-known that unless a discharge nozzle is properly designed there will be portions of it not conforming to the natural stream lines. These portions will be areas of reduced pressure and here the pitting will occur. The same condition holds with the tips of propeller blades. The pitting is greatest at the tips where the disturbance of the water is greatest and the areas of reduced pressure exist. This seems to be a more reasonable explanation than attributing it to galvanic action. If galvanic action is the cause of propeller pitting it should consistently attack the whole surface instead of a limited area near the outer ends. To prevent the pitting of discharge nozzles Mr. Smith advises that they be carefully laid out to conform to the natural stream lines for the velocity at which they are expected to work. If the velocity is variable the nozzle should be designed for the highest velocity, since a nozzle that fills then, will continue to fill when the velocity is reduced. In regard to the construction, the writer of the article advises that the straight section of discharge nozzles be bushed with some processed metal on account of the difficulty of getting perfect iron castings.

STEAM ENGINE ECONOMY.

NOTES ON THE STEAM CONSUMPTION OF DIFFERENT TYPES OF ENGINES.

In 1858, Chief Engineer Isherwood, U. S. N., published his well-known volume, "Engineering Precedents," in which he gave the results of various tests that he had conducted upon steam machinery. His work was the beginning of what may be called experimental engineering, and for several years he was almost alone in the engineering profession in attaching greater importance to the results of the actual trials of steam engines and boilers than to the deductions of theory. In 1859, one year later, Prof. Rankine's classical treatise upon the steam engine was issued. This is one of the most complete and able works that has ever been written and is in extended use to-day, but his results are derived entirely from theoretical and ideal considerations. He only alludes very briefly to the actual interchange of heat between the cylinder and steam that occurs in the real engine, and the difference between the steam consumption of an engine determined by his formulas and by a feed-water test is very great.

Since this period, forty years ago, there have been many experimenters, notably through the efforts of the various colleges which have established engineering laboratories. The first of these was founded at the Massachusetts Institute of Technology, Boston, in 1875, where a Harris-Corliss engine was set up for experimental purposes. Of late years it has come to be the proper thing to have an economy test of all important plants, and there is now a great quantity of available information upon the subject of steam consumption. There is such a variety of information to be found that an experienced engineer can usually judge from it what the performance of an engine will be under varying conditions. This information has been published in the proceedings of the various societies, in technical papers and elsewhere, and much of it has been collected and arranged for ready reference in several of the later books upon the steam engine, such as "Peabody's Thermodynamics" and "Barrus' Engine Tests," published in this country, and the treatises by Ripper, Ewing and Perry in Great Britain.

Why Theory and Practice Differ.

As hinted above, the chief reason why the calculated steam consumption of the ideal engine falls far below the actual consumption of the real engine is because of the interchange of heat between the steam and the metal in the cylinder.

Saturated steam or steam as it is ordinarily supplied by a steam boiler, is at the critical point. If it comes in contact with a body colder than itself, part of the steam will condense; or if it comes in contact with a body at a higher temperature than itself, heat will be given to the steam by that body and any moisture present in the steam will be evaporated wholly or in part.

When the admission valve of a steam engine opens, the steam passes over the cooler surfaces of the ports and passages, and impinges against the cylinder heads, piston, etc. A large part of the steam is thus condensed, sometimes 50 per cent. or more, and usually 30 per cent., forming water before the point of cut-off is reached. After the point of cut-off the steam begins to expand, and condensation may possibly continue for a short time, through contact with the cylinder walls; but the action is reversed and the water begins to evaporate again as soon as the steam expands to a temperature lower than the temperature of the metal of the cylinder. This re-evaporation may be nearly or quite enough to change back into steam all the water that was formed by contact with the cylinder walls during the first part of the stroke, but there is, nevertheless, nearly always a great deal of water present in the steam at the point of release. This comes from the fact that when steam expands and its latent heat is converted into mechanical work, part of the steam condenses and adds to the water formed by the contact of the steam with the cylinder walls. About 20 per cent. of the steam present at cut-off would ordinarily be converted into moisture by this means. The final result is that when the exhaust valve opens the steam contains from 15 to 30 per cent. of moisture.

During exhaust this water is nearly or entirely evaporated and heat is abstracted from the cylinder walls in the process. When the exhaust valve closes, part of the exhaust steam is encased and is compressed in the clearance space so that this space does not have to be filled by the entering steam at admission. During compression the temperature and pressure of the encased steam rise and the surfaces of the cylinder head, piston, steam passages, and more or less of the circumferential surface of the cylinder become heated, which tends to reduce the initial condensation of the steam during the next stroke. If this heating effect were complete, it would effectually prevent condensation of the entering steam, but, as a matter of fact, there is never enough heat transferred from the compressed steam to the metallic walls of the clearance space to accomplish this result.

The actions just outlined are the chief reasons for the difference between the calculated water consumption of an ideal engine and the actual consumption of a real engine, and all of the effective means that have been employed to improve the economy of the steam engine have been to reduce the evil effects of cylinder condensation and re-evaporation.

Tables of Steam Consumption.

The accompanying tables show the actual steam consumption of different engines and pumps operating under different conditions. The last columns of the tables show the source from which the figures were obtained. They are all from records of tests and will be convenient for reference. It was not the purpose to select record-breaking results in making up the tables, but rather to indicate what may reasonably be expected from similar engines under good conditions. In comparing results with a table of this kind, however, it must be remembered that while an engine may run with a small steam consumption when it is in good condition and the various adjustments, the load, steam pressure, etc., are all favorable—such as is usually the case when a test is made—under other conditions this same engine may use steam extravagantly. We will therefore consider some of the most important things that affect the steam consumption, either for better or for worse. Of first importance, of course, is the condition of the engine as regards repair, adjustment, etc. The piston and valves must be tight, the valves properly set, there should be arrangements for draining water from the cylinder, and the full boiler pressure should be realized in the cylinder, as nearly as possible.

Design of the Engine.

The steam consumption to be expected will depend very largely upon the design of the engine. Generally speaking, an engine with small clearance spaces is supposed to be more economical than one with large clearance, and while this may be true, it is not so much the clearance *spaces* as it is the clearance *surfaces* that affect the economy. If there is a large amount of cooling surface for the steam to come in contact with when it enters the cylinder, there will be a great deal of condensation and more steam will be required. If, however, the valves should set close to the ends of the cylinder, as in the Corliss engine, reducing the surfaces of the ports and passages, and leaving only the cylinder heads and piston and a small section of the cylinder walls to condense the steam, we should expect good economy, even if the clearance was considerable. Such a condition might exist if the piston did not travel the full length of the stroke, leaving quite a clearance space at each end, but still exposing quite a comparatively small extent of clearance surface.

The single valve automatic engine, while simple and compact, loses a little in economy, because of the long ports and of the fact that the cool exhaust steam must pass through the same passages and the same valve through which the hot steam enters. The single valve, also, does not give as good steam distribution as when two or four valves are employed, with two eccentrics. The main characteristic of the single valve is, that the earlier in the stroke it cuts off the steam, the greater will be the compression, and at very early cut-off the compression becomes excessive, so that it is possible to run the engine at this point and thus realize the full benefits of the expansion of steam. The compression, however, warms up the clearance surfaces and so is not a bad feature for this type of engine.

Expansive Use of Steam.

The most important principle in steam engine economy is that steam must be used expansively. If the greatest possible power is to be developed for a given expenditure of steam and coal, the supply of steam must be cut off from a steam engine cylinder at some point before the end of the stroke, and the steam allowed to do its work during the balance of the stroke by virtue of its expansive force, due to its latent heat.

In the direct-acting steam pump the expansive force of the steam is not utilized, and the wastefulness of such pumps is clearly shown in the second table. In a pump the steam is admitted to the steam cylinder at the beginning of the stroke and continues to act against the piston at full boiler pressure until it is cut off from the cylinder at the end of the stroke. At that point the exhaust valve opens, and the steam which fills the entire cylinder, and is at boiler pressure, is blown out into the atmosphere.

In the case of the steam engine, the steam is allowed to expand to a pressure at or near atmospheric pressure before it is discharged to the atmosphere. If it be supposed that it expanded to four times its original volume, the cut-off taking place at ¼ stroke, there would be only one-quarter as much steam used per stroke as in the case of the steam pump, supposing the two cylinders to be of the same size. It can be shown by comparing the theoretical indicator cards for the two cases, that the power developed by the engine would be about one-half the power of the pump. In other words, the pump would develop double the power, but with four times the steam. This affords a crude illustration of the fact that steam economy depends in a large measure upon using the steam expansively.

No rules can be given telling how far to carry the expansion, in any case. It is generally considered that the best results, with simple non-condensing engines, are obtained when the cut-off is at about one-third stroke; and with simple condensing engines, with the cut-off at from one-sixth to one-quarter stroke. Varying degrees of expansion are used with compound engines, the point of cut-off in the high-pressure cylinder being adjusted to give from 12 to 20 expansions in both cylinders.

Variation in the Point of Cut-off.

It is not economical to operate an engine when it is overloaded, or, on the other hand, when it is too large for the work it has to do, because the point of cut-off will come either too late or too early in the stroke for the economical use of the steam. If too early, there will be an increased loss from cylinder condensation, and if too late, the expansion of the steam will not be so complete as it should be. When an engine is running under these conditions it is better, if possible, to change the steam pressure or else the speed of the engine so as to allow the point of cut-off to be more nearly at its correct position.

The extent of the losses due to a variation in the point of cut-off is shown by the results of tests made by George H. Barrus and recorded by him in his "Engine Tests." Tests were made upon Corliss engines of medium or large size and he found that the amount of condensation and leakage, taken together up to the point of cut-off, was 60 per cent. of the steam consumed when the cut-off wat at 5 per cent. of the stroke; 45 per cent. with the cut-off at 10 per cent. of the stroke; 35 per cent. with the cut-off at 15 per cent. of the stroke; 30 per cent. with the cut-off at 20 per cent.; 20 per cent. with the cut-off at 30 per cent., and 15 per cent. with the cut-off at 40 per cent.

While the percentage of losses from these sources is thus found to decrease as the point of cut-off grows later, the total condensation may be as much, or more, with a late cut-off as with an early cut-off, owing to the larger quantity of steam used when the cut-off is late in the stroke. Of the two, it is better to operate an engine with too heavy a load than with too light a load, as far as the consumption of steam is concerned.

Running Condensing.

The safest and surest way of improving the operation of an ~~overloaded~~ engine is to add a condenser. The gain in economy resulting from the use of a condenser may be assumed to be from 20 to 25 per cent. when account is taken of the steam consumption of the engine only. When measured by the quantity of coal burned under the boiler the gain will be less than this, because it is not possible to heat the feed water to so high a temperature by means of the exhaust steam when a condenser is used as when the engine is running non-condensing.

Speed of an Engine.

It has been demonstrated by experiment that when the ~~rotative~~ speed of an engine is increased, the quantity of steam used per horse power per hour will decrease. This is because there is less time for the transfer of heat between the cylinder walls and the steam and also for the loss of heat through radiation. Tests made upon a Willans non-condensing engine, with steam at 90 pounds pressure, show a decrease in steam consumption of from 27 to 24 pounds as the speed increased from 122 to 400 revolutions. A great many tests of a similar character have been made ~~by Mr. Willans~~ confirming these figures. The fact that many high-speed engines are not as economical as engines of slower speed, is no indication of the effect of speed on economy. The losses in high-speed engines are due to other causes and would be greater were the engines to run at slower speed.

High-pressure Steam and Compounding.

Both theory and practice show that increased economy in the use of steam can be obtained by using higher steam pressures. This is because there is more heat in high-pressure steam available for doing work, in proportion to the amount of heat required to generate the steam, than is the case with low-pressure steam. Also there is a smaller percentage of the steam used in doing useless work. Part of the power of an engine is absorbed in overcoming friction and in moving the piston against the atmospheric pressure of 14.7 pounds. These two factors are constant quantities, being practically the same, whether the engine is developing a large or small amount of work. With high-pressure steam, therefore, a smaller percentage of the total pressure is required to do this useless work.

There is no gain, however, in using extremely high-pressure steam in a single cylinder engine, because of the loss from condensation due to the extreme ranges of temperature that would result. When very high pressures are to be used, compounding must be resorted to in order to keep the temperature ranges in each cylinder within reasonable limits.

In Peabody's "Thermodynamics" is the following statement of the steam pressures that may be used with good results and also of the gain that may be expected from compounding, which latter allows the use of higher pressures:

"For a simple non-condensing engine the steam pressure may be 100 to 115 pounds above the atmosphere, and for a compound engine the pressure may be 150 pounds, while for a triple engine the pressure may be 175 pounds or possibly somewhat more. The gain from compounding will be 20 to 30 per cent., and the gain from using a triple instead of a compound engine will be 5 per cent., or perhaps a little more. For simple condensing engines there is no advantage in using more than 80 pounds steam pressure, while compound condensing engines may advantageously have the pressure raised to 135 pounds above the atmosphere. The gain from higher steam pressure and compounding will be 25 to 30 per cent. The best pressure for triple engines cannot now be determined from experiments; it is, however, doubtful if there is any advantage in using more than 175 pounds above the atmosphere. Such a further increase of pressure and the use of a triple instead of a compound engine may be expected to give 8 or 10 per cent. better economy."

The above explanation and comments are intended to give a general idea of some of the principles of steam engine economy. The fact that the steam consumption of an engine is affected by the clearance surfaces, the speed, the pressure of the steam, etc., shows that no table can be given which will be an absolute guide in determining what the steam consumption of an engine should be. In this, as in nearly everything else, experience and study alone can help one in arriving at correct conclusions. There are various other expedients used to improve the economy of steam engines, such as steam jackets, re-heating receivers, superheating the steam, etc. Of these the latter is probably the most important and during the next few years will probably be introduced in many of our best steam plants. The results obtained will be awaited with much interest.

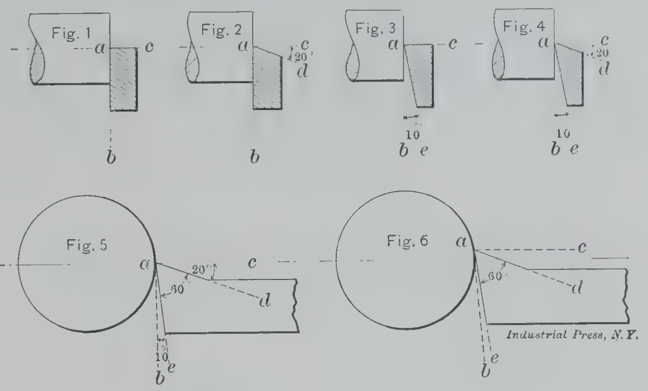
* * *

THE ELEMENTS OF CUTTING TOOL ACTION.

Sketch No. 1 represents an end view of a piece of tool steel cut from a bar and applied to the work. The left face of the tool coincides with the end of the cylinder on the line *a—b*, and it is evident that no amount of pressure in the direction *c—a* will make the tool cut. If the top face of the tool is cut down so as to present the angle *d—a—c* (sketch No. 2), the left face remaining the same as before, the conditions then obtained still exist and the tool will not cut. If, on the other hand, we cut away the left face so as to present the angle *b—a—c* (sketch No. 3), it hardly needs demonstration to show that although the tool will not cut cleanly, it can be made to remove metal by a scraping action.

By cutting away the tool on both the top and left faces, we present to the work a shape shown in sketch No. 4; and it is clear that our tool will not only cut, but will do it in a manner somewhat similar to the action of a knife in a piece of wood.

As a result of the above experiments, it is demonstrated that cutting away the face adjacent is absolutely essential, and the more the top face can be beveled down, the easier will be the cutting action. From this we conclude that the angle *b—a—c* should not be greater than is necessary to allow the tool to enter the work; so the angle *d—a—c* can be made as large as is possible without a dangerous reduction of the edge of the tool. Practical work shows that the greater the angle *d—a—c*, the larger will be the spiral into which the chip is rolled, showing less bending of the chip after cutting than would be the case with a smaller angle. Experiment has shown that more power is consumed in bending the chip than in the actual cutting; therefore, the greater the angle *d—a—c*, the less the power consumed, and owing to the clean cutting, the better the surface produced. The angle below the tool, *b—a—e*, I call the angle of clearance; the angle above the tool, *d—a—c*, the angle of rake; the angle *d—a—e*, the solid or cutting angle.



Industrial Press, N. Y.

Elements of Cutting Tool Action.

It will be noticed that the line *a——c* is normal to the work surface at the cutting point, and is at right angles to *a——b*; therefore the sum of the three angles is always 90 degrees. The angle of clearance should be a minimum and not exceed 10 degrees; the angle of rake should be a maximum and not less than 20 degrees; the solid or cutting angle, with the rake and clearance values given above, would be 60 degrees. These values are approximate only, and are varied to suit the metal being cut, the grade of steel in the tool, and the speed of cutting.

In Fig. 5 the tool is in operation on a surface of revolution instead of on a flat surface, but when set so as to advance along a line passing through the axis of rotation the action is the same as when the tool is applied to a flat surface.

Any change in setting will change the values of the rake and clearance angles only, as it is evident the solid or cutting angle cannot be changed by moving the tool. In Fig. 6 can be seen the effect of setting a tool too high. The tool and work are the same as in Fig. 5, but, by setting the tool above the center, the angle of clearance is decreased and that of rake correspondingly increased. In this position the tool will cut, but as the tool advances the angle of clearance is lessened until the line *a——b* coincides with the face *a——e* of the tool, when clearance disappears and the tool ceases to cut.

Setting the tool below the center will result in increased clearance and decreased rake. Advancing the tool will increase the angle of clearance, thereby weakening the tool, and will decrease the angle of rake, changing the cutting action to scraping and finally to rubbing, when the tool will cease to remove metal.

The diamond point tool has the rake of the side tool combined with that of the round nosed tool, or, in more technical terms, it has side rake and front rake. When used for roughing cuts, it should have more side rake than front rake, but when used for finishing, the reverse is true, as there is little metal to be removed and the chip is bent less by allowing it to come well to the front.—*From paper read by F. W. Turner before the N. E. Asso. of Teachers of Metal Work.*

* * *

Work has been begun upon the construction of a steel road way on Murray Street, New York City, which will extend from Church St. to Broadway. This road is made of two parallel lines of 12-inch by 3½-inch steel channels laid, flange downward, 5′ 6″ apart, c. to c., on a bed of broken stone. The web of these channels, which in this case forms the top, has on each edge a slight rounding flange to keep the wheels of the vehicles on the tracks.

SPECIFICATIONS FOR ELECTRIC MOTORS FOR OPERATING NAVY YARD MACHINERY.

The Bureau of Construction and Repair of the U. S. Navy Department in January, 1902, issued the following specifications for electric motors for operating navy yard machinery. Some adverse criticism, we learn, has been directed against certain features, and we have been requested to publish the specifications for the benefit of machine tool builders and others having to do with electric motor equipment. We have submitted them to a number of the leading electrical manufacturing concerns, but so far have received no unfavorable comments. The Crocker Wheeler Co. commend them, saying that while they are closely drawn, as are all Government specifications, they require nothing more than can be met easily by the better class of electrical manufacturers. The Bullock Electric Manufacturing Co. merely suggested that the efficiencies should be determined according to the rule of the American Institute of Electrical Engineers:

1. Motors to be direct current of three types:
   (a) Open.
   (b) Semi-enclosed.
   (c) Enclosed.

(a) Open type motors may be of any desired design such that the brushes and commutator are readily accessible and all parts free to good ventilation.

(b) Semi-enclosed motors are to be of such design that all parts are completely protected from external mechanical injury, and all openings into the interior of the motor are to be covered with perforated metal or wire mesh covers arranged to secure the best possible ventilation and by their removal allow access to the commutator and brushes.

(c) Enclosed motors are to be entirely enclosed and dust-proof, but provided with removable covers to allow access to commutator and brushes.

Ordinary open type motors provided with separate housings will not be accepted as enclosed motors.

2. Armatures must be of the iron clad type and have form wound coils, easily removable for repair, except that motors of less than 7 H. P. may have hand wound armatures if desired.

3. Commutators must be of pure hard drawn or drop forged copper. Cast segments will not be accepted. Segments to be insulated with mica of such hardness as to wear even with the copper.

4. Brushes are to be of carbon and not to carry more than 35 amperes per square inch at full load. The brush holder springs shall not be depended upon to carry current. In motors of 5 H. P. and above, brush holders are to be separately adjustable for tension without tools, and simultaneously adjustable for position. In motors below 5 H. P. these adjustments are not required. Brush holders to be of such design that by very slight changes in the relative position of their parts the rotation of the armature may be in either direction with equal satisfaction; also the angle of the brush to the commutator not to change as the brush wears down.

5. Bearings to be lubricated by self-oiling rings; to have oil reservoirs of ample capacity provided with means for visually determining the amount of oil in same and with means for drawing off oil. Satisfactory means to be provided to prevent oil from running along the shaft on being spilled.

6. A name plate to be attached to the motor frame stamped with the rated H. P. volts, amperes and speed, and sufficient data to permanently identify the motor in the records of the manufacturer.

7. Di-electric strength of insulation is to be tested in accordance with the rules of the American Institute of Electrical Engineers.

8. Open motors must run from no load to full load; semi-enclosed motors from no load to 10 per cent. overload; and enclosed motors from no load to 25 per cent. overload, without sparking and without shifting the brushes. Motors to run at all rated loads and speeds without vibration and without undue noise.

9. Motors are to be tested at the works of the maker in the presence of an inspector and are to run for a continuous period of 6 hours at full rated load, speed and voltage, without the temperature rise above the surrounding air exceeding the following limits for the different types of motors:

Part.	Open Motors.	Semi-enclosed.	Entirely Enclosed
Field coils by resistance...........	50	55	55
Armature, commutator, and all other parts by thermometer...........	45	50	55

All rises are in centigrade degrees. The temperature rise of the field coils is to be measured by the resistance method according to the rules of the American Institute of Electrical Engineers. All other temperatures are to be measured by thermometer. Temperature rise of bearings in no case to exceed 40 degrees. Semi-enclosed and enclosed motors are to be run with all their covers on.

During the 6-hour heat run no adjustment of brushes, cleaning or dressing of commutator, or similar attentions are to be performed on the motor, but after being once put in proper running condition it must complete a satisfactory run without further attention.

10. Motors are to stand the following overloads:

Type.	Overload for One Hour.	Overload for Three Minutes.
Open	25 per cent.	40 per cent.
Semi-enclosed	35 per cent.	60 per cent.
Enclosed	50 per cent.	100 per cent.

The one-hour overload is to be run without injurious sparking, or heating of the commutator more than 15 deg. C. above the allowed rise for full load for 6 hours, and may be started with the motor cold if desired. The three-minute overload is to be run without injurious heating, or flashing over or burning of the commutator or brushes, and is to be made within 45 minutes of the end of the six-hour heat run.

11. The full load efficiencies of motors to be at least as follows:

H P.	Open.	Enclosed and Semi-enclosed
2	78 per cent.	75 per cent.
5	83 per cent.	80 per cent.
10	86 per cent.	84 per cent.
15	87 per cent.	85 per cent.
25	89 per cent.	87 per cent.
40	90 per cent.	88 per cent.

Intermediate sizes to have proportionate efficiencies. Efficiencies to be taken with motor hot at end of heat run.

12. Controlling panels, unless otherwise specified, to consist of an enameled slate panel containing the following:

Line switch and enclosed non-arcing fuses.
Starting rheostat with automatic no-voltage release.
Adjustable overload circuit breaker.

For motors above 10 H. P., a single pole circuit breaker of approved construction entirely separate from the starting arm is to be used. 10 H. P. and under, may, if desired by the contractor, have the circuit-breaking device constructed as an interlocking part of the starting mechanism, but having the arc rupturing parts entirely separate from the starting arm. In no case will an overload device which operates by short circuiting the no-voltage release magnet be accepted. On any panel a double pole circuit breaker having each side independent as regards closing, may be used, and the line switch omitted, at the option of the contractor.

The resistance coils are to be mounted on the back of the panel and are to be entirely enclosed and dust proof.

13. All material and workmanship to be of the best quality and any defect due to defective design, material or workmanship, which may develop during the first year after delivery, to be made good by and at the expense of the contractor.

14. Bidders are to state in their proposals the manufacture of the motors and controlling panels they propose to furnish, and are to submit drawings, prints, photographs, or other illustrations from which a clear idea may be obtained as to their general construction. If bidders can guarantee their machines to give in any particular a better performance than required by the specifications, such fact should be stated in the bid.

* * *

It is estimated that in the whole world more than 1,000,000 telegraphic messages are sent each day. The total length of the conducting wires would be sufficient to encircle the earth 150 times at the equator.

ENGINEERING REVIEW.

A SYNOPSIS OF CURRENT TECHNICAL LITERATURE.

APPLICATION OF EXPANSION TO RAILWAY WRECKING.

The Engineer, November 1, 1902. p. 730.

One of the most important things which must always be taken into consideration in engineering work is the expansion and contraction of materials under the action of heat. Who has not noticed the gap between the ends of the rails on a railway line? In winter these gaps will be over a quarter of an inch wide, while on a hot day in summer, they will be almost closed. During one of the wars in South America, one of the belligerents conceived a unique method of train-wrecking. During the night he drove steel wedges into these gaps for a considerable distance. The heat of the sun next day caused the rails to expand, and they twisted themselves clean out of the chairs which clamped them to the sleepers, and the railway was rendered completely useless for traffic.

SOME MACHINE DESIGN IDEAS BY PROF. SWEET.

American Machinist, November 6, 1902, p. 1586.

Regarding the development of the engine lathe as a machine tool, no one seemed to dare to make any radical improvements all at once. First it was "new pattern heavy lathe," then some one thought to make the main bearings larger and longer, and advertised the fact. The next man followed, doing the best thing he could by making it larger and the worst thing he could do, at the same time, by making it longer. In the next twenty-five, or it may be only ten years, someone will have the courage to make his lathe main bearing 6 inches big and 6 inches short.

When someone makes the milling machine with a spindle as large as the cutter it is to drive, and a gear in proportion, and a cutter supported close up to its sides; or a traversing machine for carrying end mills with a 12-inch spindle and a 12-inch inserted tooth cutter with blades made of 1½-inch steel, it will begin to look like the milling machine doing the work of the planer.

STEEL DRIVING WHEEL CENTERS CAST WITH SOLID RIMS.

American Engineer and Railroad Journal, November, 1902. p. 349.

The general practice in steel foundries, is to cast steel locomotive driving wheel centers with the rims cut in several places in the periphery to allow for contraction in the mold and shrinkage stresses. The ends of the rim sections are afterwards slotted out in the machine shop and wedges driven in, making the rim practically solid so far as resisting the compression of the tire. It is obvious, however, that it would be preferable to have steel centers cast with the rims entire; the wheel center would be stronger and machine work and fitting would be saved.

Mr. S. S. Prince, Jr., superintendent motive power of the P. & R. R.R. has designed a steel wheel center to be cast with uncut rims. To provide for the shrinkage of the casting in the mold, the spaces between the spokes are packed with sawdust, which offers an elastic resistance to the contracting forces. To make the molder's work simpler the pattern is made with the draft all in one direction, the draft being toward the outer face of the wheel center, so this side is molded downward.

METHOD OF TREATING BUFFINGS.

Aluminum World. 1902.

In many places where copper, brass, or nickel are buffed with cotton buffing wheels, it has been a problem to know what to do with the waste products which fly off. They were formerly thrown away, but in the present economical age are sources of some revenue. If allowed to remain in heaps they not only require a large amount of space, but the danger of spontaneous combustion is quite a serious one.

Erwin S. Sperry says that one manufacturer has solved the problem, as far as he himself is concerned, in a manner somewhat out of the beaten path. He is a brass manufacturer, and makes his brass in crucible furnaces. Every night after the furnaces have been dumped, the ashes removed, and the grate bars replaced, he fills the pot holes with buffings and allows the combustible matter to burn off. The fire brick walls of the furnaces usually remain red hot for some time after the fires have been dumped. This not only serves to ignite the buffings but aids the combustion as well. The ashes, consisting of the metal in a finely divided condition, and, of course, the products of combustion, drop down into the pit. They are compact, however, and can be put into barrels without any danger of spontaneous combustion. The ashes are valued according to their content of copper and are always a marketable product. A process of this kind for treating buffings is an excellent method and is very economical as it utilizes the waste heat of the furnaces.

ELECTRIC POWER IN ROLLING MILLS.

Western Electrician, November 1, 190, p. 307.

Electric motors are now used in many of the large rolling mills of Europe, where their operation has proved very successful. The Nordisk mills at Stockholm have been using electric power for some time past. Here a large plate-rolling mill and a smaller mill are both driven by the same motor. The large mill has a set of rolls 28 inches in diameter, with table lengths of four and six feet. In this case it was not found practicable to drive the rolls directly by motors, but instead a mechanical device is used for driving and reversing the movement, and a friction clutch gives a progressive movement and avoids shocks. The plant is driven by a direct-current motor of 350 horse power working at 320 revolutions per minute. The motor is belted by wire rope to a 30-ton flywheel, which runs at 150 revolutions. The flywheel is mounted on the main shaft, from which the two rolling mills and the mechanism of the tables are operated by gearing. A friction clutch is used to throw off the smaller mill and allow the larger to work alone. This plant has been running for some time past and this method has many advantages over the old one.

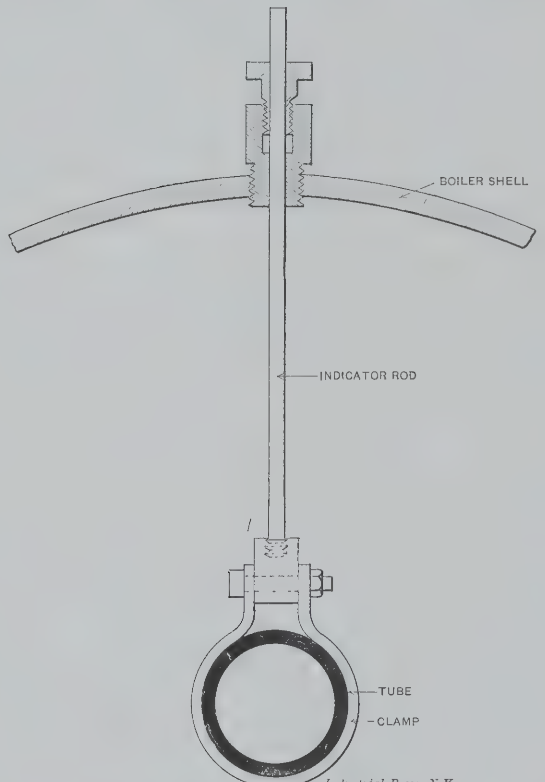
Another application of electric motors to operate steel-plate mills is found at the Antwerp Steel Works, where a plant has been lately installed. The current is furnished from the new central station erected by the Antwerp Electric Company near the city—a large plant which is to produce 25,000 horse power from blast-furnace gas. This company will furnish current for the different industries in and near Antwerp, and one of the first is the Antwerp Steel Works, for which are used two generating sets giving three-phase current. Westinghouse alternators are used here, giving 1,500 horse power each at 2,200 volts. At the steel works both high and low tension are used for the motors. A number of small motors drive different apparatus, such as traveling cranes, shears, small rolls, etc., and these all take current at 200 volts, which is fed from transformers. The large rolls, however, use the main current at 2,200 volts without transformation, employing non-synchronous motors which work at variable speed. One of the largest rolls, turning at 70 revolutions, and having a 30-ton flywheel, is operated by belt from a 325-horse power motor, and a second roll, the heaviest in the plant, has a 450-horse power motor. The two motors are lodged in the same cabin, placed between the two mills. The controlling apparatus is mounted on an elevated platform, where the operator has a view over the whole shop.

LONG BOILER TUBES DO NOT VIBRATE.

Locomotive Engineering, November, 1902, p. 484.

One of the objections urged against the use of long tubes in locomotive boilers, was that they would tend to vibrate when the engine is working, and thereby loosen themselves in the tube sheet. So when some of the fast Prairie type (2-6-2) passenger locomotives on the Lake Shore & Michigan Southern R. R. began to give trouble because of leaky tubes, it was suspected that it might be caused by the length of the tubes, which were 19 feet 6 inches long and 2¼ inches diameter. To determine the facts in the case, Mr. S. K. Dickerson, the master mechanic at Collinwood, O., made an experiment which will be of interest.

Acting under instructions, Mr. B. F. Kuhn, general foreman, made the experiment. One of the top tubes was selected and over its center a hole was drilled in the boiler shell, into which a plug with stuffing-box was screwed. The tube itself was tightly grasped by a band of iron ¾-inch wide by ⅛-inch thick, the ends of which were bolted together with a filler between, much as an air brake hose clip clamps the rubber to the nipple. Into the small filling piece was tapped the end of an iron rod, which passed out through the plug with the stuffing-box in the boiler shell. The end of the rod projected above the top of the stuffing box, about two inches, and when in normal position with steam on the engine, a gage was made to correspond with the top of the projecting rod. Any vibration or deflection of the tube, would therefore be at once visible in the altered height of the projecting rod end. The tube itself being 19 feet 6 inches long, had, of course, a slight normal deflection, due to its weight, but when the engine was working hard, the indicator rod was observed to sink down 3-16 inch, and to remain steadily in that position without vibration or tremor of any kind. As the engine was worked lighter, the indicator rod rose correspondingly, but in no case indicated any vibration of the tube in the boiler. When a stop was made at a station the indicator rod came up to normal. The stuffing box, all through the experiments, was adjusted loosely enough to leak steam so that the indicator rod could not possibly act as a stay or steady-rest for the tube. The tube did not vibrate, but it sagged down in the center the harder the engine was worked, and tended to straighten itself out when the engine was worked lighter or came to rest.



Industrial Press, N.Y.

Fig. 1. Test for Boiler Tube Vibration.

The explanation of this action which the Lake Shore people give is that the tube naturally sags slightly in the center on account of its weight, and when the engine worked hard, a greater quantity of heat passed into the tube in order to generate the larger volume of steam needed for climbing a grade or making up time, as the case may be. This greater amount of heat expanded the tube, and it being fixed at both ends and slightly sagged in the center, sagged still more, under the action of heat as indicated by the lowering of the top of the rod. They argue that had the tube been originally cambered, the indicator rod would have been pushed up when the engine was worked hard. They account for the tubes leaking by pointing to the greater work done by the tube in transmitting to the water the extra heat when the fire was forced, and the general "punishment" sustained by all tubes when heavy work is being done.

THE ADAPTABILITY OF THE TURBINE TO SUPERHEATED STEAM.

Detroit Meeting of the American Street Railway Association, October 8-10, 1902.

It is a clearly defined principle of thermodynamics that the greater the range between the initial and final temperatures of the working fluid employed in a heat motor, the greater its efficiency. That is in the equation $E = \frac{T_1 - T_2}{T_1}$, in which

E = efficiency,
T_1 = absolute initial temperature,
T_2 = absolute final temperature.

In the case of the steam engine the absolute initial temperature is the temperature of the steam at boiler pressure + 460 degrees, Fahrenheit scale. For a boiler pressure of 120 pounds gage this means a temperature of about $350 + 460 = 810$ degrees, or T_1. If the exhaust has a back pressure of, say 2 pounds gage, the final temperature is about $219 + 460 = 679$ degrees F., or T_2. Therefore $T_1 - T_2 \div T_1 = 810 - 679 \div 810 =$ 16.2 per cent. theoretical efficiency, nearly.

To secure a greater range of temperature in the steam engine without increasing the boiler pressure, it is necessary to superheat the steam; that is, to impart to it a greater temperature than it will acquire while in contact with the water from which it was evaporated. Superheated steam greatly increases steam engine economy for two reasons: The first is that the temperature range is increased, and the second is that the losses from internal condensation are reduced because superheated steam does not yield its heat so readily to the cylinder walls. But there are serious difficulties arising from the use of superheated steam in the reciprocating engine. It is difficult to find a lubricant that will stand the high temperature and at all times prevent abrasion of the working surfaces. The high temperature also tends to change the shape of the valves and thereby induce leakage. So in the superheated steam engine the two serious evils to be overcome are abrasion of the working surfaces and the leakage caused by badly fitting valves and pistons. It is quite evident that this evil rapidly increases with an increase of temperature and that there is soon reached a temperature above which it is not practicable to go. The superheated steam engines of the New York Edison plant use steam at a temperature of about 575 degrees, and while there are European engines that employ temperatures still higher, this may be regarded as about the practical limit.

With the steam turbine, however, the range of superheating is limited practically only by the limit of the superheater. There are no rubbing surfaces so that the matter of lubrication does not need to be considered, nor the effect of high temperature on closely fitted surfaces since they are not present in the steam turbine.

At the Detroit meeting of the American Street Railway Association a paper was read on the steam turbine, and in the discussion following, Mr. C. O. Mailloux of New York said in reference to the possibility of using superheated steam in the turbine:

"I have had occasion to design large plants in which I have seriously considered the question of using superheated steam, and found, much to my sorrow, that in many of the engines, as at present constructed, there is a limit to the temperature that can be allowed in high-pressure steam. When you reach very high temperatures lubrication becomes almost impossible. With a steam turbine, on the contrary, there is no limit to the temperature of superheating that you may attain. Its only limit is the melting point of the material of which the engine is made. I see no reason why you could not run a steam turbine at a point where it would be cherry red, and glow in the dark, if there was any advantage in it. Of course, we all know there is a great advantage in superheating steam."

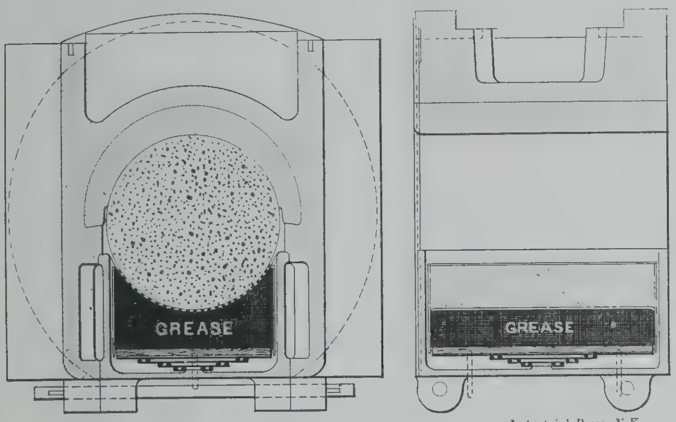
GREASE LUBRICATION OF LOCOMOTIVE DRIVING BOXES.

American Engineer and Railroad Journal, November, 1902. p. 356.

One of the most annoying and troublesome difficulties of railroad operation, and at the same time one of the most mysterious, is the occurrence of hot boxes. They are often produced by well known causes, and perhaps oftener by causes which are not known or understood. The latter are apparently not to be guarded against by usual methods. It is reasonable to suppose that a properly lubricated journal will not heat and that when one does heat it is because the surfaces for some reason become dry. Locomotive driving boxes present a difficult problem in this respect, and in spite of all that has been done to avoid it they often give trouble and sometimes with serious results. Many devices have been tried for relief and yet hot journals continue. There seems to be no sure way of lubricating driving boxes with oil to insure freedom from heating.

If grease can be substituted for oil in this case, applied at the bottom of the journal, with no openings at the top of the bearing, there is reason to hope that relief may be found.

Fourteen locomotives of the D. L. & W. R.R. have been equipped with hard grease lubricators for the driving axles, substantially as shown in Fig. 2. The principle is essentially the same as that of grease oil cups for ordinary bearings, but the application to locomotive driving axles is a decided novelty, and one that is a pronounced success. The grease is molded into cakes shaped to fit the cellars and with the upper surfaces concaved to fit the journals. The upper surface is faced with a perforated plate, through which the grease is forced by a spring bearing against a follower plate on the under side. This follower plate is made an easy fit in the cellar so the spring is free to press the grease cake against the wheel. An indicator pin is attached to the bottom of the follower and projects through the bottom of the box to show the amount of grease left of the cake. When the end of the indicator wire is flush with the bottom of the cellar, there is still ¾ inch of grease in the cake in the shallowest part.



Industrial Press, N. Y.

Fig. 2. Hard Grease Lubrication for Locomotive Driving Boxes.

As regards the economy of the innovation, one 4-wheel connected locomotive is quoted that has had an average of 9 pounds 8 ounces applied to each box, and, according to the consumption to date this amount should suffice for 50,000 miles with enough left for 10,000 miles which is the margin provided for safety. This means that the cost of the driving axle lubrication, is only 4.8 cents per 1,000 miles as against 58 cents for oil, and there have been no hot boxes. The same device has been applied to truck axles, and there seems to be no good reason why it cannot with equal profit be applied to car axles. This improvement in axle lubrication has been worked out under the direction of A. G. Elvin, master mechanic of the D. L. & W. R.R. shops at Scranton, Pa.

FLY-WHEEL AND BOILER EXPLOSIONS COMPARED.

Monthly Bulletin of the Fidelity and Casualty Co., November, 1902. P. 176.

The influences that bring about fly-wheel explosions are in some respects very similar to those that produce boiler explosions, says Wm. H. Boehm. In the case of boilers, steam exerts a radial force acting on the shell of the boiler, and whenever the steam pressure, either through accident or negligence, increases sufficiently, the radial force bursts the shell with great violence. In the case of fly-wheels, speed exerts a radial force acting on the rim of the wheel, and whenever the speed, either through accident or negligence, increases sufficiently, the radial force bursts the rim with great violence. In both cases the direction of the forces is the same, since they both act from the center toward the circumference. In the case of boilers steam exerts the radial force that produces an explosion. In the case of fly-wheels speed exerts the radial (centrifugal) force that produces an explosion. These influences are widely dissimilar in other respects.

In the case of boilers the force tending to burst the shell increases directly with the steam pressure. Doubling the steam pressure, for example, doubles the force acting on the shell. In the case of fly-wheels the force tending to burst the rim increases with the square of the speed. Doubling the speed, for example, quadruples the force acting on the rim. In the case of boilers their strength may be increased by increasing the thickness of the shell. If we double the thickness of the shell, for example, we double the strength of the boiler. In the case of fly-wheels increasing the thickness of the rim does not increase the strength of the wheel, because the weight thus added also increases the centrifugal force, leaving the wheel no stronger than before.

Fly-wheels are intended primarily to prevent sudden fluctuations of speed, although they usually carry a belt and thus serve as a driving wheel as well as a fly-wheel. Their capacity to regulate speed fluctuation depends upon their weight and speed. If, for example, we should double the speed of a wheel, we would require only half as much weight to secure equally efficient speed regulation. Inasmuch as the cost of a wheel depends directly upon its weight, it is common practice to run fly-wheels at the highest possible speed in order to save weight and economize in cost. What then is the highest speed at which fly-wheels may be run with safety? Evidently there is a danger limit for every wheel, regardless of the amount of material it contains. For wheels made in sections this limit depends upon the efficiency of the rim joints as well as upon the kind of material of which the wheel is made. For cast iron wheels as ordinarily constructed a rim speed of a mile a minute is the limit for safety. The following table is given stating the number of revolutions per minute for cast iron wheels, from one foot to thirty feet in diameter, at which the danger limit is reached.

Diameter of wheel in feet.	Danger limit, revolutions per minute.	Diameter of wheel in feet.	Danger limit, revolutions per minute.
1	1680	15½	108
1¼	1344	16	105

Table giving the number of Revolutions per minute at which the Rim Speed for Cast Iron Wheels reaches the Danger Limit of one mile per minute.

FAST STEAMERS FOR THE CUNARD LINE.

Scientific American, November 1, 1902, p. 286.

Plans have been submitted to various shipbuilding firms by the Cunard Steamship Co. for building two monster steamers to have a speed of 25 knots (28.8 miles) per hour. While it is not yet positively known, it is believed that these vessels will be 750 feet long, 75 feet beam and have engines of 50,000 horse power. It is not likely that the steam turbine will be seriously considered as it will be thought that too much is at stake to risk fitting two such costly vessels with a comparatively new type of prime mover. Hence it is probable that the great horse power of these ships will be developed in vertical, quadruple-expansion reciprocating engines; and the question which is now under consideration is whether this power shall be developed upon two or upon three shafts. If twin screws are used the proportions of propellers, shafting and engines would be enormous, since they would have to develop and carry probably not less than 25,000 to 27,000 horse power each. There is absolutely no precedent for such sizes and weights, the largest twin engines at present being those of the Deutschland, which, when the boilers have been steaming freely, have developed as high as 38,000 horse power, or 19,000 on each shaft. The new Kaiser Wilhelm II., it is true, is to have engines of 40,000 horse power, or 20,000 upon each shaft, and in actual service they are likely to develop as much as 44,000, or say 22,000 on a single shaft.

It is natural that the Cunard Company in its endeavor to keep down the sizes of the separate engines should turn to the triple-screw system of propulsion. By so doing each shaft would have to carry only 17,000 or 18,000 horse power, or less than is now carried in the case of the Deutschland. The objection to triple-screws is the very obvious one that the engine room staff would have to be greater for three engines than for two. But with this exception, it may be said that practically every other argument is favorable to the use of triple-screws. In the first place, judged from the all-important standpoint of safety of travel, there is less risk of total disablement in a triple than in a twin-screw ship. If one engine should be disabled only 33 per cent of the power is lost, and the ship still has 66 per cent with which to make port. The individual parts of the engine are much lighter, and hence it is easier to overhaul the engine in port, or, in the case of a breakdown, to make repairs at sea. Although it might seem at first that more of the ship's space will be taken up by three engine rooms than by two, the difference is not so great as might be supposed, inasmuch as the center engine would be located on the center line of the ship, astern of the wing propeller engines, and would occupy space in the least desirable portion of the ship from the standpoint of passenger accommodation. Admiral Melville, Chief of the Bureau of Steam Engineering of the U. S. Navy, is a strong advocate of the use of triple-screws, not merely for the navy, but for the large transatlantic steamships. Speaking on the important question of economy he has shown that in the case of the fast commerce destroyers Minneapolis and Columbia, which are fitted with triple-screws, there was a very decided economy realized by their use. Moreover, it is a significant fact that the French naval architects, who are among the best, if not the best in the world, and who are considered to have gone more deeply and thoroughly into the question of triple-screw propulsion than any other naval architects, appear to have adopted the triple-screw exclusively for all the large ships of the navy. They claim that, quite apart from their obvious military advantages, triple-screws show a very decided economy over twin screws. There is one other question which should be carefully considered in adopting twin-screw propulsion for transatlantic passenger ships, and that is the question of vibration, which has so much to do with the comfort of passengers. It is a well-known fact that in the largest high-speed passenger vessels, vibration is one of the most serious sources of discomfort. The effect of triple-screw propulsion in respect to vibration is a question which should receive a most thorough investigation. While speaking of vibration, one cannot but call to mind that the steam turbine, because of the absence of reciprocating parts, that is to say, of more or less unbalanced parts, is the ideal motor for passenger service. There is no question that the first transatlantic steamship that is fitted with a successful steam turbine will have a great advantage in this respect over high-powered boats driven by reciprocating engines. Broadly considered, it must be admitted that the success which has attended the installation of turbine units of great horse power in electrical plants foreshadows the day when the steam turbine will be exclusively used in transatlantic travel. We cannot but think that the Cunard Company should make a most exhaustive study of the existing high-powered turbine plants before they decide that there is any inherent quality of the turbine which renders it unsuitable for use in tandem on the shaft of a transatlantic liner. Already turbines of 7,000 horse power are under contract for electric railway plants. If they can be built in 7,000 horse power they can surely be built successfully in 9,000 horse power units, and two such turbines on each of the three shafts of the Cunard boats would give the desired maximum horse power and something over.

AN AERO-CONDENSER OF 4,500 HORSE POWER.

Bulletin de la Societe des Ingenieurs Civils de France.

According to a paper published in the Proceedings of the French Society of Civil Engineers a very large aero-condenser has recently been established in the plant of the Kalgoorlie Electric Power and Lighting Company, from which power is to be distributed to the mines in Western Australia. It works on the surface principle, making it possible to utilize the water of condensation for the feed and, at the same time, carry a vacuum which, while dependent upon the temperature of the outside air, effects an important saving in coal consumption.

It consists of twenty-seven fans, each 7 feet 2½ inches in diameter and delivering something more than 1,175,000 cubic feet of air per minute against the condensing surfaces. These surfaces are formed of corrugated sheets of steel 1 millimeter (.039 inch) thick and set up in pairs and held together by a mechanical setting so as to form hollow wavy spaces. These plates are then assembled in nests by means of oval joints, that are stamped into the plates themselves at the same time as the corrugations. The plates are held together by two bolts passing through the nests. The form of oval stamped in each sheet forms two distributing passages, through one of which the steam enters while the water of condensation flows out at the other.

The cut shows a section of the fan and a nest of the corrugated plates. It may be remarked that these plates do not suffer any deterioration whatever, since the interior is filled with water and steam containing a small amount of oil that is sufficient to prevent oxidation, while the outside is subjected to the action of dry air only. Experience has shown that plates so constructed will hold their own indefinitely without any change, provided they are not exposed to snow and rain. The fans are run at a speed of but 100 revolutions per minute so that they show scarcely any wear. Hence the cost of maintenance is practically nothing, a matter of prime importance in a plant of this kind. They are placed in groups of three, each group delivering air into a single chamber the top of which is formed by the nests of corrugated plates. The air passes over these surfaces vertically from the bottom to the top for a distance of about 3 feet 8 inches. Steam enters at the top of each nest and the water of condensation is drawn off at the bottom.

In this particular case at Kalgoorlie no attempt was made to economize in space on account of the low price of ground, while, at the same time, the high temperature of the air also tended to increase the dimensions of the apparatus beyond what would be required in a cooler climate. Steam from the engines is first passed through separators and thence into the condensing nests. The pumps handling the water of condensation are fitted with metallic valves on account of the quantity of contained oil which would be injurious to rubber at the high temperatures reached, which sometimes run as high as from 175 deg. to 190 deg. F.

All of this water is sent through two different systems of filters. The water coming from the condensers is almost entirely free from oil and can be used directly as a boiler feed. These filters are of wood charcoal and deliver the water in an almost chemically pure condition, containing only a mere trace of oil. The water taken from the oil extractors is usually sent to the sewer, but owing to the difficulty of obtaining pure feed water at Kalgoorlie the 260 odd gallons drawn per hour from the separators are subjected to a prolonged filtration first through charcoal and then through sponges. In this way, all of the water resulting from the condensation of the exhaust steam is saved and again utilized.

The oil separators used in this plant are formed of a cylinder open at each end and containing a second one concentric with it and perforated with holes. The second cylinder contains a guiding helix or screw. The steam holding the oil in suspension, enters along the axis of the cylinder and, traveling over the screw surfaces acquires a rotary motion whose speed depends upon that of the steam. The particles of oil being heavier than the steam, are thrown out through the perforations in the inner cylinder into the space between the two, whence they are drawn off.

The two-fold object sought to be obtained by this installation is the condensation of all of the steam consumed to be utilized for boiler feeding and securing of a vacuum by which a saving in that consumption will be effected. As for the latter, the following table shows the results that have been obtained with the air at various temperatures:

Temperature of Air, Fahrenheit.	Vacuum in Inches of Mercury.
50.0 degrees	20.87
53.6 “	20.47
57.2 “	20.08
60.8 “	19.69
64.4 “	18.90
68.0 “	18.11
71.6 “	17.32
75.2 “	16.54
78.8 “	15.75
82.4 “	14.96
86.0 “	13.78
89.6 “	12.60
93.2 “	11.02
96.8 “	9.45

Further observations have shown that the average vacuum obtained during the day is 15.75 inches and 20.47 inches at night with the corresponding saving in the use of steam.—G. L. F.

"FIRE-PROOF WOOD" SO CALLED.

From Report of Insurance Engineering Experiment Station.
August, 1902.

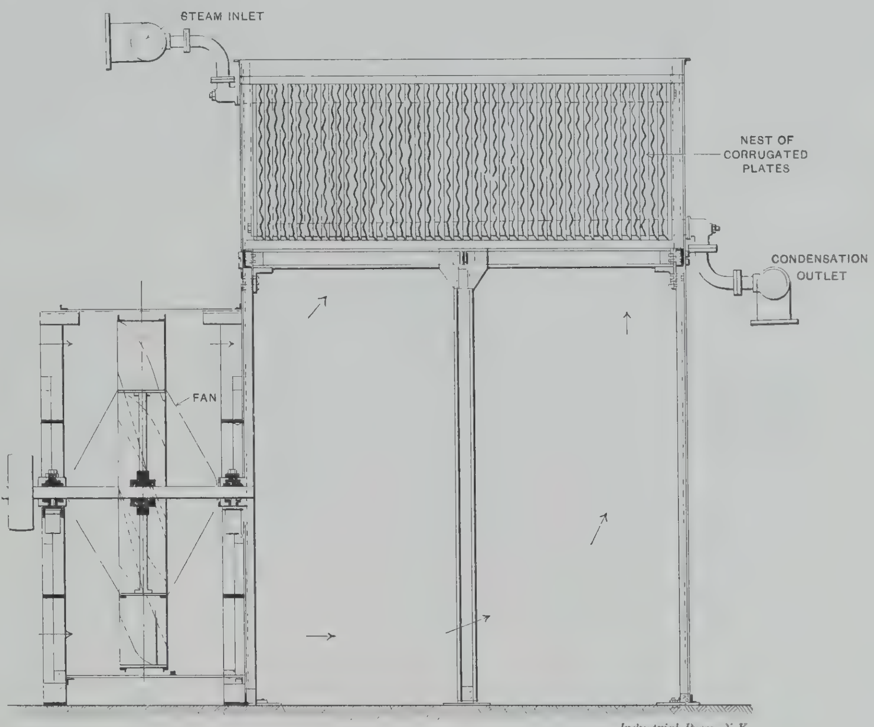
The processes of "fire-proofing" wood by saturating it with a solution which, on drying, leaves the pores more or less filled with crystals that, when heated, give out gases which retard the combustion of the wood, are not new. But the recent discussion as to the real value of such wood in modern buildings in case of fire, and as to the possibility of suitably sampling and testing the product before installing, has led to a series of experiments and examinations which are reported here. If "fire-proof wood" were in any sense fire-proof, this discussion would be unnecessary. It is not. It is similar to untreated wood except in three particulars: it is slightly less liable to be ignited by a brief and feeble application of heat; it is less likely to be ignited permanently by contact with a hot body, as an electric wire or a fragment of a projectile; and, further, it is not so likely to cause as rapid a spread of a fire in some cases, as it burns with less flame.

The wood examined in these tests was furnished by three of the leading manufacturers and since the different specimens were apparently possessed of essentially the same characteristics, it is assumed that they are representative of "fire-proof" wood.

Examination was first made to see to how much higher temperatures the treated wood could be exposed than the untreated, without its igniting or beginning to glow. It was found that the average ignition temperature of untreated woods is 840 F., while that of the treated woods ranged from 850 F. to 940 F.

The value of the treatment is then to raise the igniting point less than 100 degrees F., while some of the treated specimens show no sensible improvement. The data were derived from pieces ¼ inch by ¼ inch by ½ inch, heated at different rates in a small electrical muffle, and the agreement between different samples was within twenty degrees. Twenty samples of each wood were tested and the results averaged. It cannot, in view of these results, be claimed that the treated wood is sensibly less likely to be ignited when a temperature of 1000 degrees F. is reached.

The temperature at which the treated and untreated wood "flash" or flame instantly was ascertained by putting a brass plate into the electrical muffle and raising the temperature at a rate of about five degrees a minute until it was found that a piece ¾ inch by ¾ inch by 2 inches burst immediately into flame on being thrown onto the brass plate. In this test but little difference was found for the flash point of the treated and the untreated woods; in a few cases the treated wood flashed at a lower temperature than the untreated.



Industrial Press, N.Y.

Fig. 3. Sectional Elevation of Kalgoorlie Air Condenser.

The extent of the relative destruction of the treated and untreated wood on exposure to the action of a flame at varying temperatures was carefully studied. With a blast of gas at a temperature of from 1700 F. to 3000 F. for one, two and three minutes, the loss of a cross section of a small specimen is from five to twelve per cent. greater in the case of an untreated wood than in the case of a treated wood.

When subjected to the action of a powerful flame from a blast lamp, the *rapidity* of destruction of a small test piece also serves as an index of the value of the fire-proofing as a preventive of combustion. Specimens ¾ inch by ¾ inch by 6 inches and ¾ inch by ¾ inch by 12 inches were supported in a horizontal position by the ends and a large blast lamp placed under the center. The time elapsing before the stick burned and fell apart was noted. There is no great difference between the treated and the untreated wood in this particular. It was noticeable that all the untreated specimens furnished more flame than the treated.

The "hot plate" test was next tried and showed clearly the characteristic tendency of the treated woods, when in isolated pieces, to char without much flame and to extinguish themselves when taken from the plate. The glow and flame last only a few seconds in the case of any of the treated woods, while they may last from one and a half to two minutes or may last only a few seconds in the case of untreated woods. This test demonstrates the value of fire-proof wood as a safeguard against ignition from electric wires, yet no "hot plate" can compare in intensity with the incandescent metal and metallic vapor of many a short circuit. It is a good demonstration of the added safety of war ships when finished with "fire-proof" rather than natural wood, since one great danger of ignition in war vessels is from hot fragments of metal. In its general application to buildings this test demonstrates very little.

In response to a comment on the part of the manufacturers that large pieces could not be made to burn the following experiment was made: In a large fireplace, between two hard, dry pieces of pear wood, 4 inches in diameter and 12 inches long, there was built a fire of newspaper and "fire-proof" kindling; over this were laid on edge four boards (6 inches by 24 inches, 8 inches by 30 inches, 14 inches by 20 inches and and 14 inches by 30 inches) of "fire-proof" wood. The fire spread up and along the boards, and in about two hours the whole contents of the fireplace, except the pieces of pear wood, were consumed. The two logs were afire, but went out after the "fire-proof" wood had been consumed. The room, in the meantime, had been rendered unbearably hot by the fire, which resembled a good cannel coal fire in appearance.

In the light of the results of these experiments, it would not appear that more can be claimed for "fire-proof" wood than this: That, when heated, it gives off a gas which makes it more likely to fail to keep burning than an untreated piece of wood; and that when afire, it gives out less flame, and hence is not as likely to cause fire to spread. It is not incombustible; it is not uninflammable; it will under many conditions, support its own combustion; it is destroyed by external heat nearly as rapidly as is untreated wood. It is not as easy to work at high speed; it may cause rusting (as do some of these specimens) and the mechanical strength of the wood is slightly impaired.

In consideration, then, of the physical properties of such wood as has been examined and of the difficulty of assuring one's self of the nature of the product; and, further, in view of the possible deterioration of the wood of the fastenings and finish, the use of such fire-proof wood in ordinary buildings seems of very doubtful value.

FASTENINGS FOR EMERY WHEELS AND GRINDSTONES.

Zeitschrift des Vereines Deutscher Ingenieure, September 27, 1902, p. 1481.

When an emery wheel or grindstone is put in revolution a certain amount of tension is set up and the method of fastening should be carefully considered. The oldest fastening for this class of tool is that shown in Fig. 4. The stone has a large hole in its center and is carried by a shaft of the same type as that used on old-fashioned water wheels. It is fastened with wooden wedges, which are soaked with water in order to make them swell and tighten as much as possible. The instability of these wedges, which, by alternate wetting and drying, are constantly varying the tension put upon the stone, serves to increase the danger of the bursting of the same. This style of fastening is, therefore, seldom used at present.

A step in advance was made by the introduction of iron shafts. At first these were square in section. The stone was fastened between two wrought-iron crosses having a square hole at their centers. The ends of the arms were provided with holes through which bolts were passed for the fastening of the stone, as shown in Fig. 5. The crosses were themselves fastened to the shaft by wrought-iron wedges, so that the stone was, in this way, freed from all tension due to its fastenings. It was merely weakened in section by letting the crosses into it and by the holes for the bolts.

An essential improvement was made in the fastenings by the introduction of round shafts as shown in Fig. 6. Here the stone is fastened between two round clamping plates which are drawn together by a nut on the shaft. Through the pressing of these plates the stone is, of course, subjected to a crushing stress; it must, therefore be admitted that stresses are thus set up in it that extend beyond the outer diameter of the plates. As a matter of fact stones so fastened have been sprung to such an extent that all of the material outside the plates has been fractured. Such clamping plates have also been made with circular ribs, as shown in Fig. 7, thus forming a first-class bursting furrow in the stone. These ribs possess the disadvantage that the section of the stone is dangerously weakened by them.

Another form of fastening is that shown in Fig. 8. Here cone-shaped plates are used for clamping the stone. The hollow cones are brought to bear against it. When these come to a bearing the plate must press equally against the stone throughout its whole circumference. As they are pressed together they are distorted to a greater or less extent on account of their own elasticity; their surfaces will be forced back and the diameter of the rims increased. Through the grinding action on the edge of the stone, the latter will increase in size and this increase will be shared by the plates which will thus set up a radial stress. These cone-shaped plates which seem to be so advantageous are, therefore, detrimental in that they exert a destructive influence on the stone.

The fastening by means of plates in the form of inverted cones, as shown in Fig. 9, is a preferable one. Here, by a tightening of the plates, the rim is drawn in towards the center and a tension towards that point is created. The tensions which are produced by the pressing of the plates together are toward the outside, and counteract each other to a great extent, so that there are no unfavorable stresses set up in the stone by this method of fastening. It will

also be of advantage to make the bearing surface of the tightening nut spherical, whereby the plates can be made to better adjust themselves to any inequalities in the stone.—G. L. F.

MACHINE SHOP FLOOR PLATE WITH REMOVABLE SECTIONS.

Power and Transmission, October, 1902. p. 42.

In the early experience of heavy machine work it was the custom to take the work to the machine, but in modern machine shop practice such changes have come about that in many instances the machine is taken to the work. In nearly all modern and well-equipped iron-working plants engaged in work of the heavy class the floor plate has become a necessity, the use of which enables the work under construction to be bolted down to a level surface in the position desired, after which the machine, be it a portable slotter, shaper, planer, boring mill or drill, is set up in position, adjusted and made ready for the performance of its particular office. In other words, the floor plate might be called a universal machine, capable, with proper equipment, of unlimited variations of operation or service and with the greatest economy as to power consumption and cost of labor in resetting work requiring a variety of operations. The size of a floor plate is regulated solely by the requirements it has to meet, and must in all cases be arranged with a traveling crane overhead. The power used for driving the tools is preferably electrical, but rope and air driven tools and flexible shafts are also available.

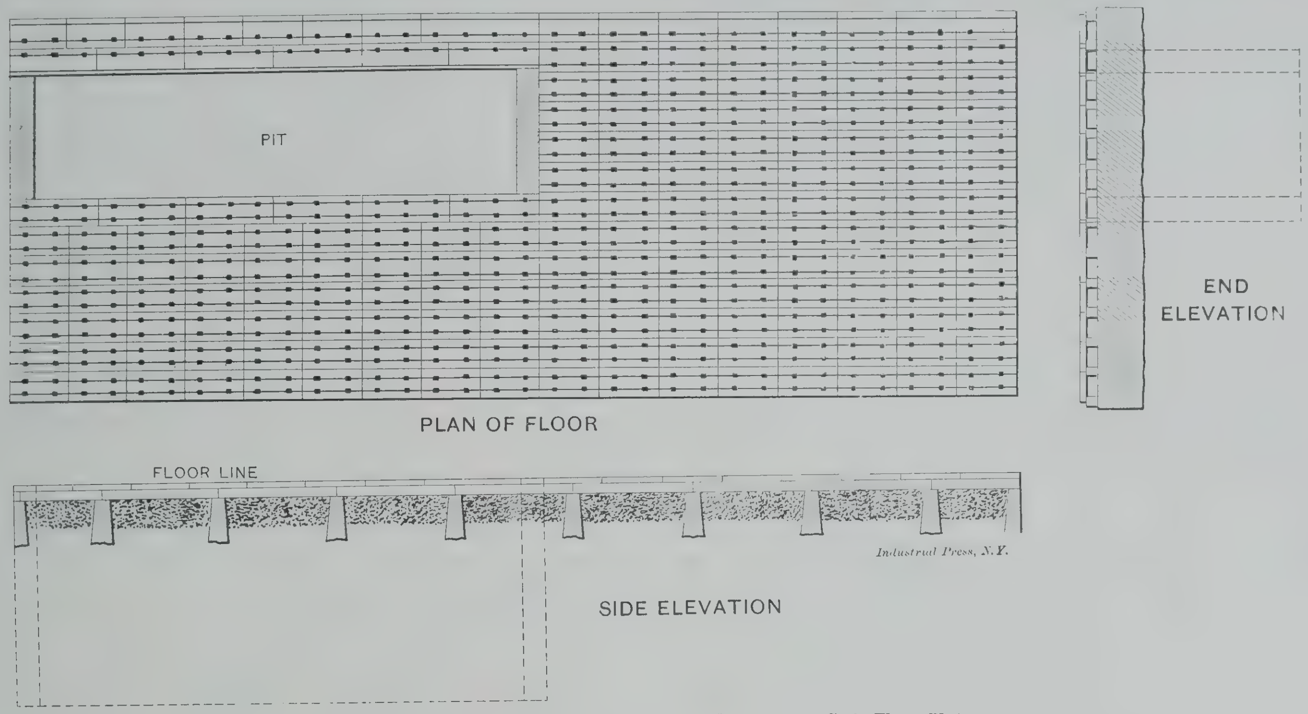

Fig. 10. Plan, End and Side Elevations of Dodge Mfg. Co.'s Floor Plate.

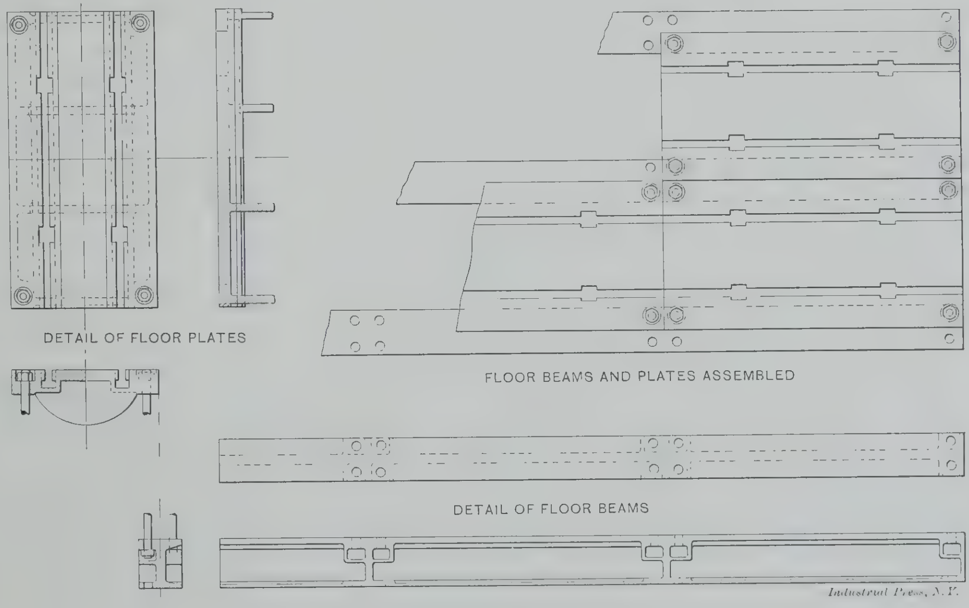

Fig. 11. Details of Floor Plate.

There are numerous plans for laying down floor plates, and the illustrations, Figs. 10 and 11, show the plan adopted at the works of the Dodge Mfg. Co., in their heavy machine department. A feature has been introduced in this floor plate whereby any section that has become pened or warped from hard service may be removed for planing or relieving the strain that it may have undergone, or otherwise correcting inaccuracies and results of wear. After a section has been repaired it may be replaced for further use, or new sections inserted as may be desired. This is a decided advantage as with many floor plates this cannot be done as the sections are cemented solidly into the foundations and no means afforded for maintaining constant accuracy of surface.

The floor plate is located beside the wheel lathe pit. Pieces that are too long or wide for setting up on the surface of the floor plate can be hung or bolted to the side of the pit convenient to the portable tool to be used. The company expect to make it a feature of their business in the near future to supply floor plate installations to manufacturing concerns.

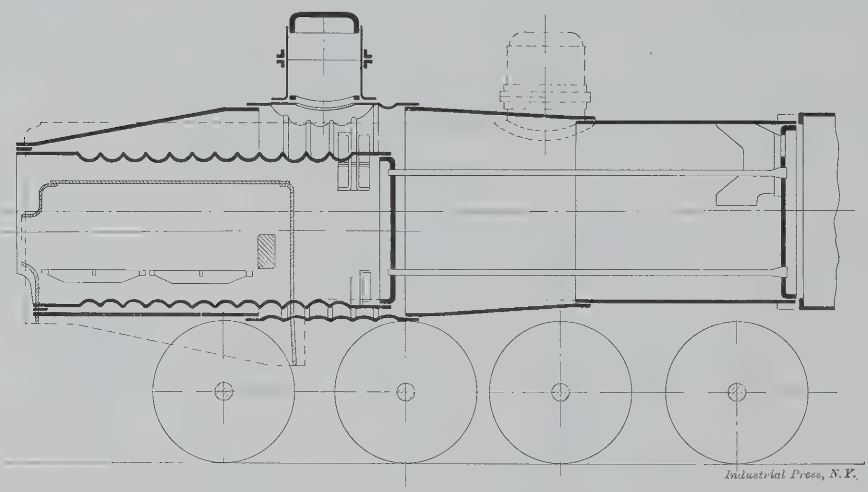
ADJUSTMENT OF STEAM ENGINE SHAFT GOVERNORS.

Iowa Engineer, March, 1902, p. 129.

Adjustments of steam engine shaft governors are made for the purpose of changing the speed of the engine or the sensitiveness of the governor, or both. The action of a governor of this type depends on a change of speed, it being necessary for the engine to run faster with a light than with a heavy load. The less the difference in speed between no load and full load, the more sensitive the governor, and *vice versa*. The two forces acting in opposition in a shaft governor are the centrifugal force of the governor weights and the elastic force of the springs. The initial tension of the springs resists the centrifugal force of the weights and the latter must exceed the tension of the springs before the governor can act when the engine is starting. The more the springs are stretched the greater the tension and the greater the centrifugal force must be to overcome it. The effect of centrifugal force to oppose the springs also depends on its moment or leverage. In some governors the lever arms are variable, and in others the centrifugal force is altered by changing the weights. If the leverage of the weights be reduced and the tension of the springs remains unchanged, the angular velocity must be increased to balance the opposing forces, which means that the engine must run faster. The converse is also true. If the tension of the springs be increased the engine again must run faster, and if the tension is reduced it must run slower.

An increase of the initial spring tension increases the sensitiveness of the governor, and *vice versa*. Sensitiveness is also dependent upon the strength of the springs, a decrease in the strength increasing the sensitiveness, and an increase in the strength decreasing the sensitiveness. Engine speed may therefore be changed either by changing the centrifugal force of the governor ball, or the initial tension of the spring. Sensitiveness of the governor may be changed by change either of the initial tension or of the strength of the spring.

The following is given, not as covering all possible cases, but the suggestions may prove helpful to such as find themselves called upon to adjust shaft governors:



Industrial Press, N.Y.

Fig. 12. Locomotive Boiler with Corrugated Waist and Firebox.

Let M = Moment of centrifugal force of the ball.
S = Strength of spring.
I = Initial tension of the spring.
Sp. = Engine speed.
Sen. = Sensitiveness of the governor.

Sen. Constant	To increase Sp.	Decrease M or Increase I and S
	To decrease Sp.	Increase M or Decrease I and S
Sp. Constant	To increase Sen.	Increase I and M or Decrease S
	To decrease Sen.	Decrease I and M or Increase S
Sp. Variable Sen. Variable	To increase both	Increase I or Decrease M and S
	To decrease both	Decrease I or Increase M and S
Sp. Variable Sen Variable	To decrease Sp. and increase Sen.	Increase M and Decrease S, or Increase M much and I little, or Decrease I much and S little
	To Increase Sp. and decrease Sen.	Decrease M and Increase S, or Decrease M much and I little, or Increase I much and S little

M may be changed by changing either the length of the lever arm, or distance from center of gravity of the ball to the center of pivot about which it turns, or by changing the weight of the ball. Provision in many engines is made so that the ball can be moved on its arm, being held in place by a set screw. In other engines this lever arm is invariable, but the weight of the ball can be changed by varying the amount of lead it contains. It may be changed by pulling up or letting down the spring. This is often effected by means of a "turn buckle" at the end of the spring opposite to that which is attached to the governor. If the spring be a leaf spring instead of a spiral spring, the initial tension can be changed by wedges put back of the spring near its point of attachment; so that the spring before being drawn up has its point thrown into such a new position that it has to be drawn up through a greater or less distance to bring it to the point of attachment. To change S usually requires a new spring if it be a spiral spring. S, however, is increased by reducing the number of coils, and decreased by increasing their number. In the leaf spring, S may be increased by adding more leaves, and *vice versa*.

The foregoing applies particularly to the older style of shaft governors in which the "inertia" principle is not prominent. Inertia governors are generally built and adjusted at the factory for the specified speed and sensitiveness. Subsequent changes, if small, can be made as above indicated for centrifugal governors by substituting moment of inertia force for moment of centrifugal force, but radical changes will necessitate the use of a new spring. Later forms of inertia governors provide for changing the point of attachment of the spring to the weight arm.

LOCOMOTIVE BOILER WITH CORRUGATED WAIST AND FIREBOX.

Zeitschrift des Vereines Deutscher Ingenieure, 1902.

The stayless locomotive boiler designed by Herr Lentz and built for the Left Bank of the Rhine Railway about ten years ago, labored under the two-fold disadvantage of being a poor steamer and subject to leaky tubes. These were due to the form of the firebox, which, being cylindrical, could not be made large enough to afford sufficient grate area, besides being too rigid to permit inequalities of expansion to take place. Mr. Vanderbilt improved this boiler by using a corrugated firebox, which permitted not only an increase of grate area but also gave some flexibility to the structure. The construction, however, does not seem to be all that is required and so the Schultz Knaudt Co., of Essen, Germany, have brought out a further improvement as shown in Fig. 12, in which a certain amount of elasticity is given to the whole structure by making the waist plate in the form of a corrugated sheet. The dome may be placed upon this sheet or upon one of the smooth sheets, as may be desired. Several of these boilers have been built but no reports have yet been made as to their performance in service.—G. L. F.

* * *

Frederick Alfred Krupp, the gun-maker of Essen, Germany, died suddenly of apoplexy, November 22. He was the son of Alfred Krupp and the grandson of Peter Frederick Krupp, the founder of the business. While the grandfather was the founder, it is to Alfred Krupp, however, that the success of the firm is principally due; for all that he inherited from his father, who died in 1826, was an iron forge employing three men, and no capital. Without money or friends he built up the greatest iron and steel business in the world and became the armorer of Europe. He was possessed of great powers for invention and research, and had an indomitable will. Alfred Krupp died in 1887. The general census of July 1, 1898, showed that 40,253 men were employed in the mines, mills and shipbuilding works of this great institution, of which 23,997 were employed in the cast steel works at Essen. Until the formation of the United States Steel Corporation, the Krupp firm were the largest employers in the world, and are now second with about 43,000 men on the rolls. In 1890 the area covered by the building property, was 11,700 acres. Since 1887 Frederick Alfred Krupp has been in charge and during that time the works have been greatly enlarged and almost transformed. He was the richest man in Germany, his fortune being estimated at $125,000,000.

NOTES OF TRAVEL.

CUTTING SPEEDS—DESIGN AND FINISH OF GERMAN AND SWISS ENGINES—SAND BLAST.

Editor MACHINERY:

Although high cutting speeds and heavy cuts for machining iron and steel have been used for some time in the States for heavy work, and the "blue chip" is now well known in the roughing-out process of heavy forgings, little attention seems to have been given to the use of the most recent special steels for rapid machining of small work. In bicycle and automobile construction the steels used for cutting tools have been driven to the utmost service by the aid of copious floods of oil, soda water, emulsions and other liquids for cooling the tool and the work. But the steels used were those which softened at comparatively low temperatures relatively to the high temperatures that the recent steels will withstand. The work done by a cutting tool was much less in a given time than is obtained with special steels.

In the works of Alfred Herbert, Limited, Coventry, England, builders of light machine tools, special steel is used on the milling machines for inserted-tooth mills, turret and capstan lathes, engine lathes, planers, shapers and other machines for performing like services. The small tools are made of "A. W." (Armstrong-Whitworth) and "Magic" steel. During a three-hour inspection of the works, the writer observed that the machines were running at very high speeds and removing metal with great rapidity. Finally an engine lathe of a swing of probably twenty inches was noticed turning off a shaving from what, on account of the white, straight chip, appeared to be lead or something of the nature of babbitt metal. A remark to that effect, however, elicited the information that it was a piece of mild steel undergoing machining, and an examination proved this to be the fact. The cutting tool was "A. W." steel. The cutting was done dry, without the use of oil, soda water, emulsion or anything for cooling the tool and work. The chip showed no color due to heating and the tool kept sharp and made a clean, smooth cut.

A notice posted about the shops, giving instructions as to cutting speeds and feeds, was read later. It is given below from a copy kindly furnished by the company. An idea of what is done can be had by reading it.

The machine tools built at the Herbert Works for this high duty are very heavily proportioned for the service to be performed. They are a combination of what is best both in American and English design and construction. Wide belts are provided for, a feature lacking in many machine tools.

On the whole the visit conveyed a most favorable impression.

Copy of Notice Posted at the Albert Herbert, Limited, Works.

NOTICE.

Trials have been made in these works of tools made of "A. W." steel, and the following tables are intended to show the amount of work that can be done. The tools will work two or three hours at these speeds and feeds. Speeds and feeds much in excess of those given can be used for a short time. A small stream of suds was used when cutting steel; more work can be done with more suds. These tools must in future be used wherever possible.

Design and Finish of Steam Engines in Germany and Switzerland.

The great simplicity in the design and finish of steam, gas and oil engines in Germany and Switzerland is strongly impressed upon one by a visit to the machinery department of the Düsseldorf exhibition, Germany, and the great engineering plant of Gebrüder Sulzer (Sulzer Brothers) at Winterthur, Switzerland. Ornamental additions are entirely absent. Cylinder lagging, safety guards and oil shields are made of heavy Russian sheet iron banded, supported and strengthened where necessary with polished steel which is often given the same color as the Russian iron. Even oil cups and other trimmings show no polished surfaces in some cases, at least the surface is not left the color of the alloy. Polished and blackened brass, or polished iron is largely used for these parts. And finally the frame, bed and other cast iron or steel casting parts have their surfaces well filled by the painter and finished to a smoothness and color resembling very closely the Russian iron. The moving parts are polished either wholly or over a considerable portion of the surface, and left bright. The machines are well proportioned, free from sharp angles and projections, and consequently beautiful in their simplicity and strength. They are pleasing to the eye in the same way as a magnificent horse free of all harness and trappings, and convey the impression of strength in the same manner.

Sand-blast for Castings.

The sand-blast for cleaning castings of medium size finds considerable favor in Germany and Switzerland. Castings small enough to go into the ordinary foundry tumbler or rattler are cleaned by the common method of tumbling. The sand-blast machine used for the medium size pieces is entirely different from any the writer has seen or heard of in the States. It is not in any respect similar to the sand-blast nozzle, hand guided for cleaning large castings, and does not take its place. The continental machines on exhibition in the Düsseldorf exhibition and in operation in various industrial establishments were made by Alfred Gutmann, of Ottensen, Hamburg. They have a horizontal circular table about six or seven feet in diameter which rotates slowly about a vertical spindle. The whole machine resembles in a way a horizontal table boring and turning mill. Two blasts of sand are blown down upon the back half of the table, which part is covered over with a sheet metal guard to prevent flying of the sand. The pieces to be cleaned are placed on the table which carries them under the sand-blasts by its continuous rotation. The table is of cast-iron grid construction to allow the sand to fall through. An attendant for one or two machines is required, for turning the castings over at intervals during the constant operation of the cleaner so that all sides will be presented to the blast. The machines are capable of taking anything that can be laid across the table and is not too high to pass under the sheet metal guard, which is placed about fifteen inches above the table. An apron of cloth or paper hung at the edge of the guard adjusts itself to the irregularities of the castings and prevents the sand from flying out.

A smooth, silvery matted surface is imparted to the casting by the complete removal of adhering and imbedded sand from the mold. Of course the scale can be completely removed if desired.

The sand used in the blast is exceedingly coarse. The force of the blast does not seem to be great, and there is no dust about the machine to cause discomfiture to the operator. It can be satisfactorily used in the open space of a foundry or cleaning room, which is not true of the high velocity sand blast nozzle tried and usually discarded for castings too large for a tumbling barrel.

Complete satisfaction with the machine was expressed in all the establishments where it was seen in operation.

Florence, Italy. FORREST R. JONES.

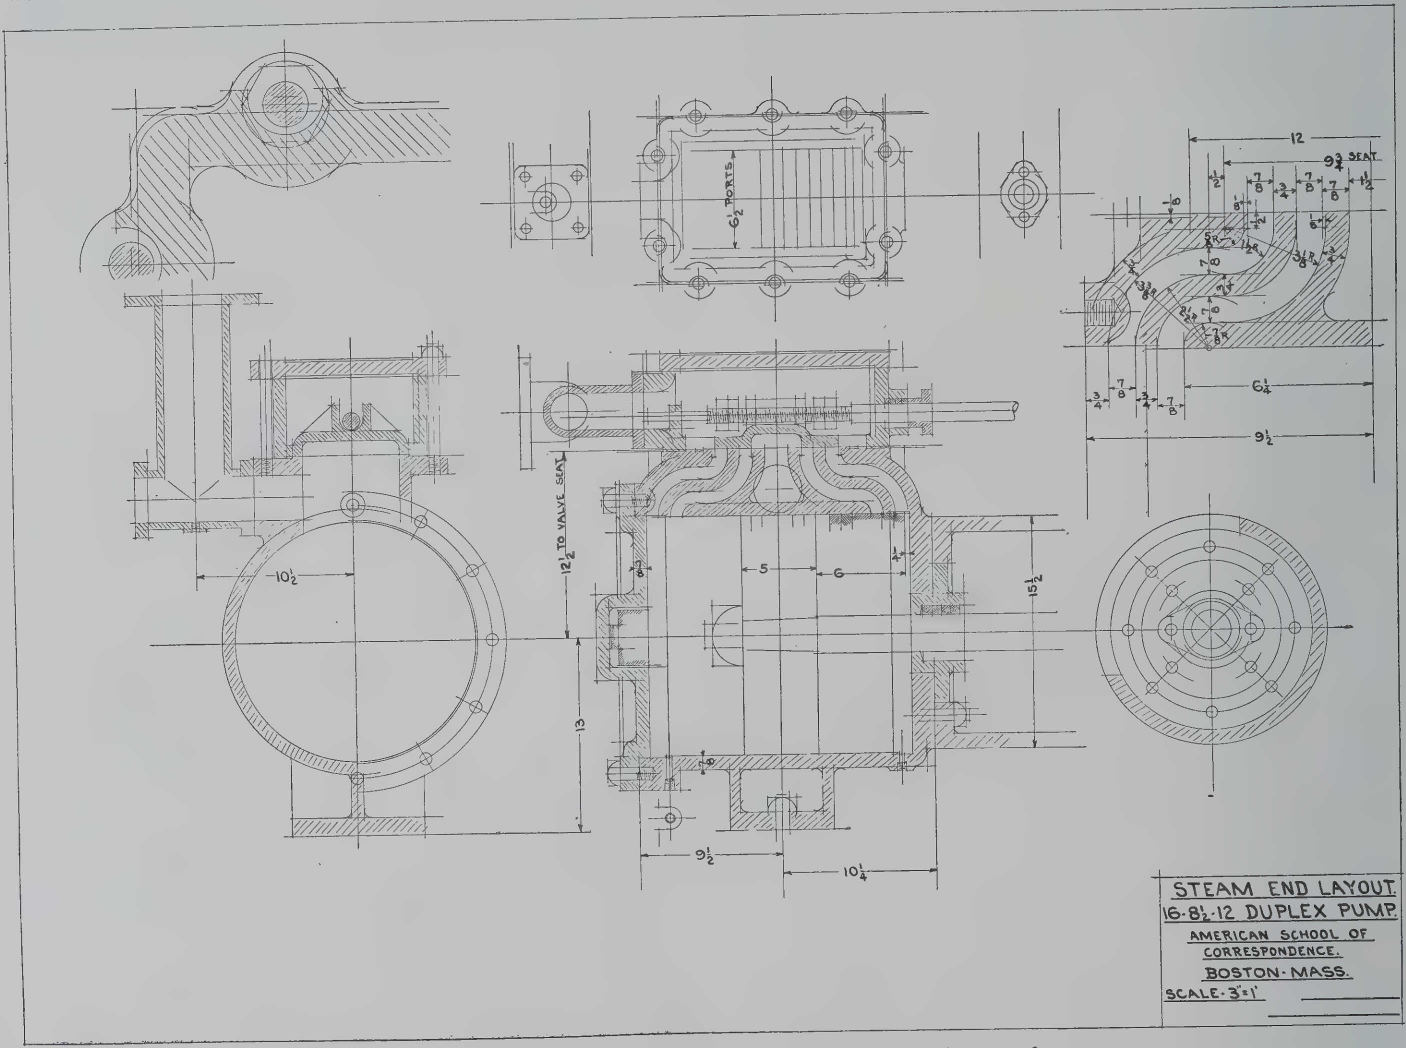
* * *

To anneal self-hardening steel so that it can be drilled and worked without much trouble J. W. Riley says: Heat the steel to a forging temperature, have some dry ashes laid on the floor and covered over with a layer of pine shavings. Lay the hot steel on the shavings, let it burn a little and then cover over with pine shavings and pack dry ashes over the top, making it air-tight. Let it remain until cold. To temper double gasket cutters heat the edges slowly to a tempering heat, not letting the body get very hot, and then cool in oil. The temper is then drawn to a dark straw.

MECHANICAL DRAWING.

AN EXTRACT FROM THE INSTRUCTION PAPERS OF THE AMERICAN SCHOOL OF CORRESPONDENCE.

In a course of mechanical drawing prepared by the American School of Correspondence, Chicago, Ill., Part VI is devoted to working drawings and was prepared by Chas. L. Griffin, Professor of Mechanical Engineering, Syracuse, (N. Y.) University. This pamphlet contains some of the most common-sense suggestions that we have seen, for the benefit of the student in drawing. It takes up the working drawings of a duplex direct-acting steam pump and follows them through from beginning to end. Mr. Griffin touches on one point in particular that should be impressed on the student in drawing, and that is, the method of blocking out or arranging the parts of a machine when designing; and he shows in a very clear manner what the essentials are in such work and how the sketches of a designer should appear when turned over to the detail draftsman. The accompanying illustration is one of several from this pamphlet and the quotations which follow indicate in a general way the direct and practical method adopted by the author.



Specimen Plate from Instruction Papers of the American School of Correspondence.

The two chief requisites of a shop drawing, under which general heads a multitude of detail requirements can be summed up, are:

(1.) Absolutely complete and definite instructions from designer to workman.

(2.) Least possible cost in dollars and cents of production of the drawing measured by the draftsman's time.

It makes no difference how much we may attempt to disguise these two elements, the fact will still be apparent that "*complete instructions furnished for the least money*" is what the manufacturing shop is after, and what will be assumed as a basis for judgment as to the highest commercial utility.

As to the first point, that of completeness and definiteness of instruction, there must be no question of degree. If the information which the drawing furnishes is positive and complete, the drawing is good. If doubt arises in the workman's mind as to what the designer intended by a certain line or dimension, or if the dimension be omitted, the drawing is bad. There is no middle ground. The instructions are either present or absent, and the drawing good or bad accordingly.

The workman of to-day is not permitted to assume dimensions or shape. It is his business to execute the draftsman's orders; it is, however, often his privilege to choose his own way of doing it, but further than this modern practice does not allow him to go. He is held as rigidly to the orders specified by the drawing as the locomotive engineer is held to his bit of tissue telegraphic order to proceed, without which he dare not enter the next block. The drawing is supreme; it is official; it must be plain, direct and all-sufficient. It is the draftsman's business to make it thus, and he is not a draftsman until he does.

This idea of positiveness must be thoroughly absorbed by the student. Positive action must be a habit which controls his every move, which marks every dimension he prints, which directs every line he draws. Every line must mean something, must have a definite reason for existence, must be necessary to illustrate the idea he wishes to convey to the workman; and every line must be a definite measurable distance from every other line, so that its location is fixed beyond a doubt. Lines which mean nothing, and cannot be measured, have no place on the drawing; they only confuse it.

Drafting-room labor is a relatively high-priced service, and the salary list easily assumes considerable proportions, so that wasteful excesses count up rapidly. One of the qualifications of proficiency invariably required for this department of shop organization is rapidity of execution. This is not dependent upon personal traits as at first might be supposed. A man may so husband his time and direct his efforts that he will easily distance his neighbor of more rapid motion. The latter may have less ability to make his energies count, and lack of judgment as to when just enough, and no more than enough, energy has been expended on his drawings. From the standpoint of *utility*, the function of a drawing is fulfilled when it has reached the stage that it *completely* instructs; more time spent in elaboration is wasted, and is an unnecessary and therefore extravagant expenditure. The student must fully realize this. In his earnestness to produce finished and complete work he must constantly strive to accomplish results in the least possible time. This does not mean careless haste; far from it. A complete shop drawing cannot be made by short cuts, but through a systematic building of line on line, dimension on dimension. This is in sharp contrast to a haphazard habit of developing a drawing, first a line here and then a figure there, with no definite purpose in mind, and no hint as to when the drawing is actually completed.

The one method constitutes the efficient draftsman who works easily, receives a high salary, and is worth it, because he wastes no time in unnecessary labor. The other marks his unfortunate brother, plodding laboriously far behind, receiving a small pittance per hour, and worth less, because he does uncalled-for labor, and loses his definiteness of purpose in a maze of unexplainable lines and figures.

A working shop drawing, commercially considered, may well be defined as being *"Complete instruction from designer to workman issued at minimum expense."*

The plate on previous page shows, as well as reproduction can accomplish, the pencil layout of the steam end of a direct acting steam pump. The layout is the first work of the designing draftsman. The drawing, as shown, is exactly the type of layout which he would turn over to a detail draftsman, whose duty would be to work up detail shop drawings therefrom.

The character of this drawing should be carefully studied. Remember that it is a layout, nothing more; also bear in mind that it is an exact, measurable working sketch. Attention is called to the sharpness of the lines, especially to the clean-cut intersections. Note the boldness, dash and businesslike style, the free-hand cross-section lines roughly put in. There is no hesitation or worry as to where the end of the line should be, or whether it crosses other lines which it theoretically should not. The intersections are allowed to indicate the termination of lines, and the rough section lines pick out the parts and separate them clearly to the eye. In this layout there is the spirit of confident, definite and rapid action, with no thought for absolute finish in line work, but with every thought for absolute results as to measurable dimensions.

There are two general rules of action in producing a drawing, which give the answer to the question that oftenest confronts the beginner: "What is to be done first?" or "What is to be done next?" These rules are:

1. Draw everything that is positively known.
2. Work from the inside to the outside.

Every problem has some positive data, assumed or calculated, to start with. The first thing to do in every case is to get this data represented by lines on the paper. An expert designer has been heard to say that until he had spoiled the blankness of his sheet of paper by some lines, he could not design. There is something in this; and almost invariably the first line to draw is a horizontal center line somewhere near the middle of the sheet; draw it! Draw it at once without hesitation, and the layout is begun. We now have something about which to build.

In this case the designer would first calculate the size of the piston rod, and determine the fastening to the piston. He would then draw the rod and build a hub around it. He would next calculate the width or thickness of piston and size of packing rings, and draw the two vertical lines 5 inches apart, to indicate the piston faces. These lines would be limited by the cylinder bore, which he knows to be 16 inches; hence horizontal lines 16 inches apart, parallel to and symmetrical with the center line, are the next to be drawn. Short vertical lines indicate the location of the packing rings. As the nominal travel of the piston is to be 12 inches, the location of the piston and rings can be shown on both sides of the central vertical line at the limits of travel. A clearance must exist between the heads and the piston (in this case ¼ inch is allowed), hence the lines of the heads can be drawn, and the general inside outline of the cylinder barrel is complete.

This is all in direct application of the foregoing rules, and is so simple, natural and direct that it hardly requires such explicit statement. We have simply taken such data as we had and put it on paper, placing it where it can be seen from all sides, and where the mind is relieved of the labor of carrying it.

If the student will only appreciate this one rule and draw all he knows about the problem, he is well on his way to its solution. *Draw everything you know, and work for what you don't know*, is what these rules say, and the first question to arise should be: "Have I drawn everything that is known about the problem?" before he asks himself or any one else: "What shall I do next?"

One other rule might be added to these two: *Keep dimensions in even figures, if possible.* This means that small fractions should be avoided. It is just as easy to bear this point in mind, and save the workman much annoyance and chance of error, as it is to disregard this matter. Even figures constitute one of the trade-marks of an expert draftsman. Of course a few small fractions, and sometimes decimals, will be necessary. Remember, however, that fractions must in every case be according to the common scale; that is, in sixteenths, thirty-seconds, sixty-fourths, etc., never in thirds, fifths, sevenths, or such as do not occur on the common machinists' scale.

* * *

THE NEW YORK 1902 MEETING OF THE A. S. M. E.

The American Society of Mechanical Engineers will hold their annual New York meeting at the Society House, No. 12 W. 31st Street, New York, beginning Tuesday, December 2, and ending Friday of that week. The titles of the papers to be read, are as follows:

Smoke Prevention by Mechanical Stoking. F. R. Hutton.

Volumetric Elasticity of Rubber. F. J. Miller.

Heat Resistance—The Reciprocal of Heat Conductivity. William Kent.

The Metric System. F. A. Halsey.

Final Report of Committee on Standard Methods of Testing Steam and Gas Engines.

A Rational Solution of the Measurements of Weights and Measures. Sydney A. Reeve.

Tests of a Twelve Horse Power Engine to Determine the Effects of Changes in Speed, Load, Point of Ignition, Ratio of Gas to Air, and Jacket Temperature. Prof. C. H. Robertson.

Deflection of Beams by Graphics. W. Trinks.

Entrophy Analysis of the Otto Cycle. S. A. Reeve.

Value of a Horse Power. A. F. Nagle.

Finer Screw Threads. Charles T. Porter.

Filing System for Office. Henry M. Lane.

Gift Propositions for Paying Workmen. Frank Richards.

Fly-Wheel Capacity for Engine-Driven Alternators. Walter I. Slichter.

A Forty-four Foot Pit Lathe. John M. Barnay.

Use of Surveying Instruments in Machine Shop Practice. C. C. Tyler.

Rotary Pumps. John T. Wilkin.

Continuous Record of the Position of an Engine Governor and the Speed of the Engine Which it is Governing. J. C. Riley.

Centrifugal Machines and Their Uses. Bartholomew Viola.

A New Oil-Testing Machine. Albert Kingsbury.

The officers named by the nominating committee to be voted for, are as follows:

For President—William Sellers, Philadelphia, Pa.

For Treasurer—F. H. Stillman, New York; F. H. Daniels, Worcester, Mass.

For Vice-Presidents—James Christie, Philadelphia, Pa.; John R. Freeman, Providence, R. I.; R. C. McKinney, New York.

For Managers—S. S. Webber, Trenton, N. J.; Newell Sanders, Chattanooga, Tenn.

LETTERS UPON PRACTICAL SUBJECTS.

A GUIDE FOR DEEP SAWING.

Editor MACHINERY:

In cutting deep slots with a thin saw, it is common practice to overcome the tendency of the saw to run out of its course by reversing the usual direction of rotation and running it down onto and with the work. The table is either gibbed up more tightly than usual, or held back against the feed screw by a weight to take out the back lash, and prevent the work from running into the cutter. With unusually thin cutters, however, even these precautions fail to keep the saw from running out and breaking. The device described below was contrived by a milling machine operator who had much of this work to do, and it has proved to be very useful. *A* is a casting, bored out as shown to encircle the overhanging arm of the machine. It is split on one side, and furnished with a screw *B* to clamp it in position. To the lower end of this casting is adjustably fastened, through screw *C* and the tongue shown, the holder *D* made of two pieces of steel screwed and doweled together. This holder is brought down over the saw and arbor as close to the work as possible, and carries six snugly fitting brass screws, arranged as shown in the drawing. The flat ends of these screws are adjusted so that they just touch the saw on each side, and thus confine it closely to its proper path. It has been found that this arrangement, when carefully used, will greatly reduce the breakage of the saws in deep cutting.

Industrial Press, N.Y.

Guide for Thin Milling Saw.

A CONVENIENT BORING BAR.

Editor MACHINERY:

The boring bar shown in the accompanying sketch is for use with a hollow spindle lathe for boring long holes in chucked work where the spring of the common boring bar gives trouble. Fig. 1 shows the bar *H*, a section of the lathe spindle *S*, faceplate or chuck *F*, and the bushing *B*. This bushing is fastened to the faceplate with two flat-head screws when the end of the spindle is flush with the faceplate, but when the faceplate projects beyond the end of the spindle, the bushing is made flush with the faceplate and a screw is put in the joint between the two, half of its thread being in each piece.

The cutting tool *T* is made of round stock and is set by an adjusting screw *C*, at the back side of the bar, and is fastened in position by means of the setscrew *E*. The clamping block *F* is shown in Fig. 2, in position on the cross slide of the lathe, *D*. When the nut is screwed down on the bolt *A*, it clamps both the bar and the block firmly to the cross slide.

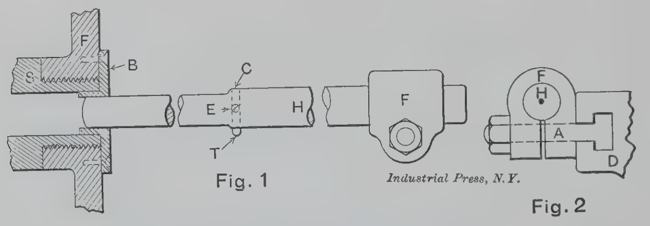

Fig. 1

Industrial Press, N.Y.

Fig. 2

Boring Bar for use in Lathe.

In making the clamping block the hole for the bar should be bored with a common boring bar, between the lathe centers, with the block clamped in position on the cross slide by the bolt *A;* this insures the hole being bored the correct height (it being assumed that the cross slide has no tilting device.) After the block has been bored a close fit for the bar, the slot is cut. The block should be bored for the largest size of bar that will be used and bushings made for the smaller bars. The end of the bar entering the hollow spindle is made smaller than the remaining portion, to allow it to be used in small holes and still keep the greater portion heavy and strong; but if desired, a straight bar could be used which would be somewhat cheaper to make.

A tight-fitting leather washer slipped on the end of the bar before it enters the bushing *B* will keep dirt out of this bearing and prevent undue wear.

When setting the bar, the tail-stock should be straight with the ways of the lathe and the cross-slide so set that the center of the bar will come on the tail-stock center.

It is always advisable to place the clamping block as near the cutting tool as the length of the hole to be bored will allow.

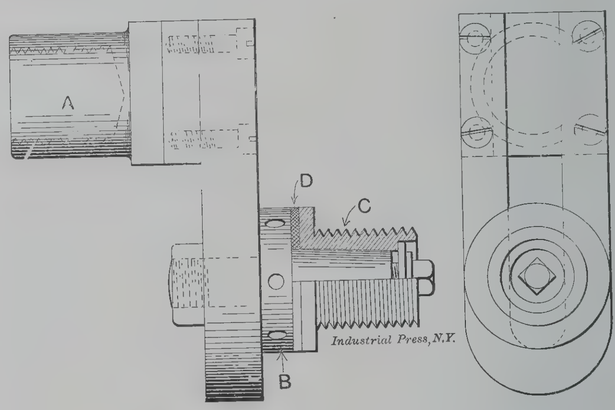
M. H. BALL.

Watervliet, N. Y.

ECCENTRIC BORING ATTACHMENT.

Editor MACHINERY:

A large number of small shops are not equipped with a lathe chuck in which articles can easily be chucked eccentrically so as to turn the article "off center." Even in shops that are equipped with combination universal and independent chucks it is always more or less trouble to chuck a piece in this manner, especially when a great amount of eccentricity is required or where the castings are of peculiar shape. In a great many cases it will be found very difficult to chuck certain pieces just where they are wanted even with the best chuck on the market.



Industrial Press, N.Y.

Lathe Attachment for Eccentric Boring

The sketch illustrates a very simple attachment that can be fitted to the spindle of a lathe, to be used with any kind of a chuck, for obtaining any amount of eccentricity that is within the range of the swing of the lathe.

This attachment may be made in one piece of cast-iron or it may be made of machinery steel, with the parts fitted together as shown in the sketch. When made in the latter way it is, of course, much more substantial than when made of cast-iron. The stock *A* is bored out and threaded to fit the spindle of the lathe on which it is to be used. In the yoke slides a T-bolt *B*, which can be moved to any distance off center that is within the limits of the yoke. On this T-bolt is the sleeve *C*, which is turned and threaded to the same size as the nose of the lathe spindle and is so arranged that it can be turned on the bolt, or by removing the back washer *D*, it can be clamped solidly to the bolt. If it is desired to bore a hole in a disk, two inches off center, all that is necessary is to set this T-bolt two inches from the center of the lathe spindle, clamp the sleeve solidly to the bolt and then screw on the chuck in which the disk has been chucked centrally. If it is necessary to bore a number of holes in the disk, each two inches from the center, all that is needed is to loosen the sleeve after each hole has been drilled and allow the chuck to revolve about the bolt *B* until each successive hole is brought in line with the center of the spindle.

This attachment can be adapted to a great variety of work and by graduating the yoke it can be very quickly set to any desired distance off center. If it is intended to use it on a high-speed lathe it will be necessary to extend the yoke on both sides of the center in order that a counterbalance may be attached to the outer end to balance the weight of the chuck.

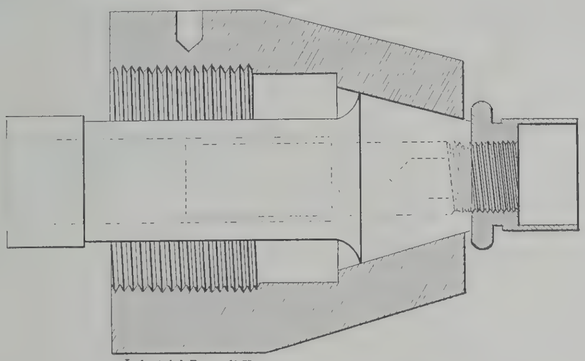
Burlingame, Kansas. CHAS. G. TAYLOR.

A SCREW MACHINE CHUCK.

Editor MACHINERY:

In the October issue of MACHINERY appeared an article under the heading: "A Screw Machine Chuck." I think the chuck is very expensive for the work done, and I send a sketch of a simple device that I have used for years, with good results, on the same class of work on a wire feed screw machine.

It consists of a plain piece the same size as the thread tapped in the piece to be operated upon, with one end threaded to fit the tapped hole.



Industrial Press, N.Y.

Chuck for use on Screw Machine.

The method of operating is to tighten the arbor in the chuck, screw on the piece, perform the operation; then to loosen the piece, open and close the wire feed chuck quickly which pushes the arbor out just enough to loosen the piece so that it can be easily unscrewed with the fingers.

Denver, Col. J. F. SHAY.

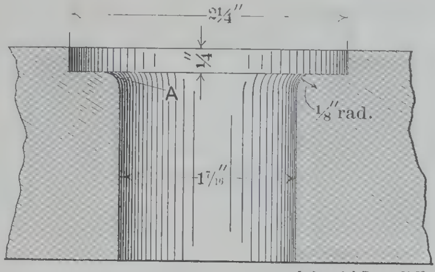
MORE COUNTERBORES.

Editor MACHINERY:

We recently made a tool for counterboring the holes shown in Fig. 1, and at the same time rounding the corners at *A*. The tool we first tried is shown in Fig. 2. It was simply a piece of 1 7-16 cold-rolled steel shafting with a 5-16 square tool held in by a setscrew. With the cutter properly ground and set it worked quite satisfactorily but as the cutter had to be removed for grinding and did not retain its form, it was somewhat difficult to keep it doing the work uniformly. So, an improvement being in order, we made the counterbore shown in Fig. 3, which is the tool now in use. There are two cutting edges and it is made to retain its proper form until comparatively worn out. The shank is tool steel, as well as the cutter, and the teat is hardened, having been ground to size after hardening.

Tools of this kind are quite readily made in the lathe. For this one a lathe was used with a four-pitch leadscrew and geared to cut one thread per inch. The cutter blank being turned it was put on an arbor in the centers and lines were scribed on the outside parallel to the axis and diametrically opposite, to indicate the location of the cutting teeth, and with the point of a thread tool a helical line was started from each parallel line and drawn half way around the blank. Then the gap in front of each tooth was cut in the shaper (on a radius) and the helix roughed out. The finishing was comparatively easy, the tool did not have to be withdrawn and the power crossfeed was used. A cut was started from the outside at one of the cutting edges and fed toward the center; when the opposite gap reached the tool the leadscrew nut was disengaged and the carriage moved back two threads on the leadscrew. The cut was then continued as before. The lathe was run by power part of each half revolution.

It will be seen that matters were much facilitated by the even pitch of leadscrew and by lathe being geared to 1 inch of carriage travel per revolution of spindle. With an uneven pitch of thread on the leadscrew it would have been necessary to withdraw the tool at each gap and it would have been more difficult to get the cutting edges on a line at right angles to the axis. The same trouble would have been experienced if the lathe had been geared to a fraction of an inch. It may not always be possible to gear the lathe to a pitch so well suited to easy manipulation as we did with this tool, but in this case it produced a nice angle of clearance. Taking the largest diameter, 2¼ inches, the circumference is 7.07 inches and with one inch advance per revolution the clearance is about 8 degrees, increasing toward the center.



Industrial Press, N.Y.

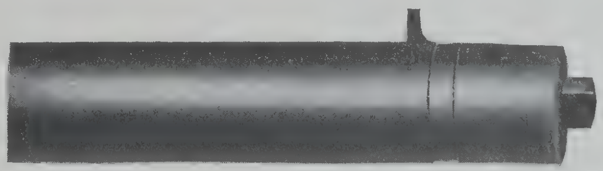
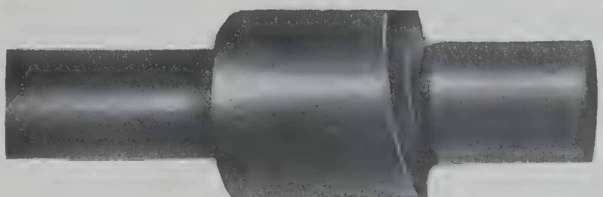
MARKING DRILLS AND TAPS.

Editor MACHINERY:

With all the progress that has been made within the last 20 years in small tools such as drills, taps and reamers, one thing has been lost sight of and that is the proper stamping of the same. As long as these were only hand tools the stamping as of old was all right, but this is no longer the case. But few shops have separate taps for hand and machine use, and when the hand tap is put into a chuck it is only a short time before the shank is so badly mutilated that the stamping is beyond recognition. For this reason the custom of marking the size on the shank, just below the square, is entirely out of place. Some manufacturers have adopted the plan of stamping reamers between the flutes and the shank, which is the only correct way.





INDUSTRIAL PRESS N.Y.

Fig. 2. The First Counterbore. Fig. 3. The Present Counterbore.

For marking taps, as most of the taps of the present day are made with concave flutes, I see no reason why they cannot be stamped there, if the marking wheel or stamp is made to conform to the shape of the flutes. This would however be practical only in sizes above, say, 3-16 inch. I do not think that the stamping in the flutes will influence the pitch or make the tap warp enough to cause any trouble.

The troubles with taps and reamers, however, are nothing compared with those which arise from the improper marking of the twist drill. The number of sizes is so unlimited and the difference in sizes so slight that accurate marking is an absolute necessity. If one looks over a lot of twist drills that have been in use for some time he will find that some of them are worn a full thirty-second of an inch below size and any marks that may have been on the shank have long since been obliterated.

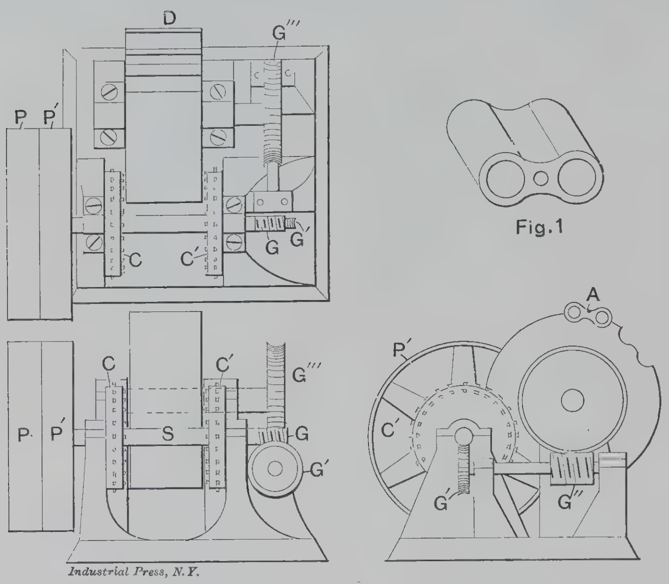


Fig.1

Industrial Press, N.Y.

Fig.2

Machine for Continuous Milling.

In a tool room where hundreds of drills are exchanged every day the time lost in looking up the sizes is by no means a small matter, not taking into consideration the amount of work that is spoiled, due to mistakes arising from lack of proper markings.

Now, as a remedy for these troubles, I would suggest that a flat be milled at the upper end of one of the flutes and the drills marked on this flat. This need not be very large, for small figures that will stay are much better than the present large figures that are worn off after the drill has been used a few times. The milling need not be very deep, as that part of the drill nearest to the flute is worn the least.

Another way would be to turn a small groove around the shank near the flutes, but this would have the objection of weakening the drill and would not be practical with the smaller sizes.

I would like to hear from some of the readers of MACHINERY on this subject, in hopes that a better method might be adopted for marking this much abused tool. Even if the stamping added a slight increase to the cost, the benefit derived would certainly warrant it. CHAS P. THIEL.

Lawrence, Mass.

A CONTINUOUS MILLING MACHINE.

Editor MACHINERY:

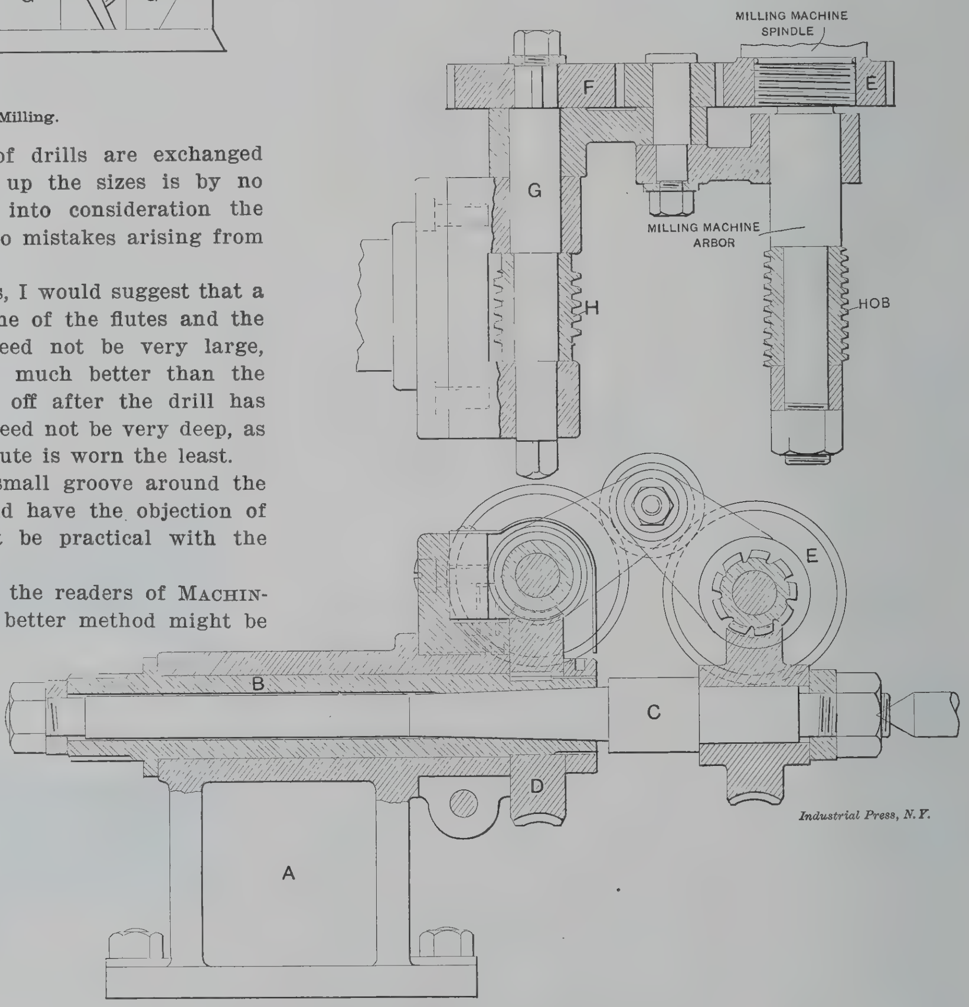
In Fig. 1 is shown a piece of work, a large number of which were to be finished on each end, all to be of the same length. This was accomplished in the continuous milling machine shown in Fig. 2. On the shaft S, bearing the tight and loose pulleys P and P', is mounted a pair of inserted tooth milling cutters, C, C', which are set the proper distance apart to enable them to face both ends of the work to the required length. On the outboard end of this shaft is worm G driving the wormwheel G'. This in turn drives the second worm G'' and the wormwheel G''', which is on the end of the shaft carrying the drum D. The periphery of this drum is shaped to form a series of seats suitable for holding the work. Only two of these seats are shown in the sketch, but on the machine they are continued around the entire circumference. A piece of work is fastened into each of these pockets, as at A, and is slowly fed between the milling cutters by the revolving drum. As each finished piece comes out from the cutters it is removed and an unfinished piece put in its place without stopping the machine. The surface of the drum is thus kept continually covered with work and the operation is continuous.

Connersville, Ind. E. M. BURGESS.

A HOBBING ATTACHMENT FOR THE MILLING MACHINE.

Editor MACHINERY:

In our line of work we have to make quite a number of wormwheels and until recently they were cut by first being nicked with a gear cutter and then finished with a hob, the hob rotating the wheel as it was cut. This was a very slow job so I made the device shown in the sketch which did away with the nicking and indexing. We had a headstock like A, which was used for circular milling; from this I removed the spindle B and bored out the rear end of it to suit a standard taper. I then made an arbor, C, on which was placed the wormwheel to be hobbed. The gear E fitted on the nose of the milling machine spindle and had the same number of teeth as the wormwheel D; and the gear F, on the shaft G, had the same number of teeth as the worm gear to be hobbed. This arrangement feeds the blank around at exactly the same rate that it would be fed by the hob and at the same time relieves the hob from all work other than the actual cutting of the teeth. Worm gears of any number of teeth can be cut by changing the gear F to one having the same number of teeth as is desired for the worm gear. Both hob and worm H have single right-hand threads, so for hobbing left-hand worm gears two intermediate gears are placed between gears E and F. For cutting gears of coarse pitch the foot stock center is used to support the arbor C. With this device we are able to finish worm gears in about one-quarter of our former time.



Industrial Press, N.Y.

Milling Machine Attachment for Hobbing Worm Wheels.

Hamilton, Ohio. HERMAN ISLER.

COMPOUND INDEXING.

Editor MACHINERY:

Having charge of the milling machines in a shop where a great variety of gears had to be cut on machines having but one index plate, it so happened that we had to send many of the blanks to be cut outside or spend a great deal of time figuring out the movements for compound indexing. I therefore made out a list of the gears that could not be cut with any single circle but which we could cut by compound indexing with two circles. I found 65 of these, as will be seen by referring to the accompanying table. This table is made out for use with the index plate of a Cincinnati milling machine, but is, of course, applicable to any index head in which the ratio of the worm to the worm gear is 1 to 40.

In order to use the compound indexing method it was only necessary to make a small index pin, mounted in a slotted brass casting, which was bolted on one of the screws used for clamping the dividing head. The side locking device having been removed, the index pin in the back holds the plate rigid while the forward movements are being made.

In referring to the table, the plus sign (+) indicates that the movements should be in the same direction, to the right; the minus sign (—) indicates that the first movement, at the left of the sign, should be made to the right, while the second movement, at the right of the sign, should be made to the left.

TABLE FOR COMPOUND INDEXING ON CINCINNATI MILLING MACHINE.

111	66	22 + 1	37	204	34	1 + 11	66	294	49	23 — 6	18
114	42	28 — 12	38	207	18	7 — 9	46	301	43	18 — 8	28
117	39	9 + 6	54	209	38	9 — 3	66	306	54	15 — 5	34
119	42	24 — 8	34	217	28	2 + 7	62	308	66	18 — 4	28
123	41	27 — 22	66	222	37	19 — 18	54	329	47	46 — 24	28
126	42	4 + 4	18	228	38	13 — 9	54	333	54	24 — 12	37
129	18	6 — 1	43	231	28	4 + 2	66	336	42	12 — 4	24
133	38	6 + 7	49	234	54	12 — 2	39	342	54	12 — 4	38
138	18	6 — 2	46	238	34	30 — 35	49	345	46	13 — 5	30
141	47	29 — 6	18	246	41	34 — 36	54	348	58	26 — 6	18
147	39	13 — 3	49	252	18	2 + 2	42	351	54	2 + 3	39
153	54	3 + 7	34					357	42	1 + 3	34

For example: To secure 51 divisions, we first move 28 holes on the 42 circle and 4 holes on the 34 circle, both movements being made to the right. This gives us

$$\frac{28}{42} + \frac{4}{34} = \frac{1120}{1428}$$

of one revolution of the worm and, since the ratio of the worm to the worm wheel is 1 to 40, we have

$$\frac{1}{40} \times \frac{1120}{1428} = \frac{1}{51}$$

of a revolution of the spindle.

For an example of the second case: Suppose that we wish to obtain 69 divisions, we would first move to the right 16 holes on the 24 circle and then to the left 4 holes on the 46 circle. This gives us $\frac{16}{24} - \frac{4}{46} \times \frac{1}{40} = \frac{1}{69}$ of a revolution of the spindle.

In executing movements to the left, pass the required hole then turn to the right to the proper hole. This avoids errors caused by back-lash in the worm gear.

Chicago, Ill. ROBERT A. LACHMANN.

SENSITIVE ATTACHMENT FOR MEASURING INSTRUMENTS.

Editor MACHINERY:

I have often wondered why the system of sensitive measurement such as is found on a Bath indicator is not more extensively used. No matter how finely and accurately micrometers and verniers may be made, dependence must in all cases be placed on the sensitiveness of a man's hand to obtain the exact dimensions of the piece to be measured. In order to overcome this difficulty and eliminate the personal equation in the manufacture of duplicate and interchangeable parts, I have tried the sensitive attachment to the micrometer shown in Fig. 1 and found it of much value.

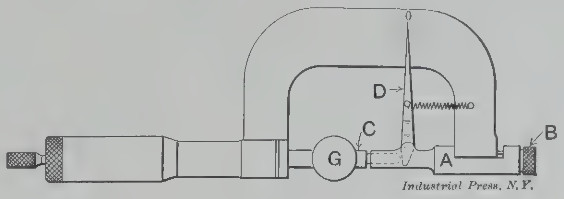

Fig. 1. Sensitive Attachment applied to the Micrometer.

The auxiliary barrel *A* is held to the anvil of the micrometer by means of a thumb screw *B*. In the inside end of the barrel is a secondary anvil *C*, the base of which bears against the short arm of the indicating lever *D*. The action will be clearly seen by reference to the cut. The micrometer is so set that when a gage, *G*, of exact size is placed between the measuring points the long arm of the indicator stands at the 0 mark. If the pieces being calipered vary in the least from the standard size it will be readily noted by the movement of the pointer. Hard rubber spheres turned from rough casting were found to vary from 3 to 5 thousandths after having passed the inspector's test with an ordinary micrometer. With this attachment the inspector's helper could detect very minute variations from the limit size. The same device was used to gage the size of small brass disks about half the diameter of the rubber spheres, and in fact anything within the limits of the micrometer can be made to show to the naked eye variations as small as a ten thousandth.

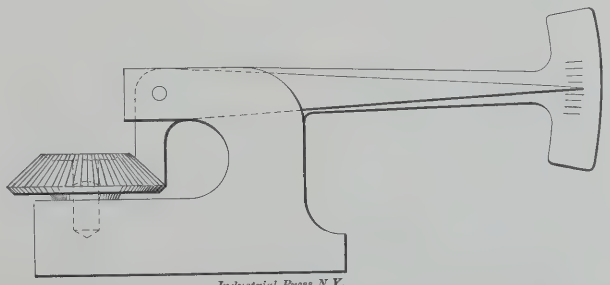

Fig. 2. Sensitive Attachment applied to Gaging Bevel Gear Blanks.

Considerable trouble was experienced with a pair of small brass miters because of the difficulty of getting the outside diameter just right. Inasmuch as they were finished on a screw machine some of the holes were not concentric with the face, causing the gears to bind. Fig. 2 shows a gage which was quite inexpensive and at the same time showed up the slightest inaccuracy. I have given only two ways in which this sensitive idea may be applied and I am sure that a wider field of application will suggest itself as its merits become more appreciated. H. J. Bachmann.

New York, N. Y.

VALVE AND PISTON MOVEMENTS.

Editor Machinery:

The following article contains some rather peculiar and interesting facts regarding the valve and piston movements of a compound pumping engine, where the center of the flywheel is considerably above the center line of the crosshead.

The pump, as originally constructed, had a 32-inch steam and a 26-inch water cylinder with a 48-inch stroke, and made 23 double strokes per minute. It was equipped with steam operated piston valves. There were two pumps of this size and style placed side by side. These pumps were straight line, direct acting and did not have any flywheel, therefore, of course, the steam was not used expansively. The indicator card showed almost the same pressure when exhausting, as the initial pressure of the steam entering the cylinder. The pumps were supplied with high-pressure steam which had to be wire-drawn at the throttle to prevent too high speed. It can easily be seen from the foregoing statements that the pumps were not of the most efficient type. It was proposed, therefore, that the pumps be tandem compounded, duplexed, and a flywheel added—which was eventually done—and just here considerable trouble was experienced due to lack of room. The pumps were placed very close together and could not be moved. The diameter of the flywheel was limited by lack of head room and various other parts of the construction were also affected by lack of room, as will be seen later. After compounding, the steam cylinders were 22 inches and 40 inches in diameter. The stroke and the water cylinder were left the same as before. There were two flywheels each 12 feet in diameter but these two were not large enough for a very short cut off, but still answered the purpose very well.

Now, with these few words of explanation regarding the conditions which limited our construction I will proceed with the conditions which we found; presenting a couple of sketches to make clear the explanation. While the conditions here presented are not new, still I know of no other case of an engine in which the conditions are so exaggerated. Of course the case is frequently met, in the Westinghouse engines for instance, where the centers of flywheel and crosshead are not in line, but seldom to such an extent as here. Shaper heads are usually designed with a quick return, on the same principle, but there, there is no valve to contend with.

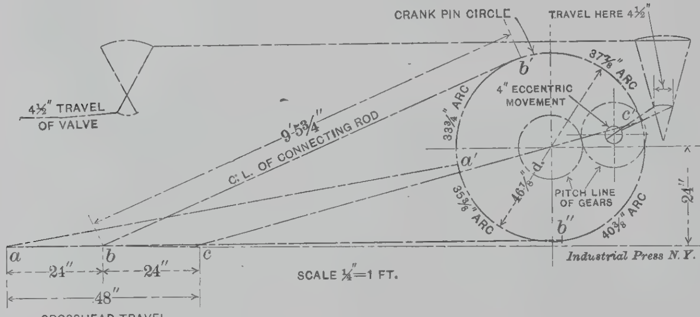

Fig. 1. First Arrangement.

As will be seen from the accompanying sketches, the travel of the crosshead is 48 inches, but the diameter of the crankpin circle is only 46⅞ inches. The length of connecting rod is 9 feet 5¾ inches, or a ratio of about 2½ to 1. The stroke of the valve, which was of the piston type, was 4½ inches.

Fig. 1 shows drawing as originally laid out and as the first model was made.

Fig. 2 shows the arrangement finally adopted.

Now starting the crosshead at a, which is the first dead center (and rotating crank pin in direction of arrow) when the crosshead reaches b, which is the first half of the out stroke, the crank pin will be at b',or will have traversed an arc of nearly 33¾ inches. While the crosshead travels the second half of the out stroke from b to c, the crank pin traverses an arc from b' to c', or nearly 37⅞ inches. During the first half of the in stroke the crosshead travels from c to b while the crank pin travels from c' to b'' or an arc of nearly 40⅜ inches. While during the last half of the in stroke the crosshead travels from b to a while the crankpin travels from b'' to a' or an arc of nearly 35⅜ inches. Now from these figures it can be seen that, with the fly wheel circumferential speed, or crank pin speed, remaining constant, the piston speed must vary considerably for each quarter and also for each half of the full double stroke. In fact the actual mean piston speed for each quarter of the stroke is as follows:

1st quarter from a' to b' is 192.1 feet per minute.
2nd quarter from b' to c' is 171.2 feet per minute.
3rd quarter from c' to b'' is 160.6 feet per minute.
4th quarter from b'' to a' is 183.3 feet per minute.

Thus the first quarter of the stroke is nearly 20 per cent. faster than the third quarter.

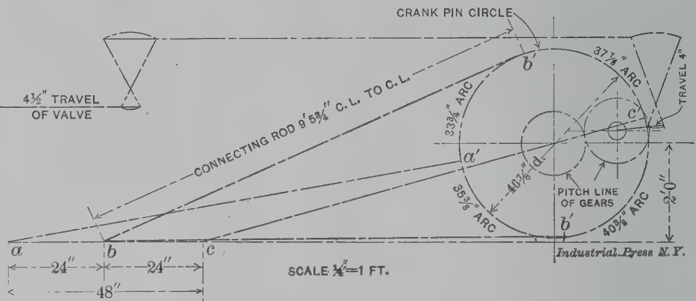

Fig. 2. Final Arrangement.

The eccentric which operated the valve could not be placed on the main shaft on account of the large diameter of the shaft and the lack of clearance room, so a gear was put on instead and this meshed with a similar gear on the eccentric shaft. The eccentric strap connected with a lever, which in turn operated a link, a lever, and another link until the valve was finally reached.

Now while the piston speed varied considerably, the valve speed was uniform because operated by the circumferential speed. Of course under these conditions no satisfactory kind of indicator card could be obtained, for when the lead and compression of both ends were equal there was 7 15-16 inches difference in the cut-offs, and the results were *vice versa* when the lengths of cut-off were equal.

To overcome this difficulty two methods were suggested, one, of making the angle between the eccentric strap center line and a horizontal line equal to the angle between the connecting rod center line and a horizontal line; also of making the ratio of the length of eccentric strap to the throw of the eccentric equal to the ratio of the length of connecting rod to the diameter of crank pin travel. By this method it was intended to make the speed of the valve directly proportional to the speed of the piston at all points.

The other method was to make cam gears to operate the eccentric. These cams were to be so shaped that the same result would be obtained.

The former method was chosen as being the more practicable and more likely to give satisfactory results.

A drawing was made and from the drawing a model, which made the piston and valve speed proportional at all points of the stroke, using the proportions explained above, when piston and valve started together from dead center; but when the advance was given to the valve, the first, or fastest, quarter travel of the valve was thrown so far ahead of the piston that the results were still poor. After changing the angle a few times, by trial, between the center line of eccentric strap and a horizontal line, the desired result was obtained as shown in Fig. 2.

These two pumps were duplexed and connected at an angle of 90 degrees, which produces the following conditions. When the crosshead of No. 1 pump is at a the crosshead of No. 2 pump is beyond b because the crank pin has an advance of 90 degrees or has traveled an arc of about 36 13-16 inches. When the crosshead of No. 1 pump has reached b the crosshead of No. 2 pump is not quite to c, because the second arc from b' to c' is more than 36 13-16 inches. During the third quarter of the revolution the piston of No. 1 pump still further gains on No. 2, but in the fourth quarter the reverse condition holds. This then presents a condition in which there is a never-ending alternate increase and decrease of distance between the two pistons, or for one-half the revolution there is less than a half stroke between the pistons and for the other half of the revolution there is more than a half stroke between them.

This, however, does not materially affect the efficient running of the pump. H. H. D.

DIES USING RUBBER AS AN AGENT FOR FORMING DIFFICULT SHAPES.

Editor MACHINERY:

The piece which is made by the dies herein described is used as a screw cap for cans, bottles, etc., and is a typical illustration of the class of work for which these dies are fitted.

Different manufacturers of such goods have different methods for rapidly producing formed blanks of this character. In some factories wax is used as an agent for forming blanks by first filling the cup-shaped blank with melted wax, and then placing under pressure. But the use of wax necessitates melting, after blank has been formed in order that the wax may be removed. Another method is to draw the blank to a cup shape and then roll the thread on, which is a very economical way where there is no bead on top of the blank.

The dies described in this article were constructed to use rubber for forming the blank and proved to be very satisfactory.

The first step in the production of the screw cap is to determine the proper diameter to make the blanking punch and die. If a formed blank is furnished as a model, then the die maker may determine the proper diameter of blanking die, by scribing a circle with a pair of dividers on a piece of sheet metal the exact thickness and of same material as the model. The circular piece is then cut out, and by carefully reducing diameter until it balances exactly with model, he may then proceed to make blanking die of same diameter as the round piece cut from the sheet metal. It is necessary that the balance scales used be very accurate.

When a bottle or can is furnished as model, then the die maker must depend largely upon former experience and also the familiar method of "cut and try." For cheaply producing any style of drawn work, a double-action press is used when possible. The shaft of such a press has two cranks or eccentrics so arranged that as the blanking punch starts on the upward stroke, after punching out a blank, the drawing punch descends through center of blanking punch and forces blank through the drawing die, which is in the center of the blanking die. This arrangement will be clearly understood by referring to Fig. 2. The edges of drawing die are well rounded, and the end of drawing punch is made on the same radius as the top of the model, and same diameter as the inside. The blank, of course, takes same shape as drawing punch, thereby lessening the amount of work for the rubber to perform.

In "setting up" a drawing die, the essential point lies in having the blanking punch "iron the blank." In other words the press is so adjusted that blanking punch presses the blank firmly at bottom of die at *S*, Fig. 2; otherwise the blanks will not draw evenly, or be of a uniform height. The stock is well oiled with a lubricant consisting of ¾ parts of pure lard oil and ¼ of soft soap thoroughly mixed. The blanks as they appear after passing through drawing die are shown at *A*, Fig. 1. They are then placed on a revolving lathe spindle that has been turned to exactly fit them on the inside. The tail spindle is turned to conform with outside end and is so constructed that when brought to bear on blank by means of a lever, the friction causes the tail spindle to revolve. The lever end of tail spindle has a ball or knob turned thereon, that runs in a ball bearing seat to reduce friction. An ordinary knurl, straight across the face, is then brought to bear upon the blanks, and it is knurled as shown at *B*, Fig. 1.

The first thing to be considered in constructing the forming die is the selection of a rigid, powerful press as it requires quite a little power to force metal. Having decided upon the press, a cast iron bolster, *B*, is made. This is shown, with the dies in place, in Fig. 4. It should have all bearing surface possible upon the bed of press, and be as thick as stroke of press and length of punch will allow. It is planed on the bottom and the dovetail on top in which the dies slide, great care being exercised to have the angular sides parallel. A hole is drilled at *C* for the adjusting screw and holes are drilled and tapped for the set screws *AA* to fasten securely one half of die and to adjust the gib for the other half. The next step is making the dies. They are made in halves as shown in Fig. 3. The steel is selected of a high grade and properly annealed. They are then planed all over to within 1-32 inch of finish size and annealed again. Annealing after scale has been removed is to remove, as far as possible, the strain that must be in the steel, and the probability of their changing during hardening, is much lessened. The dies are then planed to required size, and beveled to fit the bolster, allowance being made for the gib. One half of the die is drilled and counterbored at *C*, for the lever hinge which is shown in place in Fig. 4. A holder or sub-bolster is then made to hold dies securely while they are being turned in the lathe. The dies are then placed in this holder and fastened by means of set screws.

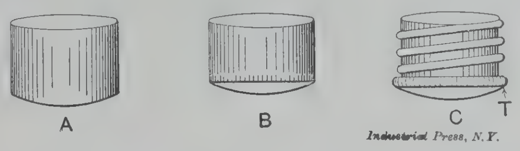

Fig. 1. A, The Blank. B, The Blank after Knurling. C, The Completed Cap.

The line where two halves meet is carefully prick punched in center of dies. The proper pitch of model is then ascertained by dividing 1 inch by the distance from center of one thread to the center of next. A templet is filed to the shape of thread and an inside thread tool made to match the templet.

The holder, or sub-bolster, is fastened to faceplate, the dies "wriggled up" by prick punch mark, and a hole bored the same diameter as inside of blank, ¾ inch deeper than length of model. The bottom of hole is turned the same radius as the model. Then, starting ¾ inch below surface of die, the hole is enlarged to diameter of outside of blank *B*, Fig. 2. The lathe is then geared to cut proper pitch, the thread is chased and the recess is bored for the bead *T*, Fig. 1. By leaving the hole at top of die the same diameter as inside of blank, the edges of the blank are prevented from cutting the rubber, besides allowing a tight fit for the punch, thereby positively confining the rubber.

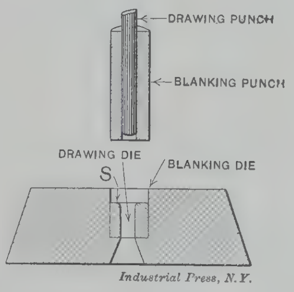

Fig. 2. Section through Double Action Press.

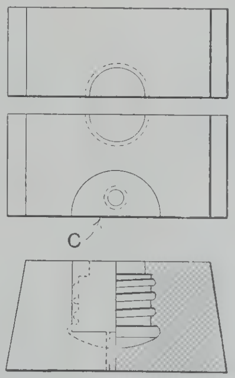

Fig. 3. The Die used in Forming the Cap.

The impression in the die is well polished, as the tool marks will show on blank if they are left as turned. The bolster or holder is then removed from lathe and without disturbing the dies, the impression is poured full of babbitt, after having been first treated with a light coating of graphite to prevent the babbitt from sticking. When thoroughly cool the dies are removed from the holder and the babbitt taken from impression and laid aside for the time being. A piece of rubber such as is used for wagon springs is turned or shaped to fit inside of the blank, sufficiently free to allow it to be easily inserted and removed and of a length that reaches nearly to top surface of dies when it is placed in the blank in the die.

Before hardening, the dies are placed in the bolster, the half *P*, Fig. 4, is fastened securely by means of the set screws and the half *R* is adjusted by means of gib and set screws so that it slides freely when moved by the lever.

The dies are then closed and the lever hinge *I* adjusted so that when the dies are together, the two parts of the joint *G* will be in a straight line, thus preventing the dies from opening when under pressure. This adjustment is accomplished by the screw *E* which is retained in its position by the check nuts, *F F*. The dies are then ready to be aligned with the punch.

In aligning the die and punch, the ram of press which holds the punch is lowered until punch nearly touches the die. The bolster is then raised by placing a substantial stick of wood up through bed of press, and lifting bolster with knee, using both hands to guide it. When the punch enters the die, the ram is lowered until bolster rests on bed of press, in which position it is firmly fastened. By pulling over the lever the dies are opened. A knurled blank, containing the piece of rubber, is now inserted and the dies closed. The rubber does not compress, when under pressure, so when the punch descends upon it the metal is forced out where not supported by the dies. When the punch ascends, the rubber returns to its original shape and is easily removed from the finished blank.

One or two blanks are formed while the dies are soft, to prove that they are correct, after which they are hardened. To get best results they are packed in a crucible, using ground bone to exclude air and insure an even heat. The degree to which they are heated will depend upon the quality of the steel, and the die maker must, therefore, be familiar with the grade of steel used. When the proper heat has been attained, the dies are immersed one at a time in a bath of clear water previously warmed. They should be held in one place, as the swashing back and forth tends to cause them to warp. As soon as the hand can be borne against the dies in the bath, they are removed, polished with emery cloth and placed at one side of fire on hot ashes until the proper color denoting temper appears. It is customary with a great many tool makers to constantly wipe the face of the die with oily waste while drawing temper. But it is not good practice, as the oil burns on die, and produces a deep straw color; and when die is cool, that same color can easily be wiped off. Therefore it is better not to put anything on die that is liable to produce a false temper. After hardening, the dies are soldered together, using the babbitt mold to keep them in line, and ground first on the bottom, then the beveled sides, and lastly the top. The faces where the two halves come together are lapped to insure a perfect joint. The dies may now be replaced in the bolster and, having been adjusted as before, are then ready for operation.

Frank E. Shailor.

New Haven, Ct.

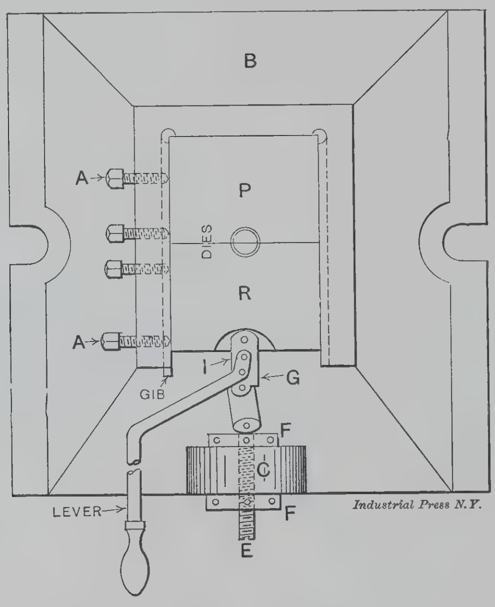

Fig. 4. The Dies in Position in the Bolster.

CLASSIFICATION OF MACHINERY AT THE ST. LOUIS EXPOSITION.

As far as now determined, the exhibits of machinery at St. Louis will be grouped under five headings, as follows: Prime Movers; Transmission of Power; General Machinery; Machine Tools; Arsenal Tools. It is not stated in the information at hand whether the section "General Machinery" will include agricultural machinery, printing machinery, typewriters, automobiles, and other lines not specified above, or whether these will be displayed in other departments of the exposition. The information so far furnished is as follows:

Prime Movers.—The generation of power from steam will be shown by the operation of all the items which go to make up a complete plant. This will include boilers and their accessories in operation, such as appliances for boiler feeding, water purifiers, fuel economizers, superheaters, chimneys, smoke consumers, grate bars, flue cleaners. The appliances for the transmission of steam, which include systems of steam piping, joints, gaskets, valves, traps, separators, condensers, etc., will lead to the prime movers using steam. Every type of steam engine, whether stationary or portable, reciprocating or rotary, will be included, together with such parts as may need special mention, such as valve gears, governors, and apparatus for lubrication. To this group will be added all other vapor engines, hydraulic motors, and the apparatus for testing the above machines. These latter will include turbines, water wheels of the tangential type, water pressure engines, etc.; gas engines and the kindred types of petroleum, carbonic acid gas, alcohol and compressed air motors; also the parts and fittings for such machines, and various other motors not specified.

Transmission of Power.—Such appliances as are essential to the transmission of power, and go to make up the last factor in the development and use of power. Under this head will be found shafting, pulleys, belts, cables, lubricators, etc., while in the proper delivery of the power thus generated will naturally be associated such apparatus as is necessary to record its performance. Thus we will find here, counters, speed indicators, dynamometers, weighing machines, testing machines, etc.

General Machinery.—Machines for moving heavy bodies, including cranes, hoists, conveyors, etc., all machines for raising water, such as pumps, hydraulic rams, and systems of piping for gas, water and air. Ventilators and blowers will be included in this group. To it will also be added fire engines, hose, and all apparatus used by firemen.

Machine Tools.—Machines for working in metal and wood will be included in this classification. In this section will be found steam hammers, machines for punching, shearing, etc., methods for working metals and the tools used in connection with these processes. Automatic machine tools, and all machines with cutting tools, such as planers, millers, drills, lathes, etc., together with such machines as are used for grinding and polishing will also be exhibited here.

Hand and hand with the advancement in metal working machinery are machines for working in wood. These include machines for sawing, planing, turning, etc., for polishing and veneering, and special machines, such as nailing, box and basket making machinery. To these classes will be added such hand tools as are essential in their manufacture, including vises, files, taps, dies, knives, graving tools, etc.

Arsenal Tools.—The increasing perfection in the world's armament and the improvements in all kinds of firearms, have brought with them the necessity for special tools, and methods of shop practice. That these facts may be recognized, these machines have been set apart in a special grouping known as "Arsenal Tools." This will include machines for forging, milling, polishing, etc., in the manufacture of guns and different arms. Also tools for the manufacture of cartridges and ammunition for both military and sportsmen's use.

* * *

According to *Poor's Manual* for 1902 the total railroad mileage in the United States on December 31, 1901, was 198,787 miles, or practically now 200,000 miles. One-half this mileage has been built since 1882.

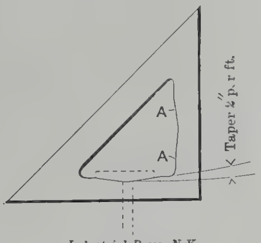
CONTRIBUTED NOTES AND SHOP KINKS.

SCALES WITH 1-100 GRADUATIONS.

X. Y. Z., Richmond, Va., writes: Many mechanics when they buy new scales still buy those without any tenths or hundredths graduation. All the principal manufacturers of scales make them and sell them at the same price as the old timers. Every up-to-date shop is using the decimal system in laying out work. It may therefore be well for apprentices and other mechanics who need new scales to buy the tempered ones with the 1-100th graduations along with the 1-16, 1-32 and 1-64 graduations; that is if they are not decided which to get.

A TRIANGLE KINK.

P. P. P. sends a drafting room kink which should prove of convenience to anyone engaged in structural drafting. Cut out the inner edges of the triangle to a taper of 2 inches per foot, as shown at *A*, *A*. This gives the proper angle for the taper of flanges of I-beams and channels.

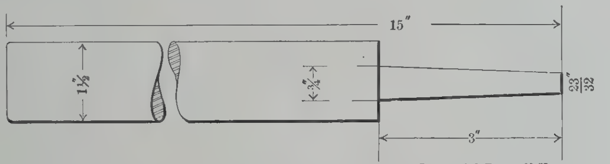


Industrial Press, N.Y.

SETTING THE HEADSTOCK FOR TAPER.

W. H. N., Chicago, Ill., sends the following kink in regard to turning a taper by setting over the headstock:

I had occasion to turn the taper shank shown below and not liking the usual cut and try method of doing the job I figured out the required set-over as follows: The difference in diameter is seen to be 1-32 inch in 3 inches, equal to an axial taper of 1-64 inch. For a total length of 15 inches this would be 15-3 × 1-64 = 5-64. This is the amount that the tailstock must be set over.



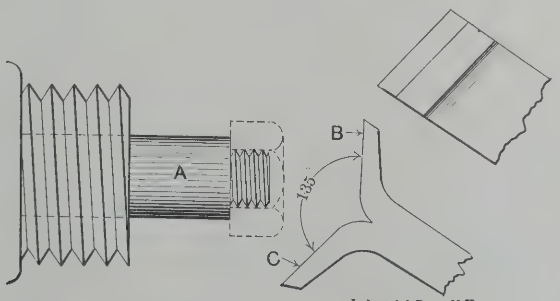
Industrial Press, N.Y.

Now the set-over screw had 12 threads per inch, so to give an advance of 5-64 inch it must be given 5-64 ÷ 1-12 times = 60-64 or 15-16 of a turn.

By putting a line on the side of the setscrew I was able to estimate the 15-16 of a turn very nearly, so that after the trial cut, the adjustment had to be altered but very little.

TOOL FOR FACING AND CHAMFERING NUTS.

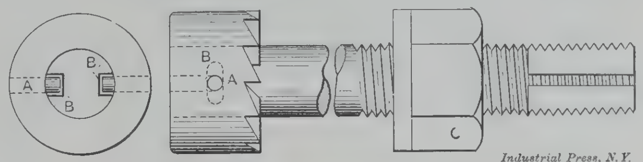
G. M. Strombeck, Moline, Ill., sends a sketch of a tool that he uses for facing and chamfering nuts in the lathe. The arbor *A* fits the hole in the end of the lathe spindle, and has a short thread at its outer end onto which the nut is screwed, as shown by the dotted lines. The tool has two cutting edges, *B* and *C* which make an angle of 135 degrees with each other. The nut is first faced with the edge *B*, and then chamfered with the edge *C*, after which it is removed, turned around and the bottom finished with the edge *B*, this completing the operation.



Industrial Press N.Y.

A BACK-FACING BAR.

Mr. Fred. Harrison, Philadelphia, Pa., sends us the sketch of a back-facing bar which, he claims, is a great improvement on the ordinary facing bar with a double cutter that is continually breaking. The object of this cutter is to do away with the keys which, in the old-style bar, are used to hold the cutter up. A rose milling cutter, after being hardened is fitted with the pins *A A*, while the end of the bar is fitted with slots *B B* for the reception of these pins. By this arrangement it is necessary only to slip the cutter on the end of the bar when a slight turn locks it securely in place. When the work is completed the cutter is simply turned forward and slid from the end of the bar.



Industrial Press, N.Y.

A nut *C* provides for feeding the cutter up to the link. The upper end of the bar is made square for the reception of a wrench, or it may be made tapering and the bar driven by power.

SPECIAL LATHE DOG.

C. D. King, Brooklyn, N. Y., sends us a "kink" that he has used for turning pieces having a square head, as shown in Fig. 1, but which will be found equally convenient for turning bolts or anything of a similar shape. It consists of the sheet steel piece *A* which is bolted to the faceplate, as shown in Fig. 2. In this strap is a slot through which the head of the bolt is passed when it is put onto the lathe center. The sides of the slot serve to drive the work, thus dispensing with the use of a lathe dog.

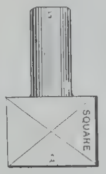


Fig. 1

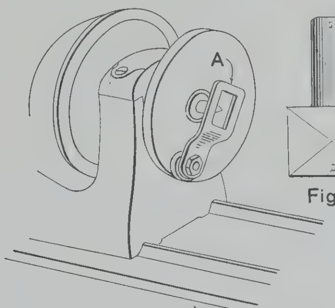

Fig. 2

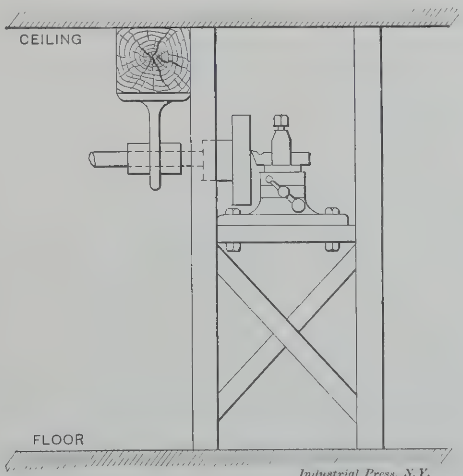
Industrial Press, N.Y.

HOW A FLANGE COUPLING WAS REPAIRED.

R. H. Hampson, Anniston, Ala., sends us an account of a rather ingenious repair job which he recently performed. The coupling of a jack-shaft had become loose and it was desired to replace it. As the shaft was seven inches in diameter and the pulleys were keyed on solidly, it would have been a very long and expensive job to have removed them in order to turn the shaft in a lathe; so the work was ac-



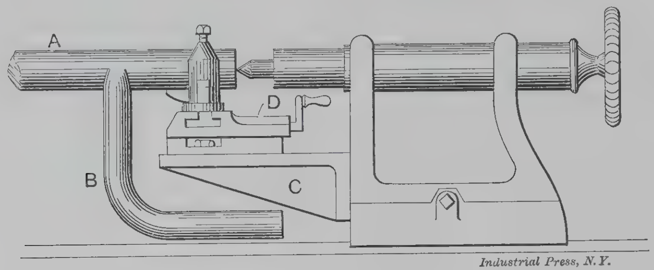
Industrial Press, N.Y.

complished in the very simple manner shown in the sketch. Four pieces of 2x4 inch timber were securely fastened to both floor and ceiling and firmly cross-braced. At the proper height a platform was constructed, upon which was mounted a carriage taken from a lathe. The old coupling having been removed, the engine was run slowly and the shaft returned. The new coupling was then shrunk on and faced off in the same manner that the shaft had been turned.

TURNING AN AWKWARD SHAFT.

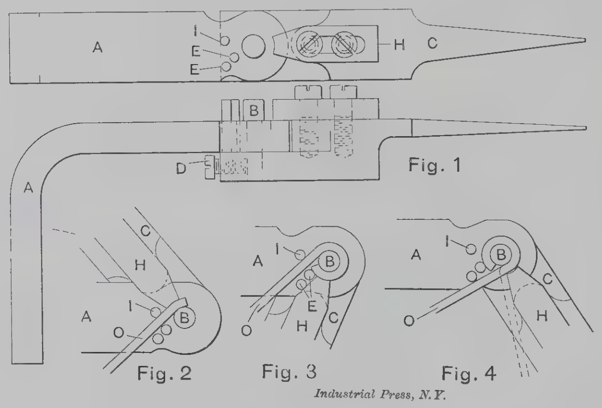
G. F. H. sends us the following:

The shaft shown in the figure was recently brought into the shop to have its journals re-turned, as they were badly worn. The curved arm, *B*, extended 6 inches beyond the end of the shaft, and when we had placed the shaft in the center of our 48-inch lathe we found we had not sufficient room to operate the lathe carriage. Finally we clamped the angle plate *C* to the front side of the tailstock and on this mounted the tool rest taken from a small lathe, as shown at *D*. Although we were obliged to feed this carriage by hand, we were able to do a very satisfactory job with this arrangement.



TOOL FOR BENDING EYES AND HOOKS.

C. D. King, Brooklyn, N. Y., describes a device which he recently made for bending eyes and hooks from wire. It consists of the angle piece *A* and the bending lever *C*. When in use, the angle piece is clamped by its lower end in a vise, shown by the dotted lines in Fig. 1. The bending lever is pivoted about the pin *B*, which is held in place by the set screw *D*. The pins *E*, *E* and *I*, are driven into the upper end of the angle piece *A*, which is cut away on either side to give sufficient swing for the lever *C*. This lever has a tang on which is driven a wooden handle, not shown, by which the fixture is operated, while on top is fastened, by two screws, the slotted movable finger *H*, which is adjusted for various sizes of eyes and wire.



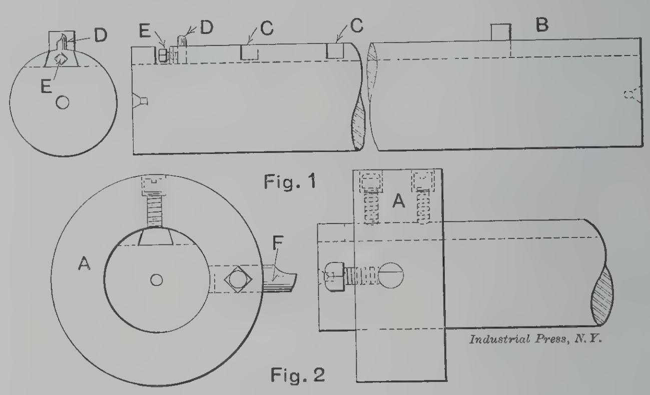
Hook and Eye Forming Tool.

The process of bending is as follows: The straight piece of wire *O*, Fig. 2, is slipped in between the pin *B* and the finger *H*, after the handle *C* has been brought to the starting position, as shown. *C* is now moved clockwise until it comes to the position shown in Fig. 3, and cannot go any farther as the finger *H* comes against the pins *E* and *E*. In these operations the pin *B* turns with the finger *H*, the wire being pinched between them by the bending action of the pin *I*, and the eye is completed all but giving a radial bend. It is now reversed, as seen in Fig. 4, and a small movement of the part *C* toward the left brings the stem *O* radial with the ring as indicated in dotted lines.

Several sizes of former pins *B* will be required for various sizes of eyes.

A CONVENIENT BORING BAR.

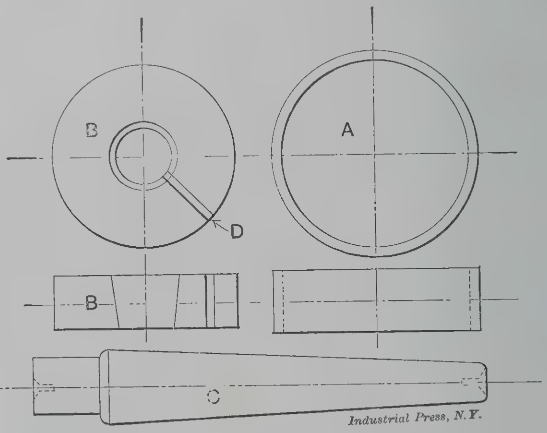
Those who occasionally have a small job of boring to do in the lathe will find such a bar as is described by W. W. Cowles, Waterbury, Conn., to be very practical and convenient. This bar is made from cold-rolled steel of any diameter and length, depending upon the work to be done. A dovetail slot is planed the entire length of the bar and fitted with the sliding rod, one end of which is turned up as shown at *B*, while the other end is drilled for the tool *D* that is held in place by the setscrew *E*. In boring out a long hole, where the work can be revolved by the face-plate and supported at the outer end by the center rest, the bar is placed on the lathe centers and prevented from turning by a dog against the tailstock. A tool is placed in the tool-post and the carriage run up until the tool strikes the lug *B*. By throwing in the feed the bar will now be pushed through the piece to be bored. Slots *C C* will have to be cut in the bar at intervals so that a wrench can be used on the set screw in the end of the feed rod. For boring larger holes the collar *A* is slipped over the bar and fastened to the feed rod by two screws as shown in Fig. 2. The cutter is then fastened in the collar as at *F*.



A Simple Boring Bar.

TURNING PISTON RINGS.

"Student" sends a "kink" which he has used for turning the outside of piston rings. The rings, shown at *A*, are first roughed out in a turret lathe and bored to the required inside diameter. The outside turning and facing off of the ends is done on the expanding head *B*. This head is bored to fit the taper arbor *C* and turned to fit loosely the bore of the rings. It is made narrow enough so that the ends of the rings project on either side. The ring is slipped onto the head and the taper arbor forced into the hole. The slot *D* in the head allows it to expand and firmly clamp the ring which is then finished in the lathe.



Rig for Turning Piston Rings.

* * *

In boring long cast iron tubes, say 16 inches in diameter, excellent results have been obtained by the use of kerosene as a lubricating agent. The holes were bored with a "packed bit," of the type used for gun boring and were finished as smooth as glass.

ITEMS OF MECHANICAL INTEREST.

LARGEST PULLEY BUILT—READING VERNIER CALIPERS—A TAKE-UP DEVICE FOR INDICATORS—NEW BELT LAW—HYDRAULIC BEAM SHEAR.

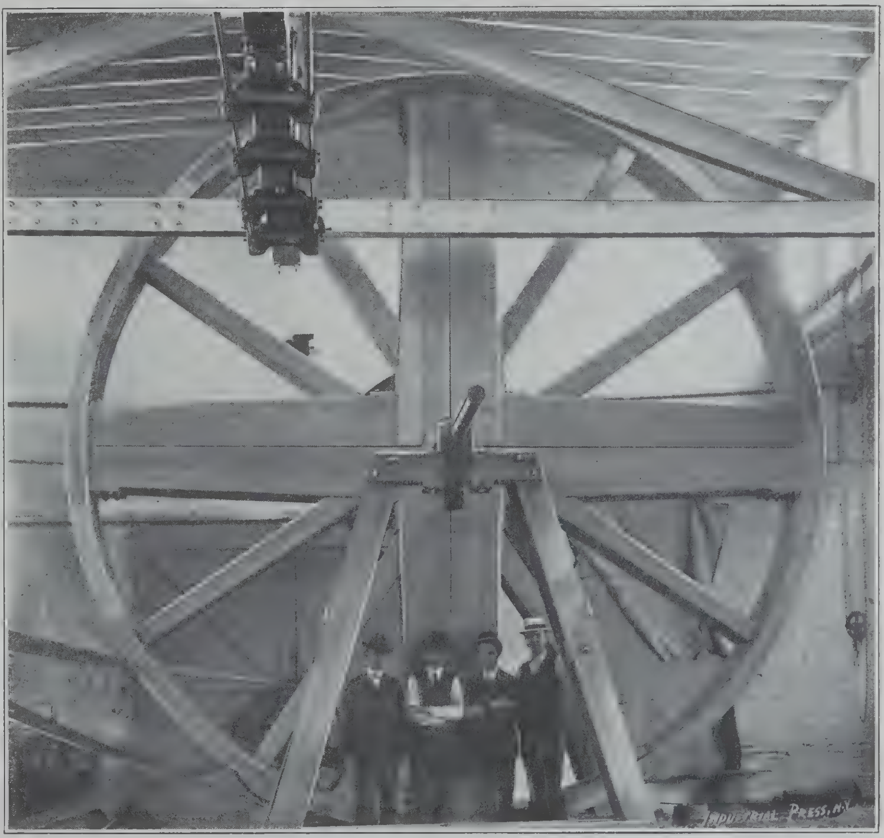
The *Canadian Electrical News* quotes a curious circumstance illustrating the difference in speed between sound, which travels through the air, and electricity through wire as its guide and conductor, that occurred in California. A certain powder works blew up in a town while a railway telegraph operator was telegraphing to another in a neighboring town. At the instant of the occurrence he telegraphed the news to the operator, who, sixty seconds afterward heard the report of the explosion. He knew it had occurred by wire just one minute before he heard the report. Sound travels at about the rate of 1,140 feet per second, while electricity accomplishes 186,000 miles in the same short period of time.

One of the changes likely to be made by the general use of electric power, is the displacement of the steam fire engine by the electric motor pump. Already in France the electric fire pump has been tried with success, being much lighter to handle and quicker to get into operation. One horse draws the pump to the fire and connection is made with the street car line circuit. The moment connection is made the pump is ready for business, and expense for power ceases the moment the current is shut off. If such a system of fire protection was developed for a city it would probably be that each fire hydrant would also be an electric "hydrant" having a socket for connecting the wires leading to the motor driving the pump. The system of electric mains could be laid underground and parallel with the water mains, where they would be reasonably secure from accidents.

A correspondent of the *Scientific American* suggests that calcium carbide may be used for quickly obtaining heavy pressures and that it might be made useful for baling cotton, hay, straw, and for many other kinds of work where heavy pressure is required for brief intervals of time. Its merit would lie in the simplicity of the apparatus. He has experimented with a four-foot steel pipe capped at one end and provided with a cap and stuffing box at the other end, through which a turned shaft was inserted carrying at its lower end a basket for the carbide. A release cock and gage reading to 400 pounds were also provided. The pipe was filled with water to a depth of six or eight inches. On lowering the carbide basket to the water and forcing the air out of the pipe, a second quick plunge forced the gage around to 400 pounds in three seconds.

A labor-saving device of the first order is a hydraulic tire setting machine for wagon wheels. The ordinary process of taking the tire off the wheel, cutting out a section, and welding the ends together, as followed by many blacksmith shops, takes considerable time and labor and is usually an unsatisfactory job in a number of ways. The distance between the bolt holes that straddle the weld is shortened, and unless the blacksmith is quite skillful the wheel is likely to be "dished" too much. With steel tires there is also the difficulty of getting perfect welds. To be sure there are tire upsetting machines which shorten the tire circumference without cutting and welding, but these require the tires to be removed from the wheels. The device referred to consists of a horizontal frame carrying, say, fourteen plungers attached to the inside of a strong circular ring and all pointing toward the center. The wheel with the tire in place is laid in the center of the ring so that the plungers bear on the tire. Then all are forced inward at the same time with a water pressure that may be carried up to 2,500 pounds per square inch. The amount the tire is shortened is under perfect control and consequently the amount of "dish." No dismantling or heating whatever is necessary. It is claimed that a tire can be set in one minute.

The use of graphite in soft paste form for lubricating bicycle and automobile chains, is by no means new, but its use in the form of cakes having a moderately high melting temperature, is comparatively so. Chain graphite is prepared in this form, by the Dixon Company, that requires a temperature of about 180 degrees F. to melt and it is to be applied to the chains while hot. It is melted in a shallow pan large enough to contain the chain coiled in a close spiral. The chain (which should be well-cleaned) is dipped and allowed to remain for some several minutes. This gives time for the air around the joints to escape and allows the graphite to penetrate to all the working parts. The advantages of chain graphite prepared in this manner, are that it forms a solid bushing around each rivet that is not easily displaced, and that it does not attract the dust and dirt of the highway.



Largest Wood Pulley ever Built.

A MONSTER WOOD PULLEY.

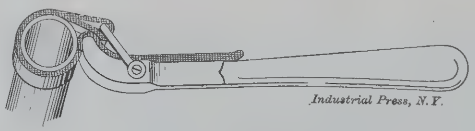
What is believed to be the largest wood pulley ever built was lately made by the Reeves Pulley Co., Columbus, Ind. This pulley, which is illustrated in the accompanying halftone, is 20 feet in diameter, has a face 30 inches wide, and is bored for an 18-inch shaft. Although larger than anything ever before attempted by the Reeves Co., this pulley was completed within 20 days from the time that the order was received. It was furnished to the Taunton-New Bedford Copper Co., New Bedford, Mass.

AN ELECTRIC WHIP.

While of no particular importance as an invention, a Georgia mail carrier has produced an electric whip which has the merit of novelty. He drove a letter carrier's wagon with doors that could be closed in case of rain. In stormy weather he naturally disliked to open one of the doors in order to reach out and apply the lash to his equine, which, being an intelligent animal, naturally took advantage of this situation and always lagged in rainy weather. To overcome this propensity the Georgia Edison attached a pair of copper plates under the harness saddle and connected them by wire to a hand operated dynamo in the wagon. When the steed began to jog up and down, without making much advance, it was time to turn the dynamo crank, which gave the horse a very evident wish to get over the ground more rapidly and almost any desired speed could be obtained, according to the number of rotations per minute given the dynamo armature. An apparatus is now contemplated, says the *Atlanta Constitution*, which paper has the distinction of first telling about this invention, for use on plows, whereby both the mule and plow hand shall be automatically shocked every few minutes. It is believed that such an attachment would find a tremendous sale all over the south, as by its use farmers could be very sure that no darkey would go to sleep between the plow handles.

WRENCH FOR SMOOTH PIPE AND TUBING.

The wrench shown in the cut has recently been brought out for use on polished pipes and tubing, where the scratches caused by the use of an ordinary wrench would mar the appearance of the pipes, or perhaps, of the entire machine. The canvas strap is passed around the pipe and held firmly by the pressure of the toe of the wrench, thus securely gripping the pipe without bringing any metallic part of the wrench in contact with the polished surface. The simple ratchet movement by which the wrench is operated, renders it especially convenient for use in close quarters, while its wide range makes it equivalent to three sizes of ordinary wrenches. An 18-inch wrench is applicable to all sizes from 1 inch to 5 inches in diameter, while a smaller size takes all pipe 1 inch diameter and under. This wrench is made by the Warnock Mfg. Co., of Boston, Mass.

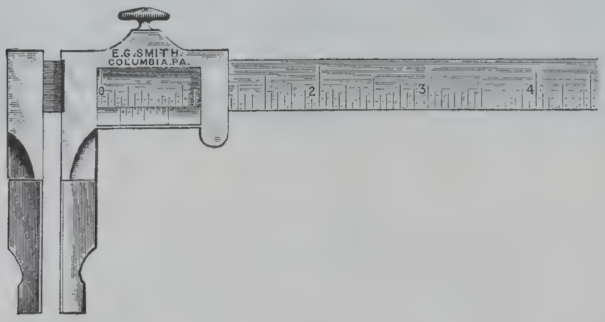


A Novel Pipe Wrench.

READING VERNIER CALIPERS.

The application of the vernier to beam calipers, for fine measurements, usually in thousandths, is familiar to most machinists. Less familiar, but equally convenient, is the use of the vernier for making the ordinary scale measurements in 16ths and sub-divisions thereof.

The cut shows a beam caliper with vernier slide, by the use of which measurements are made in 128ths of an inch. The beam is divided into 16ths of an inch, while a space of 7-16 on the vernier slide is divided into eight divisions, each one of which is consequently 1-128 inch less than 1-16. Now if the 0 line of the scale has passed a certain mark on the beam and the line at the right of the first space, on the scale, coincides with a line on the beam, then 1-128 inch must be added to the reading of the mark passed by the 0 line. If two spaces on the scale are passed before two lines correspond then 1-64 is added, and so on. In the cut it will be seen that the left hand, or 0 line, of the scale, has passed the ⅛ line on the beam and seven spaces on the scale have been passed before a line on both scale and beam coincides. Therefore 7-128 must be added to ⅛ to give the reading of the opening between the jaws of the caliper, that is 23-128 inch.



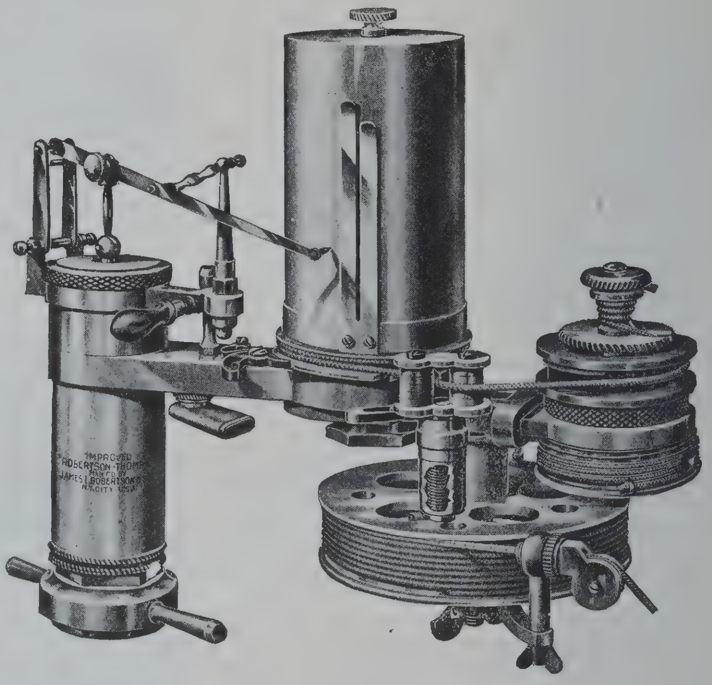
Vernier Caliper for Reading in 64ths and 128ths.

This method of graduating makes working to the ordinary scale dimensions a matter of much more accuracy than is possible with the use of the ordinary caliper and steel scale, besides being far easier on the eyes of the machinist. Calipers of the kind described are manufactured by E. G. Smith, Columbia, Pa.

A TAKE-UP DEVICE FOR USE IN CONNECTION WITH THE DETENT OF THE INDICATOR.

The majority of indicators in use at present are provided with a detent by means of which the paper drum is stopped and held stationary so that cards may be taken off and new ones put on without unhooking the cord from the crosshead. The great trouble that has been experienced in using the detent on the indicator has been caused by the slack of the cord between the drum and the reducing wheel. This slack, if not properly guided, is very likely to get fouled with some parts of the indicator and if the instrument is not wrecked the cord at least is broken, causing delay and inconvenience to the operator. In order to overcome this trouble a take-up device, which may be attached to any style of indicator, has lately been devised.

A short horizontal arm, which is fastened to the indicator, is provided at the outer end with a vertical bearing, at the upper end of which is a frame carrying two sets of steel rollers. Between these rollers passes the cord from the drum to the reducing wheel. On the lower end of the vertical bearing is a light enclosed spiral spring which causes the upper frame to revolve when the cord becomes slack as is the case when the detent is thrown in. The arrangement is such that as soon as the detent is thrown in, the cord from the reducing wheel, which ordinarily winds and unwinds from the barrel, is now automatically wound on the take-up frame while the barrel remains stationary. The spring in the take-up is so much weaker than that in the barrel that as soon as the detent is thrown out of action the cord immediately becomes taut between the drum and wheel and slides freely between the two sets of rollers on the vertical frame.



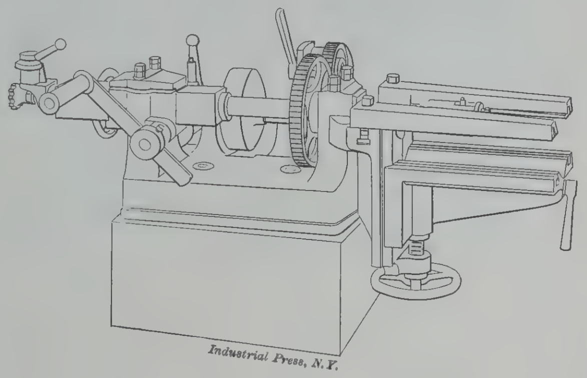
Indicator with Take-up Device.

The illustration shows the device as attached to one of the standard indicators. It is manufactured by James L. Robertson & Sons, New York.

A NEW BELT LAW.

The old law that the efficiency of a belt for transmission of power increases with its initial tension (to the limit of practical strain, of course) is so commonly accepted that the following results, directly opposed to that law, and which were sent us by the Cling-Surface Mfg. Co., Buffalo, N. Y., are of considerable mechanical interest.

Two new and identical 4-inch belts were used, leading from two similar 8-inch pulleys on the single shaft of a 10 horse power motor to two similar 12-inch pulleys on two similar generators. The centers were 8 feet. One belt had been treated with Cling-Surface, the other was as it came from the maker. A wattmeter was connected to each generator, and circuit and switches were arranged to throw full load on either generator. In the one case, intimate contact between belt and pulley was secured by the application of the Cling-Surface preparation and the tests showed that such a belt would not only run slack under full load, but would transmit more power when running slack than when running tight. This is due to the increased belt and pulley contact and great reduction of friction load. In the other case the frictional resistance between pulley and belt could be maintained only by increasing the tension and consequent normal pressure upon the pulley face, as the load increased. This resulted in increased friction load, and a reduction in the proportionate amount of power transmitted. The wattmeter readings were as follows:



Industrial Press, N.Y.

Fig. 1. Machine for Cutting Oil Grooves.

Four-inch Belt with Cling-Surface.

At 54 pounds initial tension, transmitted 7 3-5 horse power.
At 40 pounds initial tension, transmitted 7 4-5 horse power.
At 30 pounds initial tension, transmitted 8 1-5 horse power.
At 20 pounds initial tension, transmitted 8 4-5 horse power.
At 15 pounds initial tension, transmitted 9 1-5 horse power.
At 10 pounds initial tension, transmitted 10 horse power.

At this point with 8½ pounds initial tension on the belt the slack was so great that there was only 2¾ inches between the upper and lower side of the belt in the center.

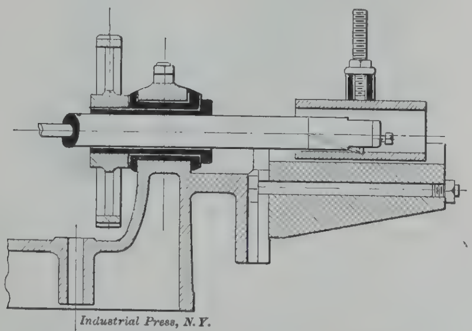
Four-inch Belt without Cling-Surface.

At 54 pounds initial tension, transmitted 7 3-5 horse power.
At 45 pounds initial tension, transmitted 6 horse power.
At 40 pounds initial tension, transmitted 5 1-5 horse power.
At 35 pounds initial tension, transmitted 4 3-5 horse power.
At 30 pounds initial tension, transmitted 4 horse power.

At 20 pounds initial tension, transmitted 3 2-5 horse power and there stopped. The belt here slipped around the pulley and would transmit no more power.

MACHINES FOR CUTTING OIL GROOVES.

Any machinist who has cut oil grooves in a long bushing with a hammer and chisel will be interested in the machine shown in Figs. 1 and 2, which is designed for doing this and similar kinds of oil groove cutting. Fig. 1 shows a general view of the machine, which is clamped to a bench in the same manner as a vise. The work is supported in a V rest which has an up-and-down adjustment operated by means of a handwheel. The tool is held in a bar and drawn through the hole in a manner similar to the action of a draw-cut shaper. By the provision of change gears, reversing gears and a friction clutch, it is possible to cut oil grooves straight, spiral, (right or left hand) or straight with spiral starting and ending. A micrometer feed and adjustable stop are provided for regulating the depth of the groove. The machine does better and more effective work than can be done by hand besides keeping collected together the chips that, when the work is done by hand, fly all over the shop. It is made by C. W. Burton, Griffiths & Co., Ludgate Square, London, E. C.

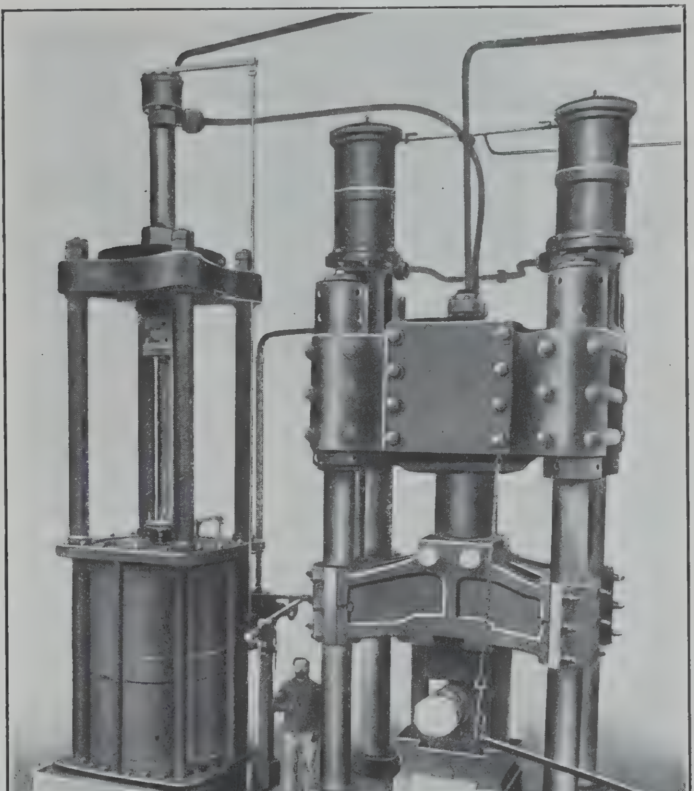


Industrial Press, N.Y.

Fig. 2. Cutting an Oil Groove in a Bushing.

ELECTRICALLY-OPERATED HYDRAULIC SHEAR.

Robert Grimshaw, Hanover, Germany, sends a photograph and brief description of an electric hydraulic beam shear, which in points of size and design is somewhat unusual. The machine consists of the shear proper and a pump driven by a 10 horse power electric motor. The shear has two cast-steel stands that are connected by a single steel casting which also forms the cylinder. The piston of the latter, which has leather packing, has at its lower end the tool-holder, which has side guides on the stand and receives in the best possible manner the side pressure unavoidable in shearing off beams of varying resistance. The lower guide prevents the tool from moving in a fore-and-aft direction. The stationary lower knife and the side knives are directly between the halves of the stand. These side knives may be adjusted by means of a spindle and hand wheel.



German Hydraulic Beam Shear.

After the bar has been cut off, water is admitted to the two reversing cylinders, shown at the top of the side columns. The pistons of these cylinders are connected with the sides of the tool holder and by them the shear is returned to cutting position. The water supply for both cylinders is controlled by valve gear on the side of the housing. The pressure pump, which is at the side of the machine, has a double piston. At first both pistons are in action, so as to expedite that part of the stroke where no work is being done; then, as soon as resistance is felt, one piston is thrown out and correspondingly higher pressure put on.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

COMBINATION TOOL FOR MACHINING STEAM ENGINE CYLINDERS AND FRAMES AT ONE SETTING.

One of the latest productions of the Beaman & Smith Co., Providence, R. I., is the combined milling and boring machine illustrated in Figs. 1 and 2. It is designed for machining small-sized engine frames of the type having cylinder, bedplate and crank-shaft bearing combined in one casting. Upon this machine these frames can be machined complete at one setting. A main boring spindle bores out the cylinder and faces it for the head, a milling cutter finishes the cross head guides, and a secondary boring spindle bores and faces the sides of the crank-shaft bearing.

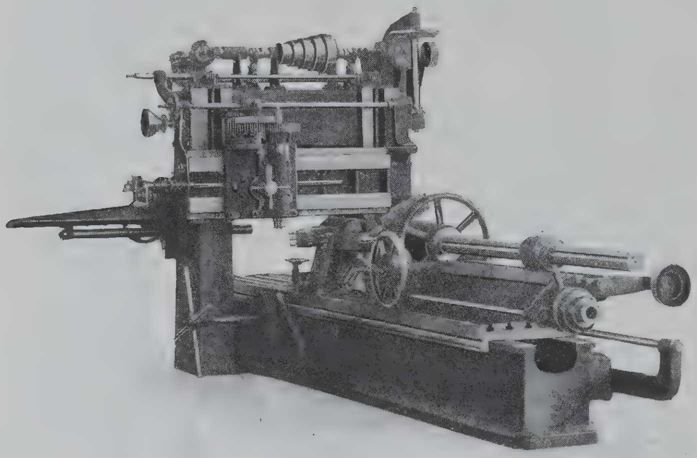


Fig. 1. Cylinder Machine, Front View.

The main boring spindle is 4 inches in diameter and is driven by a 3½-inch belt running on a five-section cone. A spindle speed of 20 feet per minute is suitable for boring cylinders from 4 to 19 inches in diameter. This spindle has a feed of 50 inches and will feed at the rate of 4, 6, 12, or 36 revolutions per inch of travel, in either direction. The facing capacity is from 4 inches to 24 inches in diameter and the tool feed, either in or out, is 1-30, 2-30, or 3-30 inch per revolution. Each facer has a fine adjustment, on its table, of 6 inches. This machine will bore and face cylinders up to 40 inches in diameter.

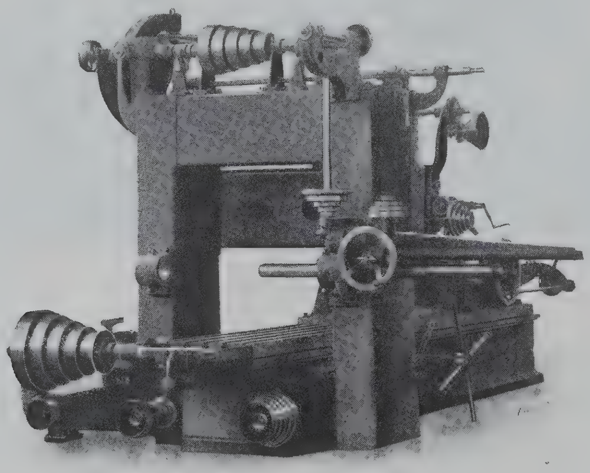

Fig. 2. Cylinder Machine, Back View.

The milling spindle, shown on the cross rail, is driven by a 3-inch belt on a five-section cone, giving speeds from 10 to 102 revolutions per minute. These speeds are suitable for cutters from ¾-inch to 7 inches in diameter running at a cutting speed of 20 feet per minute. The milling feeds run from 7 to 4 inches per minute at all speeds. The spindle has a feed on the cross rail of 40 inches and is adjustable above the table from 10 to 33 inches, 6 inches of which is the spindle head adjustment in the saddle.

The spindle used for boring the crank-shaft bearings is 3 inches in diameter and has a feed of 36 inches. It is driven by a 3-inch belt on the same cone that is used for driving the milling spindle, since the milling spindle and the crank-shaft boring bar are not used at the same time. Suitable clutches are provided for shifting from one mechanism to the other. This bar has boring speeds of 12, 16, 21, 28 or 37 revolutions per minute and is suitable for boring, at 20 feet per minute, from 2 to 6 inches in diameter. The feeds are 13 1-3, 40, 80 and 120 revolutions per inch of travel.

The table is 14 feet long and 24 inches wide, the working surface, from end of table to facing tool, being 8 feet and 3 inches. It is driven by a 3-inch stationary feed screw on which is a revolving nut provided with anti-friction ball bearings at each end. The feed is from 2 to 16 inches per minute, in either direction, regardless of milling spindle speeds. It has an automatic stop and a fast movement of about 15 feet per minute in either direction besides the hand movement. There is a clamping arrangement by which the table is locked when the machine is being used for cross milling or for boring crank-shaft bearings. The traverse of the table is about 9 feet 6 inches and the distance between uprights 40 inches. The boring spindle centers are 15 inches above the top of the table. The weight of this machine is about 25,000 pounds.

BICKFORD DRILL AND TOOL CO.'S TREPANNING MACHINE.

Fig. 2 (next page) shows some drill chips that, by comparison with the three-inch scale, will be seen to be of quite unusual size. These chips were made with a four-inch flat drill operating in solid .45 carbon steel at the rate of 1¼ inches per minute, feed .072 inch per revolution, using water as a lubricant.

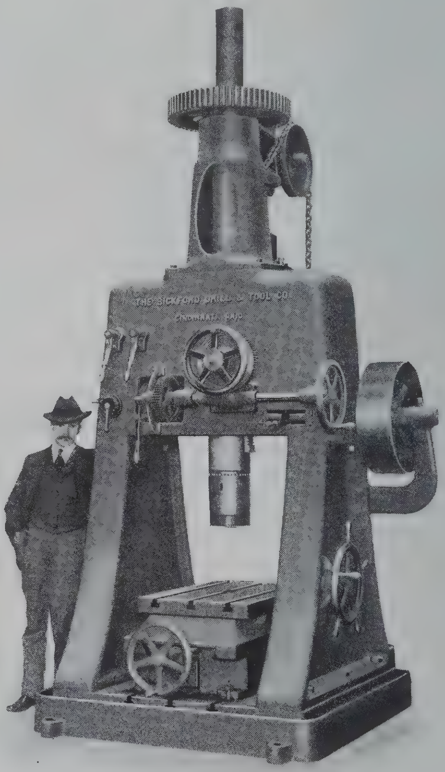

Fig. 1. Three-foot Trepanning Machine.

The machine with which this work was accomplished is illustrated in Fig. 1. It is termed a three-foot trepanning machine and is the product of the Bickford Drill & Tool Co., Cincinnati, Ohio. This is designed for all kinds of heavy drilling, facing, tapping and trepanning and is capable of receiving work 36 inches wide, between the housings. The head and cross rail are made in one piece, so designed as to eliminate all overhanging of the spindle. The table is adjustable both transversely and longitudinally, and when not needed may be slid back out of the way, for which purpose an extension is cast on the base.

The spindle has 16 changes of speed ranging from 6 to 60 revolutions per minute, and eight changes of feed ranging from .01 to .1 inch per revolution. All changes are accomplished by the movement of levers, no belt shifting being required. Both hand and power quick advance and return are also provided.

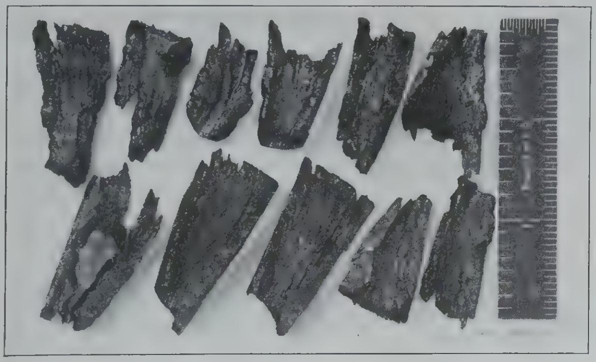

Fig. 2. Chips made with Bickford Trepanning Machine.

ELECTRIC BLUE PRINTING MACHINE.

In Figs. 1 and 2 is shown a new electric blue printing machine that has been placed on the market by the Eugene Dietzgen Co., Chicago. The general arrangement of glass cylinder with its canvas cover is practically the same that has been employed in former machines but for inserting the paper and tracing, the cylinder can be swung down into a horizontal position, making the manipulation much easier than is possible where it remains upright. After prints have been put on one side of the horizontal cylinder it is turned completely over and prints are placed on the opposite side. The cylinder is then tipped up and locked in a vertical position ready for printing. By touching a lever the arc lamp starts in its descent through the center of the cylinder at a speed that can be regulated to suit the sensitiveness of the paper employed. When the lamp has reached the lowest point of the printing surface it automatically reverses its motion and returns to its original position above the cylinder. The operating mechanism is all mounted on the back of the stand so that the machine is entirely self-contained.

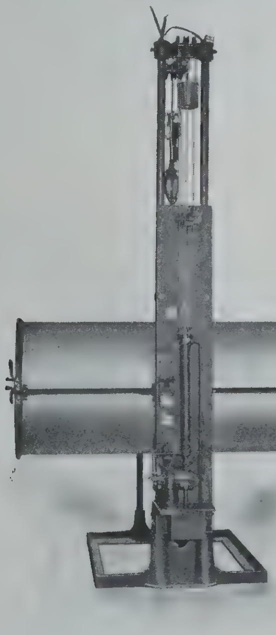

Fig. 1. In Position for Loading.

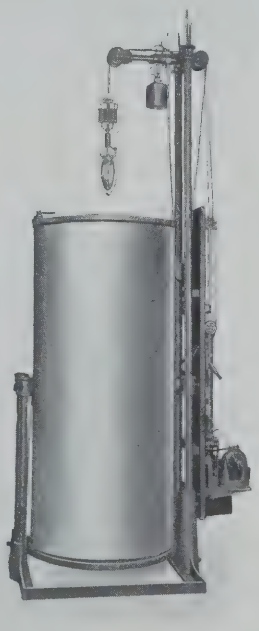

Fig. 2. In Position for Printing.

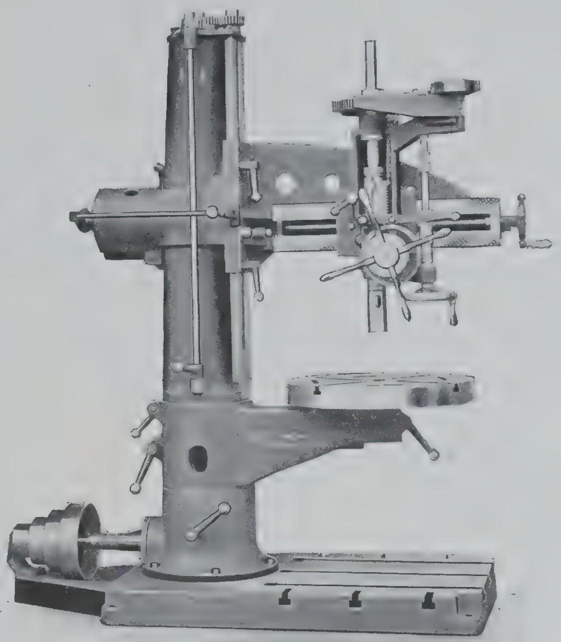
A NEW DRILL MANUFACTURED BY THE DRESES MACHINE TOOL CO.

The Dreses Machine Tool Co., Cincinnati, O, have just brought out a new radial drill which, after a thorough trial, is now ready for the market. The outline of this drill follows quite closely that of their old machines, only all vital parts have been made stronger and heavier. A lever, which may be seen protruding through the arm near the column, is used for quickly starting, stopping and reversing the spindle for tapping. It also engages the back gears according as its position is central, right or left. The little knurled head screw, passing through this lever, limits the brake power of the forward driving friction clutch and can be so adjusted that it just drives the tap but slips if the hole is too small, or when the tap strikes the bottom of the hole or any other obstruction. In connection with the gearing on the two horizontal driving shafts are four friction clutches which are operated by two levers, while any one of four quick-return levers disengages the feed and operates the spindle. This is accomplished by a single movement with but one hand. There are four changes of feed which can be varied by shifting the knob on the feed rod while the machine is in operation. The spindle is provided with a depth gage and an automatic stop.



Dreses Machine Tool Co.'s Radial Drill.

EXTENSIBLE STOCK DRAWER RACKS.

The "elastic" principle, which has long been employed by the Globe-Wernicke Co., for the construction of book cases in sections or units, has recently been applied by the Cleveland Wire Spring Co. to iron racks with steel boxes for holding tools, shop supplies, etc. One of these racks, consisting of seven sections, with drawers facing on both sides, is shown in the accompanying half-tone. A rack of this capacity is 8 feet high, 8 feet long and 32 inches deep, while the length may be increased indefinitely by the introduction of addi-

Rack of Steel Stock Drawers.

tional sections. The boxes are made of sheet steel with the angles turned on all corners, making a strong and durable box, which is very desirable in case of fire. One concern, recently burned out, lost almost all of their small tools except what they had in these trays, the contents of which were taken out practically uninjured.

These cases are used by a large number of firms who prefer them to wooden boxes on account of their convenience, cleanliness and durability.

THE NEW MODEL TURRET LATHES.

The Pratt & Whitney Co., Hartford, Conn., have recently re-designed two sizes of their new model turret lathes, retaining those features of the early machines which have proved of merit and adding new features for increasing the accuracy, capacity and convenience of the machines. While they are designed for manufacturing in large quantities, yet the tools of these machines may be set so easily that it is often of advantage to employ them for making as few as six pieces. The capacities of the two improved machines are, respectively, ⅝ x 4½ inches and 1 x 10 inches, which latter is shown in Fig. 1. As will be noticed in this cut, the headstock, bed and pan are cast in one piece. This arrangement insures alignment of the head and bed, and connects the parts in the best possible manner. The reversed position of the cones permits the front bearing to be reinforced and better provides against springing when heavy cuts are being taken. The end thrust of the spindle is taken entirely on the main bearing.

A detail of the turret and turret slide is shown in Fig. 2. The slide runs directly on the bed of the lathe, thus avoiding any intermediate construction and making the alignment more permanent. The sliding surfaces are gibbed underneath so that the transverse alignment of the cutting tool is not disturbed in making adjustment for wear. On the ⅝ x 4½ inch lathe the turret slide is moved by a lever, but on the larger size either lever or capstan wheel may be used, the change being quickly made from one to the other. The turret revolves about a heavy conical post which is bored, in alignment with the machine, to permit work being passed through the turret when necessary. The locking bolt, which is of steel, is provided with a taper gib and may be adjusted for wear without removing the turret from the slide. Locking takes place directly under the turret head, and no matter how quickly the turret may be indexed it is impossible for it to "over-run" or be carried beyond the index notch. When but two turret tools are used, the index mechanism may be thrown out by giving a partial revolution to the disengaging pin *P* Fig. 2. This allows the head to be indexed back and forth by hand between the two tools. The regular indexing is put into operation again by simply turning this pin back to its original position. On the base of the turret head is a cam *J* which, by acting upon the roller *K* and through the shaft *L*, causes the lever *M* to swing in or out as the turret revolves. The lever, therefore, occupies a series of positions corresponding to whichever hole of the turret is in working position. For each of these positions there is a stop, *S*1 *to S*6, which is adjusted to give the proper length of feed to its corresponding tool. The lever *M* at all times bears against the bracket *N*, so that when it comes in contact with one of the rods the feed of the turret slide is brought to a positive stop and no undue straining on the capstan wheel can in any way injure the turret mechanism.

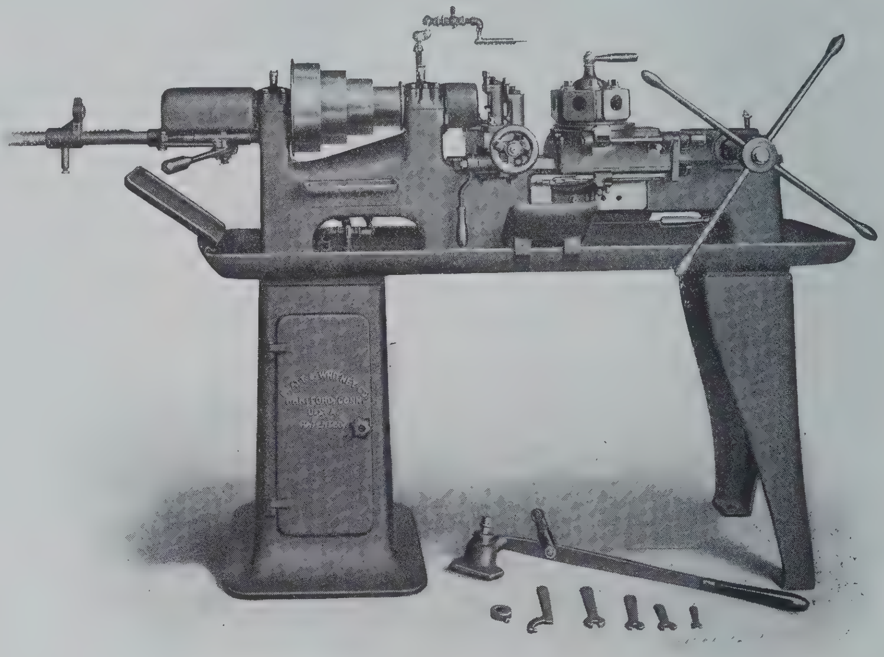


Fig. 1. 1 inch x 10 inch New Model Turret Lathe.

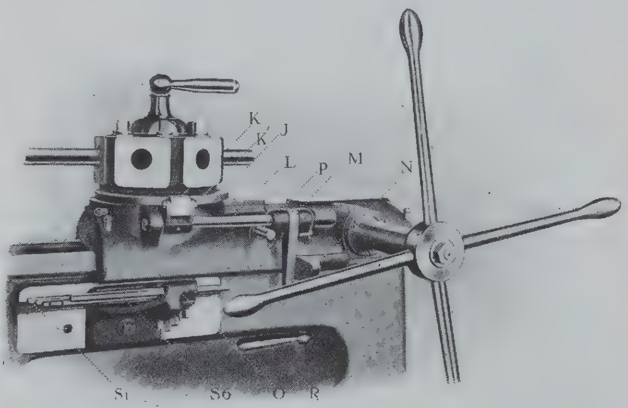

Fig. 2. Turret and Turret Slide.

The rod feed used on these machines is a modified form of the Parkhurst type of wire feed, the modification consisting in the use of a feeding sleeve operated through a link connected at a distance from the fulcrum point about double that at which the closing link is located. This construction permits, without sacrificing power in the closing mechanism, double the feed of rod to a given movement of the lever that can be obtained with the standard form of rod feed.

The collets are so arranged that, in closing, they do not withdraw or further advance the stock, a feature that is especially desirable in doing "second operation" work. For turning short pieces, such as rings or collars, which have a diameter above the capacity of the regular collets, split step chucks are supplied, thus materially increasing the range of work that these machines will handle. In these chucks the feature of the non-withdrawal of the chuck in closing is retained. By reason of the small diameter of nose-piece for a given diameter of collet it is possible to employ a heavy double cross slide directly under the collet and to support the cut-off and forming tools on the same without overhang. This slide may be placed anywhere between the headstock and the turret slides and rigidly clamped at any desired location.

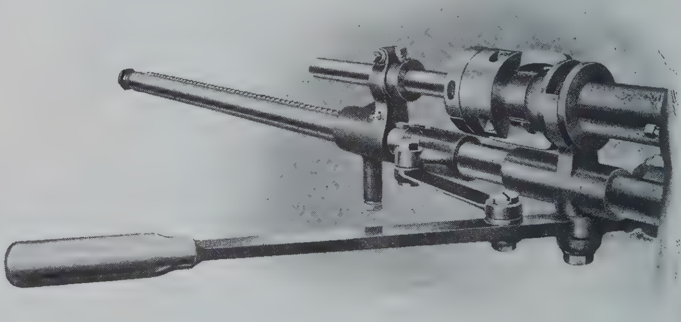

Fig. 3. Rod Feed Mechanism.

There are adjustable stops for the forming and cut-off tools. The tools may be operated by lever feed, if the work is light, or by handwheel and screw mechanism when the work is heavy or the tool not easily controlled by the lever.

The turret tools are made with a wide range of adjustment to cover a great variety of shapes. In Fig. 4 is shown the single roughing tool with steady rest. The cutter holder swings from a center so that the point of the tangent tool varies the least possible from the best cutting position, no matter how large or how small the piece operated upon may be. The cutter is adjusted by the screw at the top and locked by a clamp screw. When it is desired to withdraw the cutter, the clamp screw is loosened and the tool swung back. It is equally easy to return the cutter to its proper position by bringing the adjusting screw to the stop upon which it bears. The single finishing tool with steady rest is snown in Fig. 5. This tool has the same form of steady rest as the roughing tool but the cutter is held radially in a swinging arm.

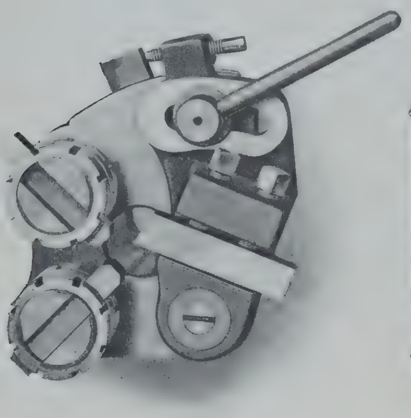

Fig. 4. Single Roughing Tool

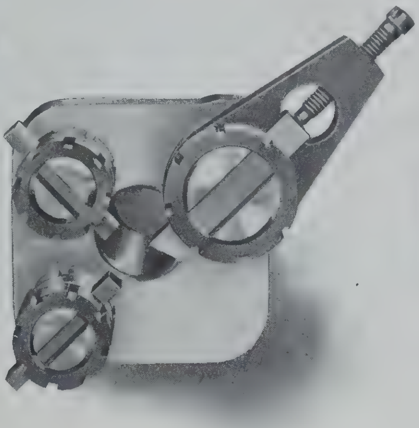

Fig. 5. Single Finishing Tool.

On work having two or three shoulders a multiple tool, one of which is shown in Fig. 6, can be used to good advantage. The tool illustrated is a finishing tool but multiple roughing tools also are made for use with these machines. The steady rests are identical with those on the single tools except that the slotted stud is lengthened to accommodate two or more jaws. Each of the cutters is entirely independent and adjustable while the distance between the shoulders may be almost anything within the total range of the tool. The shank of all of these tools is hollow, in order that work may pass directly through the turret.

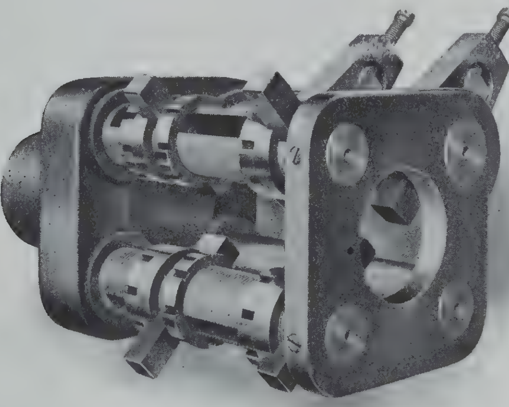

Fig. 6. Multiple Finishing Tool.

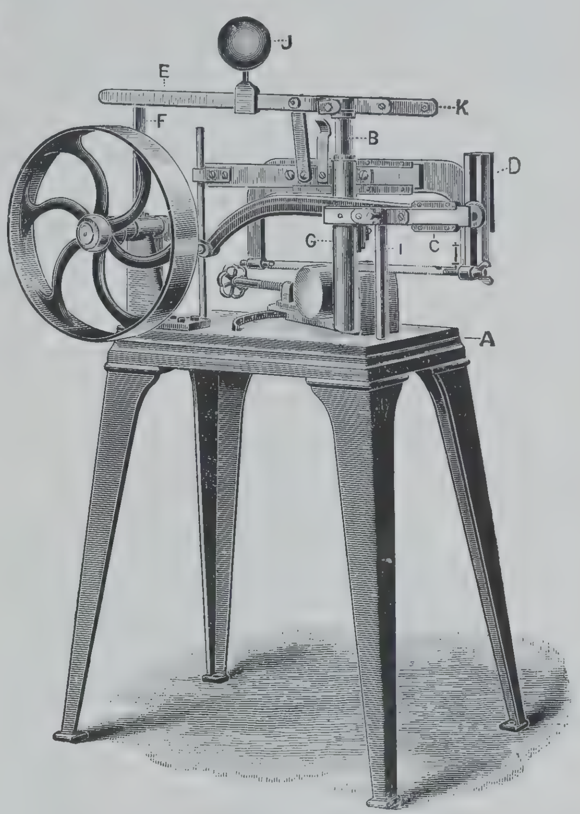
IMPROVED POWER HACK SAW MACHINE.

Although it is only a few years ago since the first power hack saw machine was brought out, it is now considered a necessity in every machine shop, and is a tool often found in other shops and in stores where bar iron and steel must be cut into lengths. The first power saws were crude tools that cut off stock, it is true, but in a haphazard and irregular way. No one would trust one of the earlier machines to saw off disks requiring to be finished to exact thickness without allowing a liberal margin for the "run of the saw."

In the power hack saw machine illustrated in the cut, we have a tool that is carefully designed and constructed. It produces quite remarkable work, it being possible to cut off very thin disks from a steel bar, showing little if any deviation from parallelism between the two sides. This result is obtained by certain features of design which constrain the saw blade to feed vertically downward in a perfectly straight line, there being no tendency for the connecting-rod to twist the saw out of true. By referring to the cut it will be seen that the connecting-rod is attached to the slide *C*, which moves on a guide entirely independent of the saw frame. The saw frame is not rigidly attached to the guide but is connected to it by a pin working in a vertical slot shown at *D*. This permits the saw to be moved up and down without changing the angularity of the connecting-rod, or in any way interfering with the regularity of the reciprocating motion. The saw frame is supported by a slide at the top moving on a horizontal guide attached to a sleeve. This sleeve encircles the vertical post *B*, the post acting as one of the vertical guides. A saw guide, adjustable in all directions, is attached to the sleeve so as to straddle the saw blade close to the work. Gages are provided for setting the saw blades truly vertical, but after a blade has once been set it may be quickly replaced by another without any adjustment whatever. This is considered to be an important feature in producing a true vertical cut, and preventing saw blades breaking. The saw frame is lifted and lowered by the lever *E*, and a weight *J* is mounted on the lever to regulate the cut. As the saw becomes dull the weight is moved outward on *E* to increase the leverage. The vise is swiveled so that it may be set for angular cuts. It is shown in the extreme angular position, or 45 degrees. No countershaft is required, there being a clutch with handle *F* attached to the machine for starting and stopping. When the work is sawed through, a bell rings continuously until the machine is stopped.



Power Hack Saw, Cutting Steel Disks.

This power hack saw machine is made in three sizes, 2x2, 3x3, and 4½x4½ inches, by L. H. Olmsted, Hasbrouck Heights, N. J.

AUTOMATIC THREE-WAY BORING AND TAPPING MACHINES.

The machine shown in Fig. 1, p. 228, is used for tapping tees, crosses, elbows, globe, angle and cross valves, or in fact, any kind of work that requires tapping and is within the limits of the capacity of the machine. It is capable of cutting simultaneously, three ½-inch pipe threads in brass.

The machine is spiral geared throughout and is absolutely noiseless. It is driven with a pair of wood and iron friction clutch pulleys with open and crossed belts. The countershaft has cones for three different speeds. The different feeds of the spindle are positive and are accomplished by change gears in a manner similar to that employed on a lathe. The feed gears are arranged with a clutch to which the spindles can be adjusted, independently of each other, for different depths of taps.

The chuck, shown in the photograph, is of the ordinary, two-jaw type with right and left hand screws, so adjusted as to receive special jaws for different kinds of work. In the place of this may be substituted a double chuck that is pivoted in the center and holds two pieces of work, back to back. The instant the taps have returned far enough out to clear the work, this chuck is revolved half way round and the new fitting is presented in front of the taps, and while the machine operates on this piece, the one previously finished is removed from the chuck and a new piece put in; in this way the delay due to taking out the finished piece and putting in a new piece, as is necessary on the single chuck, is avoided.

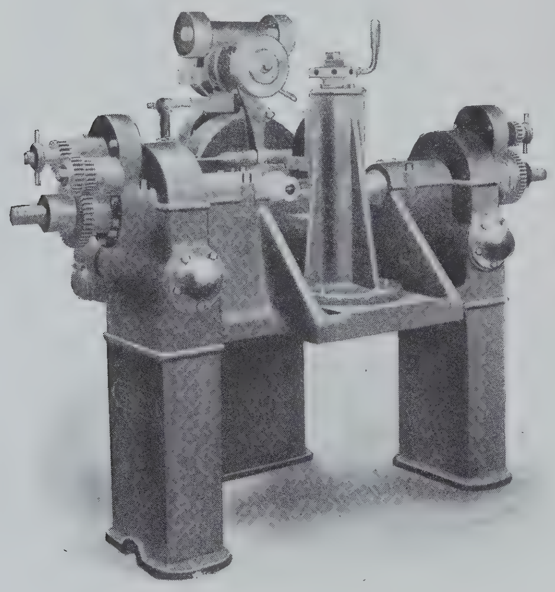


Fig. 1. Automatic Three-way Tapping Machine.

The regulator or governor is that part which is prominent on the housing of the center spindle. It has two small pulleys which are driven from the countershaft by independent belts. One belt would be sufficient for the work required but if this should break there would be no means of reversing or stopping the machine except by stopping the countershaft, so the second belt is added for safety. The regulator is of the most positive action without any storage of power in springs. When the taps have cut deep enough into the work the regulator reverses the large friction clutch pulleys, unscrews the taps out of the work and stops the machine. The operator then revolves the chuck half way around, thereby bringing a new casting into position for machining, starts the machine and the operation is repeated. The operator can at any and all times control the machine by the crank handle on front of regulator, that is, he can stop it or reverse it or run the spindles all the way back, without interfering with the automatic adjustment of the tap. When the taps are going into the work the machine will reverse automatically at the proper distance in, and on coming the proper distance out it will stop.

The machine is provided with an arrangement whereby the taps, when they unscrew from the work, will start one after the other, the benefit of this being that they will not injure the thread in the work when coming back, and will start reversing very much easier than if the three spindles should all start backwards at the same time.

For tapping iron or steel the machine is furnished with an oil pump, and a wrought iron pan for catching the chips and oil.

A companion to this is the three-way boring machine shown in Fig. 2, which is similar in construction and operation to the tapping machine but bores and faces only. It is used on valves and fittings which require boring and facing previous to being tapped.

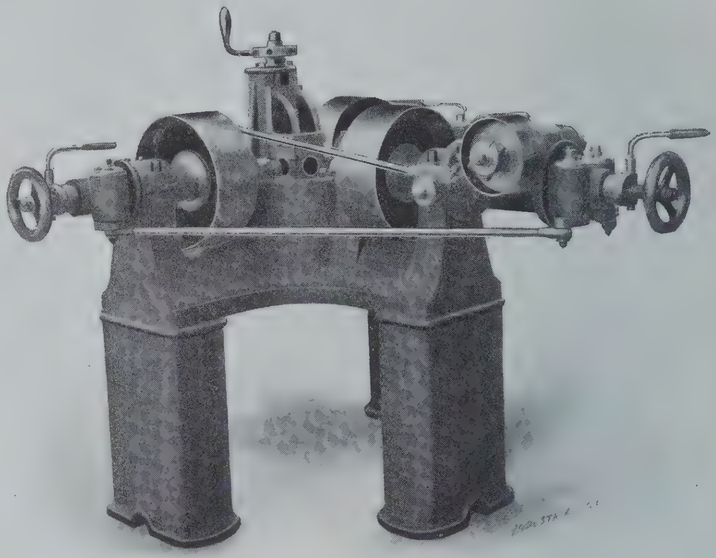

Fig. 2. Automatic Three-way Boring Machine.

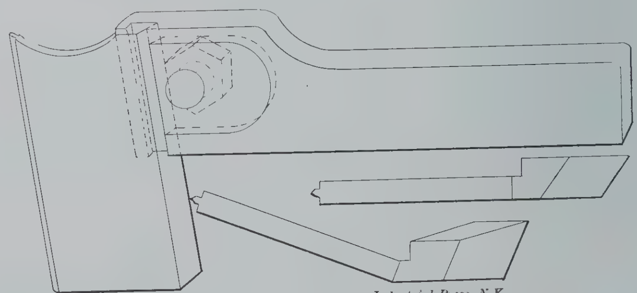
The chuck, either single or double, is identical with that used on the tapping machine and the same special jaws will fit both machines. The cutting tool is a multiple combination of counterbore and facing tool and the feeding mechanism is so arranged that when the tool first enters the work the feed is quite coarse. As the tool goes deeper into the work the feed decreases until, when the flanges or ends of the work are being faced, one or two revolutions are made without any feed at all. This produces a smooth hole and a nicely finished surface. The tools have a quick return movement and three different feeds which may be instantly changed from one to the other. As soon as the tool has been withdrawn from the work the feed comes to a standstill while the spindle continues running, but the feed will not start until the operator is ready, when it is started by lifting a small handle on the front of the machine. Each spindle is provided with independent adjustments for depths.

Both of these machines are manufactured by Edward P. Walter, Bridgeport, Conn.

THE O. K. CUTTING-OFF TOOL.

A new and convenient cutting-off tool that has recently been patented and placed on the market by the O. K. Tool Holder Co., Shelton, Conn., is illustrated in the accompanying cut. The peculiarity of this tool, as will be seen, is the formation of a point in the center of the cutting edge. This breaks up the chip and causes the tool to make a clean cut. In order to grind the blades they may be removed from the holder without changing its position, while the shape of the blades is such that grinding does not disturb the accuracy of the cutting edge. The tool can be adjusted to take a chip of any thickness and will not dig in, break or spoil the work. Straight or off-set blades may be used in the holder as is desired.

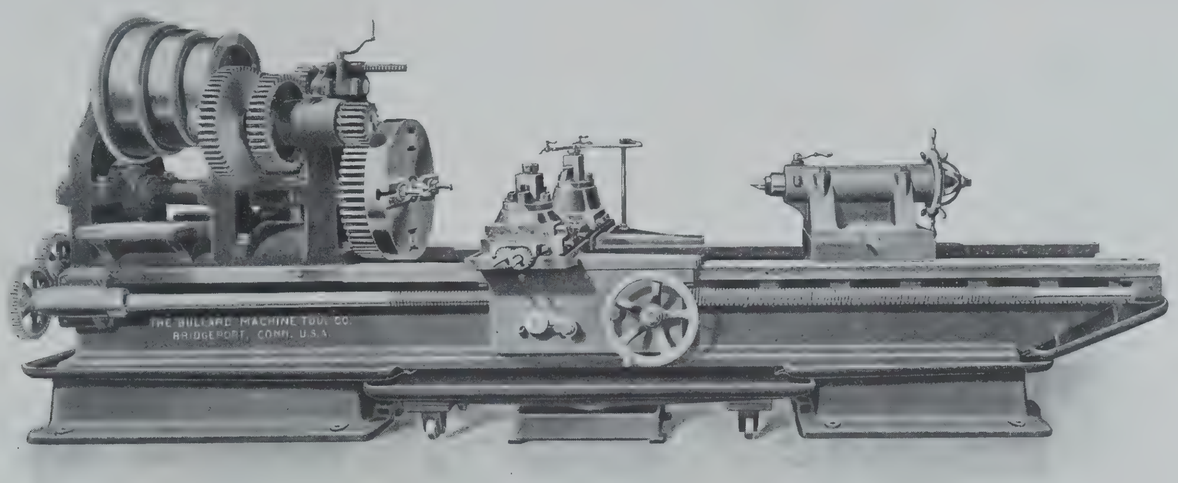


Industrial Press, N.Y.

O. K. Cutting-off Tool.

TWENTY-SIX INCH RAPID REDUCTION LATHE.

With the advent of the present high grades of tool steel, allowing cutting speeds of 100 to 200 feet per minute, a demand has arisen for tools that are qualified to withstand the increased service which the use of such speeds involves. It is to meet this demand that the Bullard Machine Tool Co., Bridgeport, Conn., have produced the "rapid reduction lathe" which is here illustrated. The simultaneous demand for great power and high speed makes the use of large gear reductions out of the question so that efficient driving power must be depended upon for accomplishing the work. Realizing the importance of this, the builders have designed this tool to be driven by a six-inch double belt, or, when electrically operated, by a 20 horse power variable speed motor. The lathe throughout possesses weight and solidity far in excess of that usually met with in machine tool construction. It swings 26 inches over the ways and 15 inches over the carriage. The bed, which is exceptionally heavy, weighs about 375 pounds per running foot and is regularly made in 14- and 16-foot lengths, taking 6 and 8 feet between the centers, but special beds can be furnished of any length desired.



Twenty-six Inch Rapid Reduction Lathe.

The tops of the column legs are completely surrounded by drip pans while between the legs are large pans that are mounted on rollers to facilitate their use. This arrangement of pans permits the copious use of water, which is supplied by a rotary pump capable of delivering five gallons per minute. The ways are flat and thus give an ample bearing surface for the carriage, while wipers on the ends of the carriage prevent chips from lodging and cutting the ways.

The headstock has a three step cone, the steps of which are respectively 18, 21 and 24 inches in diameter, and is faceplate geared in the ratio of 8 to 1 and 16 to 1. These gears are all completely inclosed by casings which are not shown in the photograph, having been removed in order to show clearly the details of the headstock. An equalizing driver is incorporated into the faceplate, thus permitting the use of double tailed dogs. All of the headstock journals have chain oiling bearings and liberal reservoirs are provided for the oil supply.

The carriage is gibbed, both front and back, and has a full length bearing of 38 inches on the ways. The cross slides, of which there are two, are square locked throughout, adjustment for wear being obtained through taper gibs. The front slide has a compound movement for dividing the cut between the front and rear tools. These tools are made from 1½ x 2½-inch stock. The slides are independent in their movements and have no power cross feed. The feed is driven by gearing and a powerful leadscrew which is located close to the bed and well under the forward way. This screw is engaged by a long lock nut operated from the apron, the Acme standard thread with which this screw is cut making engagement and disengagement very easy. Feed reverse is obtained by use of an intermediate gear on the headstock. On the long beds the leadscrew is carried in supports that are automatically placed, at given intervals, by the carriage as it travels along the bed. A quick-acting power traverse is provided for moving the carriage rapidly, also a rack and gear for moving both carriage and tailstock by hand. The tailstock has a 5-inch steel spindle and set-over movement. Center and follower rests partake of the same rigid and substantial features that are characteristic of the other parts of the lathe.

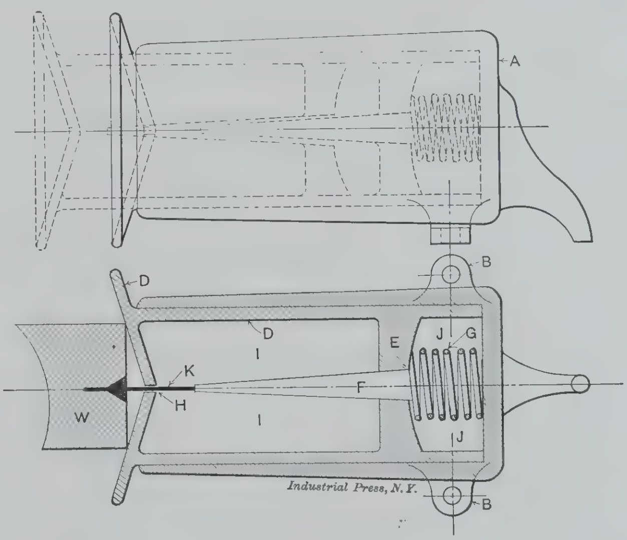
When it is desired to operate this tool electrically, a 20 horse power variable speed motor, capable of running 600 to 1,000 revolutions per minute, is mounted on brackets cast on the headstock, the armature shaft of the motor replacing the cone shaft of the belt-driven machine. This motor is operated from the lathe apron.

DEVICE FOR CLEANING AND LUBRICATING CENTERS.

A. B. Christman, of Cleveland, Ohio, has brought out the appliance shown in the accompanying cut, which is for the purpose of removing oil, chips, or dust from the countersunk holes in the ends of work held between centers. It may be attached to the legs or column of centering, milling or grinding machines or to lathes or benches.

The cylinder *A* is fastened by screws through the lugs *B B*, so that it will stand in a vertical position.

Inside of this cylinder is a sliding piston *D*, provided near its lower extremity with the piston head *E* and having an inverted cone at the top. Fixed to *E* and central with the small hole *H*, in the cone, is the nozzle *F*. A spring *G* keeps the piston well up in the cylinder, as shown by the dotted lines. The spaces *I I* and *J J* contain benzine, kerosene, or soda water. If it is desired to lubricate the center simultaneously with the cleaning, lard or machine oil is mixed with the cleaning fluid. The work is grasped in the hand and inserted in the cone as shown at *W*, with a slight downward pressure. This pushes the plunger *D* downward and a stream of the



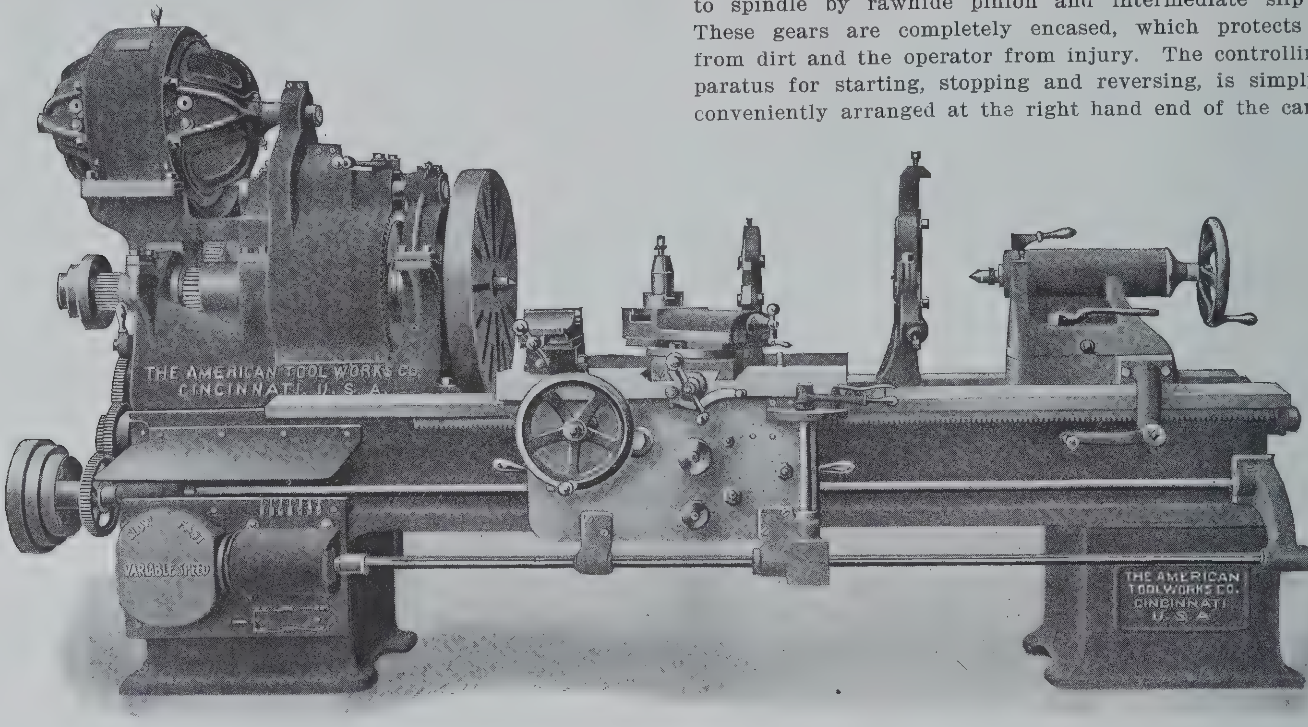
Center Cleaning Device.

liquid is forced upward into the center as shown at K. The liquid returns by gravity through the hole H into the chambers I and J, carrying with it all particles of dirt and chips, which are retained by the partition E. Cleaning of the device is necessary only at comparatively long intervals and is accomplished by lifting the piston D out of the cylinder and dumping. The capacity of the cleaner is about six ounces of cleaning fluid.

NEW "AMERICAN" MOTOR DRIVEN LATHE.

The application of electric drive has been adopted by the American Tool Works Co., Cincinnati, Ohio, for operating their 24-inch engine lathe, a photograph of which is here reproduced. This is their standard lathe having the leadscrew on the inside of the bed.

The motor is of the double commutator type, 3 H. P., and is mounted on a saddle on the head, with communication direct to spindle by rawhide pinion and intermediate slip gear. These gears are completely encased, which protects them from dirt and the operator from injury. The controlling apparatus for starting, stopping and reversing, is simply and conveniently arranged at the right hand end of the carriage.



24-inch "American" Motor Driven Lathe.

There are four fundamental speeds obtainable from the motor itself through the speed controller directly under the head. This with the spindle gearing, gives a total of sixteen distinct and positive spindle speeds available. The efficiency of the motor is practically constant at all speeds. The motor, when reversed, runs at the same speed as when going forward.

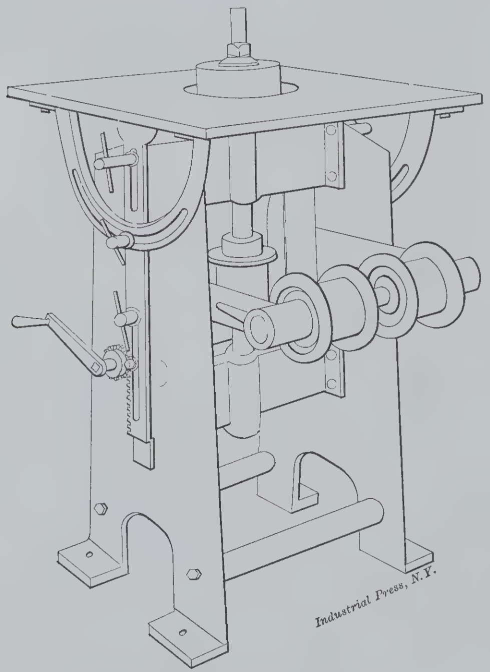
VERTICAL EDGING AND INSIDE GRINDER.

The Tucker Machine Co., Cincinnati, Ohio, have recently brought out the vertical grinder shown in the engraving. This machine was originally built for use in stove foundries but has proved of value for grinding many kinds of castings such as plate castings, architectural iron work, etc. It is of the greatest convenience for grinding the inside of scrolls, circles or other parts that cannot be reached by the ordinary horizontal grinder. The work to be ground rests upon a horizontal table, two feet square, that can be tilted to any desired angle and may be raised and lowered, by means of a crank handle, through a space of four inches. The machine carries a wheel 2 inches to 8 inches in diameter by 4 inch face.



Vertical Edging and Inside Grinder.

LEAD VS. NICKEL (OR EDISON) BATTERIES FOR AUTOMOBILES.

Those interested in automobiles are waiting patiently for further information about the Edison storage battery, of which so much is expected. While, from the testimony of Mr. Edison, this battery has undoubted advantages, the most important of which are large capacity for a given weight and increased durability, it would appear from a paper read recently by Mr. Hugh Rodman before the Electro-chemical Society at Niagara Falls and reported in the *Electrical World and Engineer*, that the lead battery may still lay claims to favorable recognition. After discussing the numerous possible storage battery combinations and the corresponding reactions the conclusion is reached that the list of available anodes and electrolytes finally reduces to lead in sulphuric acid and nickel in an alkali hydroxide. Practically there are only two classes. First, lead peroxide and spongy lead upon lead plates in sulphuric acid—the battery in general use; and, second, mercuric or nickel peroxide upon nickel plates, together with cadmium, nickel or iron sponge upon iron or nickel plates in an alkali hydroxide—the battery proposed by Mr. Edison.

The alkali battery possesses a great advantage in making its support plates of a stiff, easily-worked metal. The stiffness insures absence of buckling (a trouble which must be considered and compensated for with lead plates), while the stiffness and ease of working together admit of a high mechanical perfection. It should be borne in mind, however, that the ordinary antimonial lead grid used with pasted lead plates is neither prohibitively heavy nor short-lived; it will probably last as long as the nickel grid when subjected to electrolytic action only; the inferiority lies in its mechanical weakness and in the difficulty of making fine castings.

In refilling the alkali cell pure or distilled water must be used, which is not necessary with the acid cell, and the alkali is also more troublesome in handling owing to its tendency to spread and its more destructive effect on clothes, hands and woodwork. The voltage of the alkali cell is only about one-half that of the lead cell, and for the same energy output we must double either the current or the number of cells. The alkali cell also has comparatively a small mass of electrolyte to draw upon.

Data are wanting upon the capacity of the alkali cell per unit of volume and weight, but it seems reasonably certain that neither will be far different from that of the pasted lead battery. As for reliability, which must not be mistaken for long life, data on the alkali cell are again wanting and must be wanting until the cells are put into ordinary service with ordinary care and attention.

For light service, such as for electric wagons, where watt efficiency and cost are to some extent subordinate to convenience, the choice between these two types will depend largely upon capacity and reliability.

The commercial life of lead plates in truck or cab service is about 15,000 to 20,000 miles for negatives, 12,000 miles for Plante positives and 6,000 miles for pasted positives. In other words, a four or five ton truck running 20 miles per day for 300 days in a year requires new positives once in a year or once in two years, according to the type of plate used, the choice of one or the other being determined by the character of service and length of run desired. Cabs and lighter wagons have about the same life, with a capacity of 40 to 100 miles on one charge.

* * *

In the June, 1902, issue of MACHINERY a description was given of the Keller pneumatic riveting hammer made by the Philadelphia Pneumatic Tool Co. Some readers who have studied the sectional cut, or who are familiar with the hammers themselves, may have wondered how the long 3-16-inch holes are drilled in the barrel parallel with the cylinder bore. In some of the long-stroke riveting hammers these holes are fully 13 inches long, so it would seem like a quite difficult job to drill them with ordinary appliances, but that is how they are done, except that the appliances are somewhat better than ordinary ones.

Seven Brown & Sharpe sensitive drilling machines built specially for this work are used in drilling the long holes in each barrel, the work being done progressively. The hammer barrels are mounted on jigs having a round, flat base, and each one remains in its jig until the holes are drilled clear through. The first operator starts the holes with a short 3-16-inch drill, and drills them to a depth of perhaps 2 inches. The next operator takes it on his machine and deepens the holes, say, 2 inches, and so on, the skill of the operators increasing with the depth of the holes and their ability to avoid breaking drills and spoiling work. The last operator in the line is a deaf mute and not likely to be distracted, which may partially account for his position in the line. The holes being drilled in this manner the long drills are always supported throughout most of their length by the walls of the hole, which insures the holes being straight, and because of the frequent changes there is not so much danger of their heating.

FRESH FROM THE PRESS.

A GRAPHIC METHOD FOR SOLVING CERTAIN QUESTIONS IN ARITHMETIC AND ALGEBRA. By George L. Vose. No. 16 Van Nostrand Science Series bound in paper boards. Published by D. Van Nostrand Co., New York. Price 50 cents.

As the title indicates, this little book describes a graphic method that may be employed for solving certain problems in arithmetic and algebra. The graphic method is one that usually appeals to the practical man, and in this work he will find some quite knotty problems worked out with surprising ease by the use of simple diagrams.

PROBLEMS IN MECHANICS FOR ENGINEERING STUDENTS. By Frank B. Sanborn, Professor of Civil Engineering, Tufts College. Published by the Engineering News Pub. Co., 220 Broadway, New York. 155 pages illustrated. Price $1.50.

This little handbook should prove of great value to students. It is a collection of a large number of practical problems in mechanics, with their answers. It is thoroughly indexed, and as a class-room book and an aid to the instruction of students it will be found useful. The best way to learn mechanics is by working out problems, and one who has faithfully gone through this little volume cannot fail to gain a good knowledge of the subject.

MACHINE SHOP ARITHMETIC. By Fred H. Colvin and Walter L. Cheney. 131 pages and 8 diagrams, nicely bound in cloth. Published by the Derry-Collard Co., 256 Broadway, New York. Price 50 cents.

This is the third edition, eighth thousand, of a little book that has proven popular with machinists and others who have felt the need of a "pocket book containing some of the problems of everyday shop happenings, and affording their fast and accurate solution by easy methods." It is a book we have often recommended to young machinists who have not had the advantages of a good common school education, and who, realizing their deficiency in calculating simple shop problems, have been anxious to acquire a ready knowledge of machine shop arithmetic. The matter contained in the new edition has been revised and brought up to date. Larger type has been used and a larger page which materially improves its appearance and legibility. A chapter on the metric system and metric conversion tables has been added, also a page index.

WORM AND SPIRAL GEARING. By Frederick A. Halsey. No. 116 Van Nostrand Science Series. Published by D. Van Nostrand Co., New York. 85 16 mo. pages with numerous diagrams. Price, boards, 50 cents.

This book is a reprint of Mr. Halsey's articles on the above subjects that originally appeared in the columns of the *American Machinist.* The first part, dealing with the worm gear, considers the theory of worm efficiency, limiting speeds and pressures, and the various types of thrust bearings for use with the worm. The theoretical treatment is supplemented by a number of cases from actual experience showing the efficiency that can be obtained and the factors tending to produce this efficiency. The second part, after a few pages explaining the general principles of spiral gearing, illustrates the subject by the solution of a practical problem which is solved both by the analytic and the graphic methods. The concluding pages are devoted to a short treatise on the selection of spiral gear cutters by Mr. J. N. LeConte.

THE SLIDE VALVE. By Julius Begtrup, M. E. Published by D. Van Nostrand Co., New York. 143 8-vo. pages. Illustrated. Price, cloth, $2.00.

In this book Mr. Begtrup explains the principles of the various types of slide valves and also analyzes and describes a number of special valve constructions in order to exhibit in a comprehensive manner how the exacting conditions of high steam pressure and high speed have been met by modern engine builders. The information is presented in a more or less explanatory form supplemented by graphical demonstrations of the valve movements. The valve diagrams used in this book have been in use for the past ten years with, it is claimed, more general satisfaction than others that are better known. Beginning with a chapter on the common slide valve, the chapters successively deal with the improved forms of slide valve, including double-ported, balancing and piston valves; four valve systems, of which the Corliss is the most familiar type and independent cut-off valves. A chapter is also devoted to the slide valves of pumps, the valves of all the well-known makes of pumps being considered. The last chapter deals with the angularity of the connecting rod and eccentric rods and the effects which this produces on the steam distribution.

MATERIALS OF MACHINES. By Albert W. Smith, professor of Mechanical Engineering in Leland Stanford Junior University. Published by John Wiley & Sons, New York. 133 pages. Illustrated. Price, cloth, $1.00.

In the words of the author, this book is the result of an effort to bring together concisely the information necessary to him who has to select materials for machine parts. It is a systematic treatment of the materials with which the machine designer has to deal. It is therefore natural that a greater part of the work should be devoted to the subjects of iron and steel. The metallurgy of these materials is first taken up and this is followed by a description of the different steel processes and a few pages on foundry practice. A chapter is also devoted to the subject of testing, illustrated by stress-strain diagrams. The common alloys, principally the bronzes. are considered and the final chapter takes up the different parts of the steam engine and machine tools and discusses the material best suited for the construction of each part.

A MANUAL OF DRAWING. By C. E. Coolidge, assistant professor of machine design, Sibley College, Cornell University. Published by John Wiley & Sons, New York. 92 8-vo. pages and 10 full-page plates. Price, paper, $1.00.

This manual was prepared for the use of the technical student with the object of presenting a standard drawing room system, the one embodied in this book being an average of the drawing room systems in use in the United States at the present day. It is the intention of the author that the system here outlined shall be supplemented by notes of the student's own acquirement, and for this purpose each page of reading is bound alternately with a blank page. The first part of the manual contains a treatment of the general subjects of drawing instruments, their care and use, drawing materials and blueprint reproduction. The second part is devoted to commercial mechanical drawings, closing with a few pages on the subject of Patent Office drawings. The text is quite thoroughly illustrated by 10 full-page plates of the various conventional forms, mechanical drawings and a Patent Office drawing.

MODERN ENGINEERING PRACTICE, published by the American School of Correspondence, Chicago, Ill. With an introduction by Frank W. Gunsaulus, President Armour Institute of Technology. 10 volumes, of about 350 pages each. Illustrated. Price for the set, $40.

The instruction pamphlets of the American School of Correspondence have been written by a selected list of writers, and these papers on mechanical engineering have been gathered together and published in this set of books. In reviewing the books it should be remembered that they are designed first of all, for home instruction and are intended for the man with limited education who wishes to advance in his chosen line of work. They are, therefore, elementary in their treatment and written as simply and clearly as possible. They are not to be considered as reference books for experienced draftsmen or engineers. Were a man, however, to make himself familiar with the contents of the volumes, he would have a good general knowledge of mechanical engineering and would have laid a substantial groundwork for future study. The mathematics of this course would carry him far enough so that after completing them, he should be able to read intelligently some of the more advanced text books by other publishers. The books are substantially bound, with leather backs, and the printing is clear. Part of the illustrations are from drawings made for this work and part are reproductions of cuts made for manufacturers' catalogues or for other purposes.

VOLS. I. AND II., MATHEMATICS, MECHANICS AND HEATING.—The first volume is taken up with a treatment of arithmetic, mensuration and elementary algebra. The second volume is a treatment of plane geometry, followed by chapters on elementary or applied mechanics and a brief treatment of the subject of heat. The chapters on mathematics cover about the same ground as the usual high-school text books except that the treatment is more condensed; and some subjects are omitted that are frequently taken up in high schools, especially in the treatise on arithmetic, which devotes more space to the fundamental rules and less to other branches of the subject, such as commercial arithmetic, etc. The algebra and trigonometry appear to be the most complete. The subjects of mechanics and heat are covered more fully than in the ordinary text book on physics, though not so completely as, for example, in Jamieson's, Dana's or Wood's elementary mechanics, with which some of our readers may be familiar.

VOLS. III. AND IV., FOUNDRY, FORGE AND MACHINE SHOP PRACTICE.—This volume contains about 300 pages in which space the three subjects mentioned above are treated and, as a matter of course, are not covered with anything like completeness since elaborate text books could be written on almost any one branch of shop work. The attempt is made rather to present the general principles of common shop operations such as would be taught in a manual training school and which would help the apprentice in making a start.

Vol. IV., Machine Design and Boilers.—The chapters on machine design in this book follow very closely the lines laid down by such writers as Unwin, Low and other authors of standard works on this subject. Sketches are given of keys, cutters, bolts, bearings, clutches, flanges and other common machine parts and either formulas or tables are given for proportioning them. The author did not attempt to leave beaten paths or to collect material about recent advances in machine proportions. The sketches are for the most part similar to those in the older standard text books. By far the best part of the work is the treatment of boilers which contains rules or proportions for steam space, heating surface, tubes, grate area, etc., that apparently are well selected, together with a description of various types of boilers and boiler exhausters, including the steam calorimeter.

Vol. V., Chemistry, Metallurgy, Engines.—The chemical subjects are evidently calculated to give the mechanical man a general idea of the composition of ordinary materials that enter into machine construction. They are not intended to touch the subject of chemistry as a separate study. The treatise on the steam engine covers about the same ground as the usual handbooks on the steam engine for stationary engineers, but the subject is treated in a much better manner. There are first descriptions of different types of engines, including pumping engines and condensers and sketches with descriptions of the detailed parts of steam engines. This is followed by a description of governors and flywheels with simple calculations of pendulum and flywheel weights. Following this is a very good treatment of the steam engine indicator, much better than the usual treatise, largely because it is directly to the point and a lot of useless matter is omitted. After this is an explanation of the Zeuner valve diagram, with descriptions of several types of valve gear. The book closes with matter upon the action of steam, in which are calculations involving the use of steam tables, the capacities of condensers, the work done in an engine cylinder, etc.

Vol. VI., Marine Engine and Locomotive Work.—This is really a volume II. on the steam engine, taking up marine engines and locomotives. The subjects are treated in the same manner as the general principles of the steam engine are discussed in the last part of the previous volume. There is a chapter on marine boilers, one on railway cars and one on the air brake.

Vols. VII. and VIII. Electricity and Electrical Engineering. Vol. VII. forms a text book on elementary electricity and magnetism. following which generators, motors and electrical measurements are considered. Numerous calculations are introduced throughout this volume, none of them, however, of an advanced character, and they should be handled easily by one who has taken the earlier mathematics of the course. In volume VIII. are descriptions of various types of dynamo-electric machinery, an explanation of the alternating current transformers, with information upon electric railways and power transmission. These two volumes will be appreciated by men who are familiar with mechanics, and would like to have an advanced treatment of the elements of electricity, as practically applied in modern science.

Vol. IX., Heating, Ventilation and Plumbing.—Relatively speaking, these books seem to be more complete than the others mentioned, because the subjects themselves cover less ground and can be more fully treated within the scope of a single volume. This volume compares very favorably with other treatises upon the subjects, with which we are familiar. It will apparently meet the requirements of a mechanical man in a very satisfactory manner.

Vol. X., Mechanical Drawing.—This, it appears to us, is on the whole the most satisfactory volume of the series, and we believe it will prove as satisfactory to instructors and students as any text book on drawing we have seen. It takes up the usual geometrical work, projection, etc., and this is followed by a rarely good section on working drawings, quite original in its treatment and from which we publish an abstract in another part of the paper.

ADVERTISING LITERATURE.

The Billings & Spencer Co., Hartford, Conn. New circular and price list of drop-forged lathe dogs manufactured by this company.

E. G. Smith, Columbia, Pa. Pamphlet descriptive and illustrative of the "Columbia" calipers, spherometers, and screw micrometers. Also of the "Which Way" pocket level.

The Ransom Mfg. Co., Oshkosh, Wis. Catalogue "F" of grinding and polishing machinery. The various sizes and styles of these machines are described and illustrated.

The Frank Mossberg Co., Attleboro, Mass. Pocket catalogue of wrenches and of bicycle and automobile bells. The wrenches are made in several sizes and for various purposes, and the Mossberg bells are fully described and illustrated.

The Billings & Spencer Co., Hartford, Conn. Catalogue and price list of standard automobile forgings. These include forgings of every description in iron, steel, copper and bronze. A number of detail illustrations of various automobile parts are also given.

The Joseph Dixon Crucible Co., Jersey City, N. J. Leaflets giving information about the Dixon graphite pipe-joint compound for insuring a tight joint, but one that can be taken apart easily when necessary.

The Cleveland Wire Spring Co., Cleveland, O. Catalogue of agricultural implement springs and steel receptacles such as mortar and brick hods, hand barrows, nail boxes, various styles of shop boxes, etc.

The C. B. Manchester Gas Furnace Co., Providence, R. I. Circulars of gas furnaces. Twelve styles of furnaces are illustrated. These are for heating cutters, dies, reamers, etc.; for annealing work of steel, iron, brass and other metals; for wire annealing; for melting, plating, tempering, etc., and each is made in several sizes.

Hill, Clarke & Co., Boston, Chicago and New York. Circular descriptive of the Chicago speed lathe, built in 10-inch and 12-inch sizes by the Chicago Machine Tool Co. Also circular calling attention to the line of air compressors, pneumatic tools, pneumatic hoists and appliances manufactured by the Hill, Clarke Co.

The Diamond Machine Co., Providence, R. I. Proof sheets of the revised edition of their 1901 catalogue, indicating the changes in dimensions and measurements of a number of their machines, and in several list prices. Descriptions of their "E" standard grinding machine and of their Nos. 1, 2 and 3 improved water tool grinders will also appear in the new edition.

The Buffalo Forge Co., Buffalo, N. Y. Folders treating of the company's new mechanically-induced draft fans and of Buffalo automatic engines. These engines include the center-crank horizontal, the side-crank horizontal, and the single upright types, simple and compound; also single upright marine engines and the double upright engines of the single and double-acting types.

The Derry-Collard Co, 256 Broadway, New York. Catalogue of books sold by the Derry-Collard method. This is one of the handsomest and most tastefully gotten up book catalogues we have seen. It lists 148 choice technical books, giving each a short and comprehensive description of the contents, number of pages, size of page, and character of binding. An index to the contents is given, which makes reference to any book description easy.

United States Gutta Percha Paint Co., Providence, R. I. Standard catalogue of Rice's 20th century finishes for machinery. These include adamant cement, machine paint, iron filler, enamels, shellac varnishes, etc. They also manufacture a paint thinner for thinning their steel-color paints which dries quickly and costs very little more than turpentine. Three pages in the back of the catalogue contain testimonials from a large number of firms using these products and showing the great variety of work for which they are fitted.

William Jessop & Sons, Ltd., Sheffield, England. Handsomely illustrated catalogue entitled "Jessop's Steel and How They Make it." The subjects of Sheffield steel, "blister steel," crucibles, melting furnaces, shear steel, Siemens steel, etc., are touched upon, and a large number of fine half-tones illustrate the various departments of the company's large works at Sheffield. The manufacture of a crankshaft from the ingot to the finished shaft is also illustrated. In the first pages appears an announcement of the establishment of an American works at Washington, Pa., where Sheffield steel is to be manufactured.

The Northern Electrical Mfg. Co., Madison, Wis. Catalogue No. 26 of the Northern electric motors. Illustrations are given showing these motors driving drill presses, radial drills, grinders, lathes, planers, milling machines, etc., and many other varieties of machines such as sewing machines, paper cutters, ice machines, and air compressors. Vertical motors are shown, of the open and inclosed or dust-proof type for use in cases where other styles of electric motors are not practicable. Much interesting reading on the subject of electric driving is contained in this catalogue and it should prove valuable to those interested in this subject.

The Christensen Engineering Co., Milwaukee, Wis. Catalogues Nos. 53, 54 and 55, standard size, of the air brakes and electrical machinery manufactured by this company. Catalogue No. 53 describes the various parts that comprise the straight air brake equipment for electric cars or trains. No. 54 treats of Christensen air brakes and illustrates the company's new plant, with fine views of its various departments. No. 55 illustrates the direct-current motors and generators, alternating current generators and transformers they manufacture, and contains description of this electrical machinery and of its parts, together with other data and tables and detail drawings relative to the subject. All three catalogues are handsomely gotten up and will prove of value to those interested in the subjects there treated.

The Acme Machinery Co., Cleveland, O. 1902 catalogue of bolt and nut machinery. This catalogue is standard size, very complete and profusely illustrated. It calls attention to the many new features that have been added to their machines since the issue of their last catalogue. The new Acme die head is described and cuts are shown to illustrate its various parts. Then follow engravings and data of the regular Acme die head; Acme bolt cutters for work from ½ inch to 6 inches; 1½-inch single staybolt cutters; a large variety of double and triple bolt cutters, of two, four, and six-spindle nut tappers, etc. A full description, with illustrations, is given of heading, upsetting and forging machines for work from ¼ to 4 inches diameter, and a number of useful tables are reproduced together with much valuable information as to how to make, recut and grind dies, etc.

MANUFACTURERS' NOTES.

Mr. C. H. Schokmiller, for eight years master mechanic and foreman at the Inland Type Foundry Co., St. Louis, Mo., has resigned his position.

L. E. Rhodes has purchased the business of the Des Jardins Type Justifier Co., Hartford, Conn., and will begin the manufacture of high-grade special machinery and tools.

The C. W. Hunt Co., West New Brighton, N. Y., received the gold medal at the Dusseldorf exhibition for the "Hunt" conveyor manufactured by them.

The National-Acme Mfg. Co., Cleveland, O., announce the opening of a New England office at 45 Oliver St., Boston, Mass., in charge of Mr. M. M. Brunner.

The Cling-Surface Mfg. Co., Buffalo, N. Y., report a busy month, with increasing demands from abroad. Shipments of Cling-Surface have been made to England, the Bahamas, Russia, Australia, South Africa and Java.

Hardinge Brothers, Chicago, Ill., have purchased from Messrs. A. W. Gump & Co., Dayton, O., their entire Cataract precision lathe business and will hereafter manufacture this tool under the name of the Cataract precision lathe.

Pawling & Harnischfeger, Milwaukee, Wis., state that the demand for their cranes and hoists is excellent. They have recently booked orders for cranes and hoists from sixteen prominent firms in this country.

The W. P. Davis Machine Co., Rochester, N. Y., report that business has increased steadily. They have outgrown the building erected for them a few years ago. Two buildings in the rear were recently added, but these have proved insufficient, and the store next to them has just been leased.

The Burt Mfg. Co., Akron, O., have equipped a number of mills at the American Sheet Steel Co. with their Cross oil filters and Burt exhaust heads. The large new plant of the Allis-Chalmers Co., West Allis, Wis., has also recently been equipped with Cross oil filters.

The Marshall & Huschart Machinery Co., Cleveland, O., are now occupying their new warerooms, Nos. 24-26 Lake St. Their ground floor is 60x150 feet, and they have installed there a number of electrically-driven machines, manufactured by sixteen firms which they represent, which are in operation.

The Cushman Chuck Co., Hartford, Conn., advise us that to make additional room at their factory they have leased a large store and basement at 189 Allyn Street, near Union Station, to which their general office, with stock of finished chucks, has been removed. This makes available a considerable space in their factory which, together with contemplated additions, will be utilized for new machinery.

The E. Horton & Son Co., Windsor Locks, Conn., manufacturers of the well-known Horton chuck, are adding to their works another large building which, when completed and equipped with machinery, will enable them to more than double their present output. They are among the oldest chuck manufacturers in existence, having been in the business about fifty years.

Charles H. Besly & Co., 10-12 N. Canal St., Chicago, Ill., desire to call attention to their large and varied assortment of seamless brass and copper tubing. Brass rod, sheet, wire and brazed tubing; braziers' sheet copper, soft and cold-rolled copper anodes, brush copper for electrical purposes, German silver sheet, rod and wire are also carried. Their new store building on Clinton Street is progressing rapidly.

The Wilmarth & Morman Co. Grand Rapids, Mich., report that in the month of October their shipments were larger in amount than for any month for a full year past, and included New Yankee drill grinders only: A number of their dry grinders, 11 of their wet grinders, and in addition, 12 drill grinders to foreign countries. Also two of their large Style "G" or "Whale" grinders, the only drill grinder made for grinding drills as large as five inches.

The Philadelphia Pneumatic Tool Co., Philadelphia, Pa., state that their anticipated volume of business for September was fully realized, the sales for that month having been 20 per cent. more than any previous month. Large orders have recently been received from Great Britain, France, Italy and Denmark. Their German representative, Mr. Chas. G. Eckstein, is now in this country and will probably remain for some weeks.

MACHINERY.

January, 1903.

IMPORTANT GAS-ENGINE INSTALLATION.

THE FIRST OF TWENTY-FOUR ENGINES AGGREGATING 40,000 H. P. NOW IN OPERATION AT BUFFALO—BLAST FURNACE GAS USED.

The illustration on this page is of a 1,000 horse power gas engine of the Koerting type, well-known in Europe, recently built by the De La Vergne Refrigerating Machine Co., New York, for the Lackawanna Steel Co., at Buffalo. This fact in itself may have no special significance, but there are certain features connected with this installation which make the engine of unusual interest and possibly of sufficient importance to say that it marks an epoch in gas engine construction in this country.

A gas engine of 1,000 horse power cannot at the present time be said to be unusual, as several machines of about this power have been built in America and quite a large number are in use in England and on the Continent. This particular machine, however, is the beginning of what will be the largest gas-engine plant in the world and, furthermore, the plant will be operated by the waste gases from the blast furnaces of the steel company instead of by producer gas or natural gas, as has heretofore been the case in this country. We are informed that the Pennsylvania Steel Co. are also installing a blast furnace gas-engine plant, so the movement toward larger gas engines, operated by blast-furnace gas, appears to be well established.

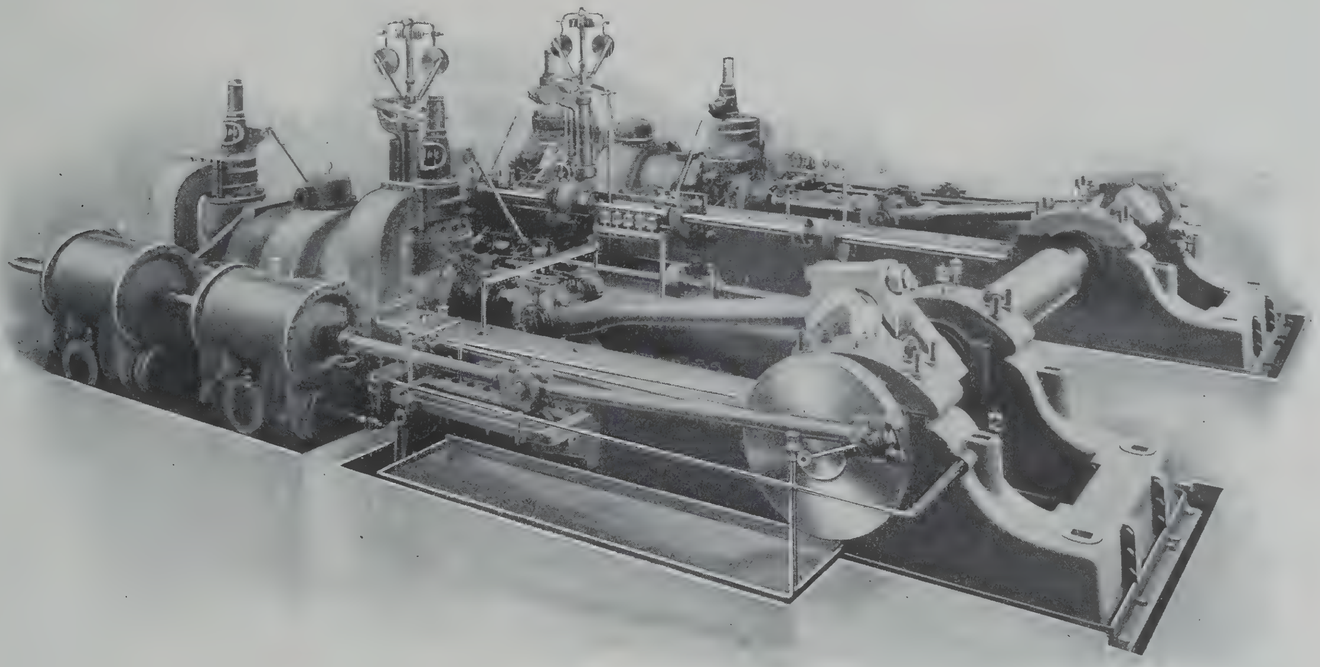

Fig. 1. Koerting Gas Engine of 1000 H. P., built by the De La Vergne Refrigerating Machine Co., New York, for the Lackawanna Steel Co., Buffalo. There will be eight Engines of this size and sixteen of 2000 H. P. each, all Operated by Blast Furnace Gas.

The Lackawanna Steel Plant.

The plant of the Lackawanna Steel Company, where the Koerting engines are being installed, will be the largest individual steel plant in the country, if carried out as now projected. The Lackawanna Steel Company was formerly of Scranton, Pa. It was decided to move to Buffalo, however, and something over a year ago work was begun at the new location. The site occupied is on Lake Erie, south of Buffalo, near what is known as Stony Point, and covers an area about 3½ miles long by 1¼ miles wide. The plant will include blast furnaces, Bessemer and open hearth furnaces and a large number of coke ovens, and will be in active operation within three or four months. Some work is already being accomplished while the building operations are in progress. A large machine shop, 500 feet long, has been running several months and work is being pushed on large rolling mill engines for the Lackawanna plant, which were designed by the engineers of the company and are intended to be heavier than any similar engines ever built. Not the least in importance in the great undertaking is a ship canal, extending three-fourths of a mile into the property from the lake shore. It will be 200 feet wide, 25 feet deep, and will be served by ore handlers which will transfer the ore from the holds of vessels in the canal to the storage yard near by. The most impressive sight, however, to one mechanically inclined, is the two large power plants in which are to be located the gas and steam engines for electric generating, for furnishing the blast for the blast furnaces, and other miscellaneous purposes. The larger of the two power houses is 700 feet long and will contain, besides several large steam engines and air compressors, eight 1,000 H. P. Koerting gas engines, direct-connected to two 500 K. W. generators. The first gas engine was erected and started in the latter part of November and ran satisfactorily. It was first tested by compressed air and is now being run by a temporary gas producer plant, pending the completion of the blast furnaces. The other power plant will contain sixteen 2,000 horse power Koerting gas engines, of the same type as the one shown on this page, but will be used for operating blowing cylinders mounted on vertical frames directly over the cranks of the engine. These cylinders are being constructed by the Southwark Foundry and Machine Company, Philadelphia, and the proportions of the machines can be judged by the fact that the total height above foundations will be 31 feet.

The Koerting Gas Engine.

The Koerting engine is a German machine, designed by Ernst Koerting, which operates on the two-cycle plan and is also double-acting. This gives an impulse at every stroke just as in every steam engine. Nearly all successful gas engines have heretofore been of the Otto four-cycle type and single-acting, with an impulse at every fourth stroke. Apart from its connection with the immense power plant of the Lackawanna Steel Co., therefore, and its operation by blast furnace gas, the machine has certain constructive features that will well repay careful study on the part of the student and of the engineer.

In the two cuts herewith will be found sectional views of the Koerting engine, one being a plan view and the other a cross-section taken in elevation. As stated above, the engine is double-acting like a steam engine, hence the crank end and the head end of the power cylinder are similar. The admission valves are located in the valve boxes, which are bolted to the cylinder heads, and no exhaust valves are required, as the products of combustion escape through slots or ports cast in the middle of the cylinder from where the exhaust pipe leads. These slots are covered by the motor piston itself. For this purpose the piston is made very long and is packed at each end by the customary self-closing spring rings.

The combustible mixture is admitted through two double-acting auxiliary pumps, the one for gas, the other for air. These pumps are so proportioned that their combined action always secures the proper mixture necessary for complete combustion and introduces the same to the working cylinder. The compression spaces of the pumps are divided, so that the crank ends of the air pump and gas pump discharge into the crank end of the power cylinder, and the head ends of the pumps discharge into the head end of the power cylinder. The gas and air are compressed by the pumps to about nine pounds per square inch.

Referring to Fig. 2, it will be seen that the piston is at the outer dead point, and that the exhaust ports are exposed toward the opposite or head end of the engine. The instant the piston begins to uncover the exhaust ports, the pressure of the residual products of combustion in the cylinder drops rapidly to that of the atmosphere; when this has taken place, the inlet valve is opened and a fresh charge admitted by the pumps. The valve gear of these is so designed that air only is supplied first, to separate the burnt gases from the succeeding mixture, and afterward gas and air, mixed in proper proportions.

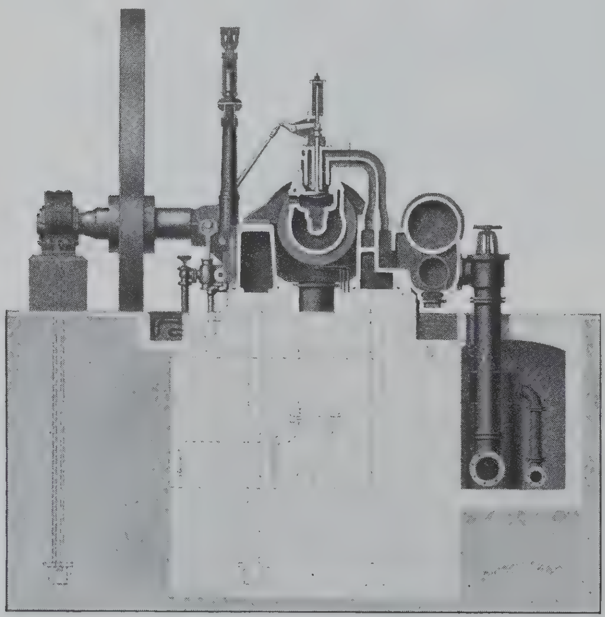

Fig. 3. Sectional Elevation of Koerting Engine.

The combustible mixture of gas and air is produced only at the inlet of the cylinder. There is no storing of it, and by suitable construction of the admission device, mingling of the air first introduced with the burnt residue gases, or with the succeeding charge of the combustible mixture, is adequately avoided. For the same reason, loss of mixture through the exhaust ports, which are open during this period, is prevented.

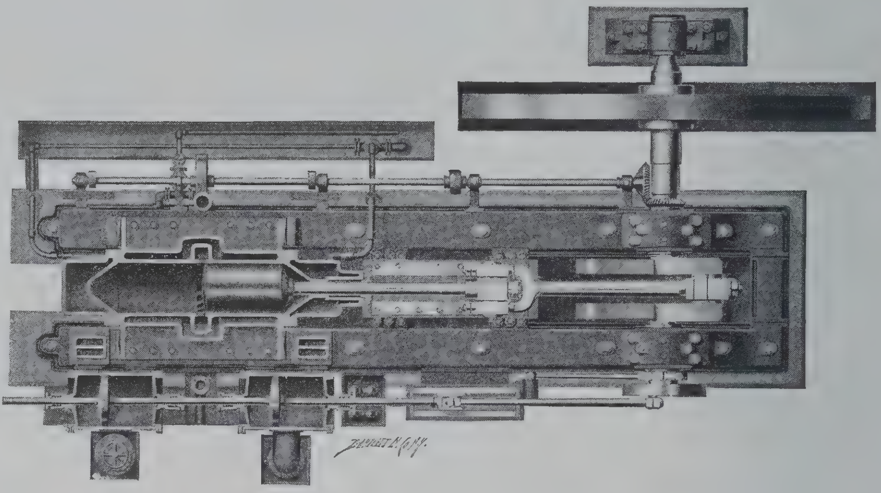

Fig. 2. Plan View of Koerting Gas Engine, taken in Section.

Shortly after the exhaust ports are again covered by the receding piston, the air and gas pump pistons arrive also at their dead point position, and the supply of mixture is interrupted. The inlet valve closes and the charge is compressed in the cylinder in the usual method, till, at the dead point of the stroke, ignition takes place.

At the next movement of the main piston, the ignited charge exerts its driving power by expanding till just before arriving at the other dead points, when the piston uncovers the exhaust ports again and allows the consumed charge to be blown out. On the opposite end of the piston the same operation takes place. This arrangement necessitates the double passages between the small cylinders and the large one, as shown in the two sectional views.

In order to secure the separating layer of air above referred to, between the hot consumed gases and the fresh charge, the gas pump is so constructed that no gas is delivered until after a certain point in its compression stroke. The pump is provided with piston valves with the valve gear so arranged that its maximum capacity cannot exceed 50 to 60 per cent. of its total displacement. For after the pump has completed the suction stroke, the gas suction port is left open during a portion of the succeeding (compression) stroke, so that the gas can return without increase in pressure until the suction port is closed, when the gas is compressed and passed out through the compression port.

The amount of gas thus furnished corresponds to the maximum power of the engine.

Regulation of the power is effected as follows: When the load on the engine is reduced, the gas pump begins to furnish gas at a correspondingly later period, thus discharging a diminished quantity of gas into the working cylinder. This is accomplished either by the valve gear of the pump, and controlled by the governor, or by a by-pass located between each pump end and respective compression channel which leads to the inlet valve on the main cylinder. The throttling device in this by-pass is also under the control of the governor.

It is evident from the above that the engine operates with a variable amount of mixture, and that correspondingly more or less air is sent first into the power cylinder. This air stays near the middle of the cylinder, while the combustible mixture remains at the heads of the cylinder near the inlet valves and igniters. The peculiar shape of the cylinder heads prevents mingling of the layer of air with the following mixture of gas and air.

For ignition there are provided two spark coils at each end of the power cylinder. These are operated by a separate shaft, driven by spur gearing from the cam shaft. The gear on the igniter shaft is not fast; it is connected with a sleeve having a feather, which is set spirally around the shaft so that by a sliding movement of the wheel the igniter shaft may be set behind or in advance of the cam shaft. Thus the time of ignition can be changed during running of the engine to suit whatever kind of gas is being used. A further advantage secured by this arrangement is, that at starting, the point of ignition may be so set that ignition takes place only after the piston has passed the dead point, and the engine started very slowly without incurring any pre-ignition. Very lean gases require much earlier ignition than is otherwise usual. In practice, indicator cards are taken from time to time to check the timing of the ignition, and to see whether the combustion of the gases is without fault. Igniting of very poor gas mixtures presents no difficulties at all with this arrangement. The engine is started with compressed air. Engines to which a blowing cylinder is attached are easily started with air under 150 pounds pressure; for those without such cylinders 90 to 120 pounds per square inch is sufficient.

A piston valve is provided for admitting the compressed air at front and back ends of the cylinder, as in a slide-valve steam engine. This piston valve is operated from the cam shaft by an eccentric, which can be thrown in or out of gear like a clutch. Filling the cylinder with air twice is generally sufficient for starting up, after which the engine runs itself.

The power cylinder and piston are cooled by circulating water, which in the case of the piston enters the tube carried through the crosshead pin and hollow piston rod, and returns the same way, but on the outside of the tube. The stuffing boxes in the cylinder heads are surrounded by water. The cylinder walls also are cooled throughout, except at the middle where the exhaust slots are. By maintaining the piston cooler than the cylinder, the expansion of the former is under entire control and the result is good running of the engine.

The Development of the Gas Engine.

It will be interesting to note in this connection that gas engines were not considered of any importance in this country, or anywhere else for that matter, previous to the Centennial in 1876. At that time the Otto "silent engine" attracted considerable attention and for several years until the patents expired this make of engine was the only one in evidence. Later, many other firms started in the gas engine business but the machines which they built were all of small sizes and all operated on the Otto cycle. For the most part gas engines have been used where only a small amount of power was required and have been run with illuminating gas, thus making a very convenient motor and one which could be located almost anywhere. With suitable modifications they have been adapted to use with gasoline vapor or with natural gas. It was not until 1897 or 1898 that large gas engines began to be built in this country—one of 650 horse power being completed by the Westinghouse Machine Co. in 1899. In fact, it was generally considered that while a small gas engine was a convenient and economical motor, large gas engines would meet with almost unsurmountable difficulties and might never become important competitors of the steam engine.

It is obvious that when operating on the Otto or four-cycle plan, with an impulse at every fourth stroke, an engine of 1,000—or even of several hundred horse power—would require a cylinder of enormous size and other parts in proportion. If operated with illuminating or natural gas, it would involve the handling of large volumes of a highly inflammable gas and there would be occasional violent explosions, which would be positively dangerous. These two facts, drawn from experience with small engines, probably had their influence in delaying the construction of large machines. As has frequently been the case, however, English and other European engineers were ahead of us. They got around the difficulty of the large cylinder by using two cylinders in tandem or two engines in pairs, and by the perfection of the two-cycle type like the Koerting. They also successfully introduced producer gas, which is less inflammable than illuminating or natural gas. Even producer gas in the proportions in which it was first made would not have been successful for large engines because it contained a considerable proportion of hydrogen, which ignites and combines very readily with the oxygen of the air at comparatively low temperatures.

One of the earliest advocates of producer gas was Mr. J. Emerson Dowson, who called attention to its possibility in the *Journal of the Society of Arts*, in 1882.

In 1894 the idea of utilizing blast furnace gases was suggested by Mr. B. H. Thwaite, in England, who showed that its elements and the proportions in which they existed were about the same as with producer gas, and who built a 20 horse power experimental engine to demonstrate the feasibility of the plan. While gas engines will now undoubtedly be used more and more in connection with blast furnaces there is still the objection that blast furnace gas is heavily loaded with dust which will cut the cylinders unless the gas is thoroughly cleansed, and the constituents of the gas are such that it is not easily ignited in the engine cylinder.

Using Blast Furnace Gas.

The usual blast furnace plant contains, in addition to the blast furnace, two blowing engines for producing the blast, three brick stoves (four are used at Buffalo) for heating the blast on the regenerative principle and several boilers for generating steam for the blowing engines. The waste gases from the blast furnace are alternately burned in one or two of the stoves, while the blast is forced through the remaining one or two, previously heated. The process is one of alternately heating and cooling. The waste gases are also burned in the furnaces under the boilers, which latter are generally of simple construction, and not economical in operation, since there is always more gas produced than can be utilized in connection with the stoves and blowing engines. When it comes to using the waste gases in internal combustion engines, a horse power can be produced with one-quarter to one-sixth the quantity of gas consumed per horse power under the boilers in the usual manner, and it is possible to derive enough power to light the works and operate much of the machinery about the plant. This fact being realized, and the large gas engine having proven a success, a new era in power development will be the result.

When the gas leaves a blast furnace it is at a temperature of from 700 to 1,000 degrees, is charged with more or less steam and, as before stated, is laden with dust. Before being suitable for use in a gas engine cylinder the dust must be removed by a scrubbing process, such as passing out through a tank containing coke, through which water runs, or by spraying water on the blades of the fan usually employed to draw the gas through the pipes from the blast furnace and deliver it to the engine cylinders. The gas is also cooled to condense the steam and allow it to separate from the gas, leaving the latter drier and more suitable to use.

The calorific capacity of blast furnace gas is low, as shown by the comparative figures given below:

	British Thermal Units per cu. ft.
Natural Gas	1000
Illuminating Gas	650
Water Gas	450
Producer Gas	125
Blast Furnace Gas	100

While an engine must be larger if it is to be operated by blast furnace gas than if used with a more efficient fuel, its size need not be as great as indicated by the number of heat units, since a much larger charge can be used than with natural or illuminating gases, which are more inflammable.

* * *

The *Electrical World and Engineer* says that a 60,000-volt power transmission line 105 miles long is projected at Guanajuato, Mexico. Power is to be transmitted from a waterfall by the tri-phase alternating system and the line wires are to be supported on steel towers 440 feet apart, making 12 to the mile. The line wire is a cable made up of 19 strands of copper wire having an aggregate section equal to a No. 1 solid wire. The reason for using a cable instead of solid wire is that the tensile strength is increased fully 50 per cent. over the solid wire, and high tensile strength is quite necessary with such long spans. It is estimated that the cost for the tower-supported line will be no more than for a pole line.

SHOP CONSTRUCTION.—4.

FOUNDATIONS.

OSCAR E. PERRIGO.

It is but quoting an old maxim to say that if we are to build a good house we must have a good foundation to build it on. And we may just as pertinently say that if we are to build a good and substantial foundation, we must have something solid to lay it upon. Otherwise we shall be like the man who built his house upon the sands. The diversity of the ground, at the surface and down through the stratifications of material of various densities and strengths, from the solid nature of rock to the almost fluid condition of alluvial soil, must be considered. Each of these conditions requires special treatment according to its nature.

To properly secure a firm bed for the foundation of a building, we must either excavate down to firm and solid ground, technically called "hard pan," or we must by artificial means produce a substantial surface upon which to begin the masonry. It is quite impossible for the architect, the mason or the contracting builder to tell us by a superficial examination of the ground how deep we must go to reach solid ground, or "hard pan." To some extent this may be ascertained by "sounding;" that is, by making small excavations at various points, to obtain the necessary information upon which to determine not only the depth to which the foundation must extend, but whether the nature of the ground renders such artificial support as piles necessary.

It may be found that at some points in the foundation of extensive buildings we need excavate only a few feet, while at others, very deeply; and still at other points the ground may be of such a yielding nature that piles must be driven. Or we may find that the use of piles would be a much more economical method than very deep masonry. But whatever the depth we may be obliged to go to, or the process by which we produce our bed for the foundation, all parts of it must be, not only firm and practically unyielding but level. Hence, when we excavate to varying depths the earth must be "benched out," as it is called, as shown in Fig. 5.

Great care should be taken to have all parts of the bottom of the excavation of as equal density and resisting power as possible, that they may equally support the great weight of the wall to be built. This condition becomes all the more important as the walls of the building are higher and the consequent weights and strains correspondingly increased. It is, of course, true that no ground can be found so absolutely solid as not to yield somewhat when the weight of the building is put upon it, and therefore we must not expect to wholly prevent a certain amount of settling; but we should use all possible care to have this settling as equal as possible over the whole area of the foundation.

Having ascertained the nature of the ground as far as possible, we may determine the kind or kinds of foundation necessary. If the ground is so soft and yielding that excavation to solid earth will have to be very deep, making a stone foundation excessively expensive, piles should be driven as deep down as possible—say, two feet apart, from center to center—and cut off level at the top, and be down low enough to remain always wet. Upon these piles timbers of sufficient size are placed, being laid across each row of piles; then upon these another course of timbers, at right angles to the first. These may be laid close together or two or three inches apart, the size of the timbers being determined by the weight of the wall they are to support. For instance, for the walls of the machine shop proposed in these articles, the timbers may be 10x12 inches laid on edge. Fig. 1 gives a plan view of this method and Fig. 2 shows a cross section of the same. It is not always necessary to arrange the piles in three lines, with those in the center row in line with those of the two outer rows, as shown. Where the weight of the superstructure is not excessive it is often preferable to begin by setting three piles in a row, then two so they will come opposite the intervals of the first row; then, the next row of three in line with the first; then another row of two piles and so on. Where there is considerable depth from the top of the piles without side support it is necessary to drive "sheet piling." Set planks three inches thick, or thicker, with their edges close together so as to enclose the work on both sides, and afterward fill in the spaces between these planks and the solid earth with tightly rammed gravel, and if necessary fill the spaces between the piles with stones or concrete. This will give them quite sufficient support to make a very firm foundation bed and prevent any lateral movement which might result from the bending of the piles.

Timber should not be used under a foundation unless it is in a position to be kept continuously wet by the surrounding soil, for the reason that if always wet enough to exclude the air it will endure for a very long time, but if so situated as to be sometimes wet and again dry, it will soon decay. Therefore, if the use of timber, as above described, is not feasible we must use stone and so arrange the piles, regarding the distances from center to center, as to allow the use of such stones as are available, cutting off the tops of the piles below the water line if possible, or at least so low as to have them always wet. This arrangement is shown in Fig. 3.

Sometimes fairly solid earth may be reached within a reasonable depth, but it requires digging quite a depth beyond this before reaching really solid ground or "hard pan." In such a case it may be advisable to lay down first, a course of concrete four to six inches thick, then a layer of timber and another course of concrete, which will furnish an excellent bed for the foundation. The second course of timber may be replaced by a course of 3-inch planks if the wall is not a very heavy one. Circumstances might also warrant three courses of timber. The width of the timber work should be from two to three times the thickness of the wall. Fig. 4 shows such an arrangement.

A prominent public building has stood for many years on very soft and yielding alluvial soil, upon which such a foundation as that described above was laid over the entire area to be covered by the structure, and many feet deep. Then the stone foundation proper was built upon it, after which the very heavy and massive stone building was erected.

Where excavations vary in depth at different points of the same wall the ground should be cut out in steps, or "benches," so that the bed whereon the foundation is built may be perfectly level. The lower steps should be built in with as large stones as possible and brought up to the level of the more shallow parts. For the larger stones require a smaller number of cement joints and will settle less and consequently, are less liable to disturb the work by yielding unequally. See Fig. 5. In all cases the excavation should be made below the reach of frost.

In building up a foundation of stones they should be laid with as near horizontal joints as possible so as to prevent the lateral movement of the stones by the weight put upon them. They should also be laid as far as possible in courses, and each course leveled off before commencing the next, the thickness of the courses necessarily depending on the thickness of the largest stones. These points are all the more important at corners, where tendencies to disintegrate are the most liable. The foundation is laid considerably wider at the base than at the top, either in a wall gradually decreasing in thickness (that is, technically, with a "batter" of so much per foot, as in Fig. 6) or more commonly by a wide footing of one or more courses of larger stones. Above that it is built with regular vertical faces as shown in Fig. 7.

However the foundation wall may be built, the space between it and the sides of the excavation should be filled in, either by tightly rammed earth or gravel, or better still by "puddling," that is, by flooding the space with water, throwing in the earth or gravel and allowing it to settle, ramming only from six inches to a foot of the top. The foundation of stone should be carried up above the level of the ground, from one to two feet according to circumstances. If the main floor of a building is to be raised several feet above

Sketches Illustrating the Subject of Foundations for Manufacturing Plants.

Industrial Press, N.Y.

the ground level, it is usual to build the foundation high enough to rest the floor timbers upon it, filling in the spaces between them with brick and leveling up ready for the brick wall.

The importance of using strong mortar in foundation work seems to demand that particular attention be paid to the proportions of its ingredients which will make the best compound of its kind. Use two parts of Portland cement, one part of slaked lime, and about three parts of clean, sharp sand. The quantity of sand must be varied according to its fineness, sharpness, and freedom from dirt. A larger quantity of fine sand will be needed than of coarse. Some sand has a more rounded grain instead of the sharp angles of the better quality. Of such sand more must also be used.

Foundations are generally laid in mortar having a greater or lesser proportion of cement. They should also be stronger in this respect for the lower or underground courses than for the upper ones so as to better resist the action of water. In fact much of a foundation is frequently laid in mortar composed of only cement and sand, omitting lime altogether.

Thus far only the foundations for buildings have been considered. These have for their principal object to sustain the weights of the superstructure erected upon them. In the case of the foundations for machinery it is quite different. Here not only the weight must be sustained but the question is complicated by the jars, strains and shocks due to the operation of the machines; and this must also be considered. These vary largely in different cases, as for instance, the steady revolutions of a large lathe, the reciprocating motion of an engine and the vertical concussions of the steam hammer or drop press. Foundations for engines, large lathes, planers, boring mills and so on, are built in a manner somewhat similar to that for the foundation of a building, except that they are usually much broader at the base, conforming in a general way to that shown in Fig. 8. Only a good quality of hard bricks should be used, and the entire work should be laid in strong cement mortar.

The holding-down bolts, when it is necessary to use such fastenings, are made long enough to reach well down in the foundation, if not entirely through it, and are provided with large washers or plates at their lower ends. These are put in place as the foundation is built up and their top ends are held in position by a templet made of boards in the form of a frame, and representing the base of the machine. In a large foundation of this character, blocks of dressed stone should be worked into the finishing courses of bricks so as to bring them level with the top. These are usually placed crosswise, one at each end; and others at such points as to furnish firm support for the cylinder, crank shaft, pillow block, and guides of an engine; for the headstock of a lathe, and for suitable points along the length of the bed; under the uprights or housings of planers and at each pair of legs, or at proper intervals where the entire bed rests on foundations without the use of legs. Usually, in the case of a planer, and often of a large lathe, the foundation is composed of a series of piers built up separately at the points to be supported, each pier being capped by a stone of sufficient size to cover it.

In laying out the foundation for a planer of say, 36x36 inches or larger, a pit should be provided under the center; that is, from a point one to two feet back of the face of the uprights to a point three to five feet in front of the uprights, and five to six feet deep. It should be broad enough for the building of narrow steps leading down into it. This pit will receive a great portion of the chips produced, and in it, resting on large and firmly set stones, should be two cast-iron columns, with strong jack screws tapped into their tops, and coming up into contact with the under side of the bed at a point near the face of the uprights. Thus arranged, they are very useful in maintaining the proper alignment of the planer. A foundation now in use, upon which large lathes are erected and tested, was built as shown in Fig. 9. Solid ground was found about five feet below the floor level, and a course of concrete was first laid, then three courses of stones, and upon these hard bricks, cement being used throughout. Upon the top of each pier a cast-iron plate 1½ inches thick was placed. This plate had downwardly projecting flanges all around it, deep enough to cover three courses of bricks. In the top of these plates was a hole six inches in diameter. When the brickwork was finished these plates were put in place and leveled up so as to leave about half an inch space between the plate and the top of the bricks. Around the lower edges of the flanges the space was carefully closed with cement. Then cement was mixed thin enough to flow easily, and was poured into the hole at the top until the entire space at the top and sides was completely filled, and the whole was allowed to "set." The tops of the plates were about ¼ inch above the top of the floor, which was built up closely around them. Very heavy lathes are moved on and off these piers almost daily without injury, and the piers have not settled to any appreciable extent, or so as to cause any difficulty in leveling up machines to be tested.

In placing high-speed engines or planers, which are liable to lateral shocks, it may be advisable to provide cast-iron plates as described above, with the downwardly projecting flanges to cover the upper courses of brickwork, and also with upwardly projecting flanges enclosing sufficient space for the base, cabinets or legs, as the case may be. After leveling up the machine with steel wedges, say a ¼ to a ½ inch, the space is filled with melted lead or brimstone, which when cool will form a very secure, serviceable and durable arrangement.

Foundations for machines subject to considerable vertical shocks, such as steam hammers, drop presses and the like, must be treated in an entirely different manner. From the nature of the work a solid foundation of stone and brick is not usually considered as best adapted to the conditions. Such a foundation would soon be spoiled by cracks and disintegration from the shocks, and serious consequences to the machine might ensue, the parts broken, for instance, or the dies ruined. For such cases many experienced men prefer foundations that may be elastic enough to relieve the machines somewhat of the sudden strains and shocks of heavy and oft-repeated blows. In these cases the foundations are composed of timbers. There are two common types of these foundations. The first one, for small or medium sizes of drop presses or hammers, are built with timbers set on end and firmly bolted together in sufficient numbers to form a foundation of the required size, as shown in Fig. 11, the bolts going entirely through the mass. Timbers 10 x 10 inches or 12 x 12 inches are a convenient size, and hard pine is found by experience to be best adapted to the work. The excavation is first made to solid ground, then a foot or so of hard gravel is tightly rammed down in the bottom, to form the bed. The timbers are cut of a proper length to reach the surface, but should not be less than five feet long. They are bolted together, lowered into place, and leveled up and good hard gravel is tightly rammed in around the timbers filling the space between them and the sides of the excavation.

This form of foundation is adapted for drop presses and small hammers in which the anvil is a part of the machine itself. In case a hammer is of such size as to have the anvil detached from the main frame, the latter is supported upon a stone foundation, or on one partly of stone and partly of brick (built in two piers for a double hammer), as in Fig. 10. The foundation for the anvil is built of timbers laid horizontally, the base being spread over as large an area as practicable, in order to resist the force of the blows of the hammer. In a double hammer the anvil foundation must be restricted in width, but may be extended in length at the base so as to present the form shown in the engraving.

The size of the foundation is necessarily proportioned to the size of the hammer, but approximately as follows: Supposing the width between the upright parts of the main frame to be six feet, the width of the timber work will be about four feet, the length on top eight feet and at the base twelve feet—assuming the necessary depth to be four feet. If solid ground is not found at this depth, the excavation may be filled up with hard gravel, stone or concrete; or a layer of concrete may be placed at the bottom, then a course or two of stone laid in cement mortar, and finally hard gravel well rammed in. The timbers should be bolted together at the corners or securely spiked, but owing to constant shocks, bolts are to be preferred. The top corners of the timbers should be bolted together horizontally. The masonry piers and timber foundations must not in any way be connected, as the constant concussions would soon disintegrate the masonry. All spaces around the masonry and timber work should be tightly rammed with hard gravel. The size of the timbers may be from 6 x 6 inches and larger according to the size of the structure; but they are usually 10 x 10 inches or 12 x 12 inches. Timbers used in places where decay is feared should be coated with hot gas tar as a preservative.

On one occasion, in soft and very yielding ground, a machine of forty tons weight was supported by a foundation built by excavating nearly 30 feet deep, piles being driven at two feet centers over an area about three times the width and length of the base. Upon these was built a timber structure in the manner described, up to within six feet of the surface of the ground, and gradually drawn in to four feet larger all round than the base of the machine, which was quite high in proportion to its width of base. On this timber work stone laid in cement mortar was built up to the level of the ground and the machine erected upon it. The foundation proved successful.

* * *

NOTES ON CORRESPONDENCE INSTRUCTION.

SOMETHING ABOUT THE WORK OF THE INTERNATIONAL CORRESPONDENCE SCHOOLS, AND OF THE AMERICAN SCHOOL OF CORRESPONDENCE.

The remarkable progress in correspondence instruction during the past few years is the most interesting fact connected with the great educational movement of the present time. It is said there are more correspondence school students in the state of Massachusetts alone than in all the colleges and universities of the whole country. This means that there are thousands of persons, mechanics and others, who do not believe the saying to the effect that a workman is hired to work, not to think. The best mechanics are those who do think, who are well informed, who are well grounded in the foundation principles of their trade; and the same is true, only to a greater degree, as they advance to the higher positions of foreman, superintendent, and so on.

A representative of MACHINERY recently stopped at Scranton, Pa., en route to Chicago, to call at the International Correspondence Schools, and later, when in Chicago, a visit was paid to the American School of Correspondence in their new quarters adjoining Armour Institute. As many readers are personally interested in correspondence instruction it is believed that a brief report from these two institutions will be welcome.

It is generally known, of course, that the International Correspondence Schools are conducting their work on a large scale, but it is doubtful if many appreciate the enormous proportions to which the schools have grown during the few years they have been established. There is now an enrollment of nearly 500,000 students, or nearly half a million, with a rate of increase of about 13,000 students per month. There are 1,200 employees of the schools in Scranton alone. In 1898 a large executive building, of stone and four stories high, was erected for office purposes, also a printing office with accommodations for 200 workmen. But here, as in other departments, the growth has been so rapid as to exceed all anticipations and the buildings were no sooner completed than they were found inadequate, and at the present time additional rooms are rented in every available office building in the city. In the matter of printing, conditions are even more inconvenient. All the new text books are printed in New York City, and all the printing offices of Scranton are assisting in printing the circulars, blanks, etc., used by the schools.

The outcome of the whole matter is that still another new building is being erected for both office and printing purposes, which it is hoped will meet the requirements of the concern, for a time at least, and to provide for the future it is so planned that it can be enlarged to twice its present size. The building will be 460 feet long, 167 feet wide, divided into three bays—one at each end three stories high, and a middle bay 300 feet long, partly one and partly two stories high, where will be installed the printing offices and machinery. Mr. T. J. Foster, the founder of these schools, is taking much pride in having the new building a model of architecture in every respect, that may be held up to the students as an example for their guidance. It is being constructed of Pompeiian brick, both inside and out; the machinery will be motor driven, the elevators of the plunger type, and the power plant will be of the most approved type in every respect, with reserve units for emergency use. This building is perhaps the most interesting feature to report upon at present.

There have, however, been several changes and additions in the courses of instruction and an extensive revision of the papers of all the courses is in progress, including the course in machine shop work to which we have referred in a previous number of the paper. One secret of the rapid increase in the business of the schools is that new courses have been frequently added, taking up different departments of work, and adapting correspondence instruction to new fields where there appeared to be a demand for instruction. There are now 142 different courses, and they include such unusual subjects as the packing house industries, the manufacture of leather and of soap, window dressing, metallurgy of gold, silver and copper, etc., these being mentioned to show the diversity of instruction. Two new departments have been established, the School of Navigation and the School of Textiles, the latter acquired through the purchase of the Correspondence School of Textiles of Bedford, Mass. In preparing the various instruction papers outside writers are employed, if the time of the instructors at Scranton does not permit, or the experience of those intimately connected with commercial work is desired.

There is now being issued, in a library of about 50 volumes, a collection of the best instruction papers upon various technological subjects. As a matter of course the subjects of the various courses overlap to a greater or less extent and it is believed that many would like a reference library, written in elementary style, which treats of the different technical subjects, but without duplication. This library will be added to until it contains upwards of 75 volumes. In preparing these, special attention is given to the illustrations, as will be appreciated by those who have seen the International Correspondence School papers, which are probably the best illustrated of any technical books at the present time, not excepting books by our best publishers.

The American School of Correspondence.

The American School of Correspondence at Chicago, recently removed from Boston, is pleasantly located in buildings adjoining Armour Institute of Technology and owned by the Armour interests. The offices are novel in that they occupy what were formerly apartments, or flats, two whole apartment buildings having been secured for the purpose. They make an almost ideal arrangement, however, for so diversified a business as correspondence instruction, where there are many departments and private offices are needed by the various instructors.

As most of our readers are probably aware, this school is trying a new and important experiment in correspondence instruction. The removal from Boston to Chicago was because of arrangements by which the correspondence method of the American School of Correspondence is to supplement the work of Armour Institute; or more properly, perhaps, is to be supplemented by the work of the institute, in so far as students of the correspondence courses are able, through their preparation, to profit by the superior advantages of a residence course at Armour Institute. It is proposed that a student shall have the opportunity of enrolling in the school of correspondence with the idea of eventually completing his studies as a regular student at Armour Institute.

The arrangement by which the two schools are to cooperate in offering instruction has been in effect for so short a time that it is impossible to estimate at present to how great an extent the correspondence studies may be made of service to prospective Armour Institute students. Before the full benefit of the arrangement can be secured some of the papers of the correspondence course must be rewritten to conform to the instruction given at the institute, and this work will be under the supervision of the Armour Institute faculty. It must be remembered that as the correspondence courses now stand they are intended to give elementary instruction of a more or less superficial character, adapted to the needs of the workman with limited education. They were prepared from an entirely different standpoint from the courses of a technical college.

There are three different departments or grades of study under the direction of the Armour Institute. First and most important is the School of Engineering, corresponding to the best technical colleges, which give a degree upon the satisfactory completion of four years of study; second, is the Academy, of high-school grade, which equips students to enter the school of engineering; and lastly the Armour Institute evening school.

It is not expected that a course of correspondence will enable a student to cancel any of the studies in the school of engineering, as it is desired for the present, at least, that a person shall spend four school years at Chicago, before receiving his degree, so that he may come into intimate contact with the instructors and derive the full benefit of the laboratory instruction. What will be accomplished, however, and is now to a considerable extent, is to apply as much of the correspondence instruction as possible to prepare a student to enter the school of engineering without taking the course in the academy. It is believed that a person will be able to fully qualify to enter the institute in this way, and at the same time his correspondence studies will make his residence course easier for him and possibly enable him to take other additional studies that he could not otherwise complete. A course in correspondence will also enable a student to cancel certain studies given in the evening school.

The papers that are now being prepared for the correspondence schools are being written by outside authorities, for the most part, or by Armour Institute instructors, and the custom is adopted of putting the author's name on each paper. This experiment in technical instruction is similar to what is being done with success by the University of Chicago in general studies, and it will be carried along on conservative lines and, we believe, strictly on a high plane.

* * *

INTERNALLY AND EXTERNALLY FIRED BOILERS.

The art of steam making is one that has probably received as much attention from inventors and engineers as any other, yet there seems to be a general misunderstanding, on the part of many practical men, of the laws that govern combustion and the best way to absorb the heat from a fire into the water of a steam boiler. The common and mistaken idea is that the water-backed surfaces should be as close to the fire as possible and preferably that they should surround the firebox on all sides. This is a mistake. Economical steam-making requires that: 1. The fuel be burned at the hottest possible temperature. 2. That the heat of the fire be absorbed by water-backed surfaces after combustion is practically complete. To burn the fuel at the hottest temperature the fire must be removed from refrigerating effect; that is, it must not come in contact with water-backed surfaces until combustion is complete.

In a circular of internally-fired boilers recently received, some strong claims are advanced for this type which occasion these remarks. The internally-fired boiler is claimed to be superior to the externally-fired type requiring a brick setting because as the fire is surrounded on all sides by water-backed surfaces, there cannot be so much loss of heat as with a brick setting. The externally-fired boiler is referred to as being a modification of the camp kettle with the addition of a masonry setting which absorbs and radiates much heat, etc. No one can deny that the internally-fired boiler has many good points nor that it is indispensable for marine, locomotive, portable or similar service where brick settings would be impracticable, but the fact remains that the internally-fired boiler must work under conditions that do not favor perfect combustion. The water-backed surfaces surrounding the firebox reduce the firebox temperature and the gases escape into the flues only partially consumed. The tubes cool the temperature of the gases still more, so that they finally escape in a partially consumed state—smoke.

The ideal boiler setting is one in which the fuel is burned in an isolated furnace constructed of firebrick and properly protected to prevent radiation. From this sort of firebox the hot gases are conducted against the water-backed surfaces of the boiler to give up their heat. Firebrick piers may be provided in the path of the hot gases, which become red-hot and tend to maintain an even temperature while the furnace is being fired with fresh fuel. Such a furnace when properly constructed will burn the fuel with little or no smoke and in a most economical manner, but we are not saying that such a construction is always desirable or that it is practical under many circumstances because it is not. It takes up a great deal of room and is expensive. In general, however, these conditions may be very well approximated, in the horizontal tubular boiler with brick setting, by building a firebrick arch over the grate so as to prevent direct radiation of heat to the boiler shell. The objection to this scheme is that it is expensive to build and maintain, and that it increases the total height of the setting. The advantages will probably offset the disadvantages in most cases.

In regard to the character of brick work in a boiler setting it has recently been pointed out by a foreign authority that it is better to have the internal surfaces rough rather than smooth. If the surfaces are smooth the gases have a tendency to travel in parallel lines without intermingling, whereas if the surfaces over which they travel are made rough, the mixing of the gases is favored, and consequently more perfect combustion. The irregular surfaces are obtained by simply laying the bricks so that every alternate brick projects half its length into the furnace. Not only do the projecting bricks break up the stream lines, but they become intensely heated and have a regenerative effect, something after the plan of the Siemens steel furnace.

GOLD DREDGING IN NEW ZEALAND.

In the November issue allusion was made to a novel gold dredging machine which is in limited use on the Pacific coast. This description having come to the attention of Marshall, Sons & Co., who have large works at Gainsborough, England, they have sent us some interesting literature on the subject of gold dredging, from which we quote in substance:

The gold dredging industry originated on the Clutha River in Otago, New Zealand, about the year 1860. The industry has proved immensely profitable in that province, there being upwards of two hundred dredges at work, many of which are paying monthly dividends of 5 per cent., and more. The spoon dredge was the first type of machine used, but this has been generally superseded by the traveling bucket dredge having one central bucket ladder. The bucket ladder is mounted in an inclined position near the center of the dredge, with the lower end, of course, reaching to the river bed from which the traveling buckets convey the mud and sand. The dredges are built self-contained so that the engine, boiler and separation apparatus are all on board. A traveling conveyor carries the refuse to a spoil bank. The buckets usually deliver into a shoot leading to a revolving perforated screen which separates the stones from the fine stuff carrying the gold. The gold-saving tables are efficient and little gold escapes. An example is mentioned where one hundred particles of fine gold were separated and found to weigh less than one-tenth of a grain. The efficiency of the dredging apparatus is so high and the cost of operation so low that it is said to be profitable to work deposits carrying only one grain in weight per cubic yard. Gold dredging machines are profitably worked in the beds of ancient rivers, even if little water is available. Where no water is at hand, it is carried to the scene of operation in pipes. As the water is used over and over again, the volume of water required is not great, after enough is once obtained to float the dredge. A gold dredger is capable of cutting its way into the bank of a river, and this is often done where the river has changed its course. In such cases the river is left behind, sufficient water seeping through the tailings to float the dredge.

A LARGE HOISTING DRUM.

BUILT BY THE NORDBERG MFG. CO.–THE LATHE IN WHICH IT WAS TURNED.

The striking illustrations in this connection are from the works of the Nordberg Mfg. Co., Milwaukee, Wis., builders of steam engines, hoisting machinery, steam stamps, air compressors, and a general line of mining machinery. The Nordberg Mfg. Co. are now occupying their extensive new plant near the city line of Milwaukee, on the Chicago, Milwaukee and St. Paul Railway, and are unusually well equipped in every way for building the varied line of heavy tools for which they are well known. The plant is the result of much careful thought and study and there are numerous features of interest connected with its arrangement and equipment, and with the engineering work in progress, which we intend to refer to in a subsequent number.

At the present time the most important work on hand is a hoisting engine for the Tamarack Mining Co., Calumet, Mich. In its main features and dimensions this will be practically a duplicate of an engine built for the same company about four years ago, which was designed to hoist from a depth of 6,000 feet, or 720 feet more than a mile, and at a maximum speed of 5,000 feet, or nearly a mile a minute. The famous Tamarack mine, for which these machines were designed, has the deepest shafts in the world, and the two hoisting engines are the largest of their kind and in points of efficiency, safety and convenience show the result of engineering skill of a high order. In general form, they have a massive triangular bedplate, with the rope drum and its shaft supported in bearings at the upper apex of the triangle. There are four inclined Corliss engines resting on the faces of the bedplate and arranged in pairs, one pair operating on a single crank at one end of the shaft and the other pair operating on a crank at the opposite end.

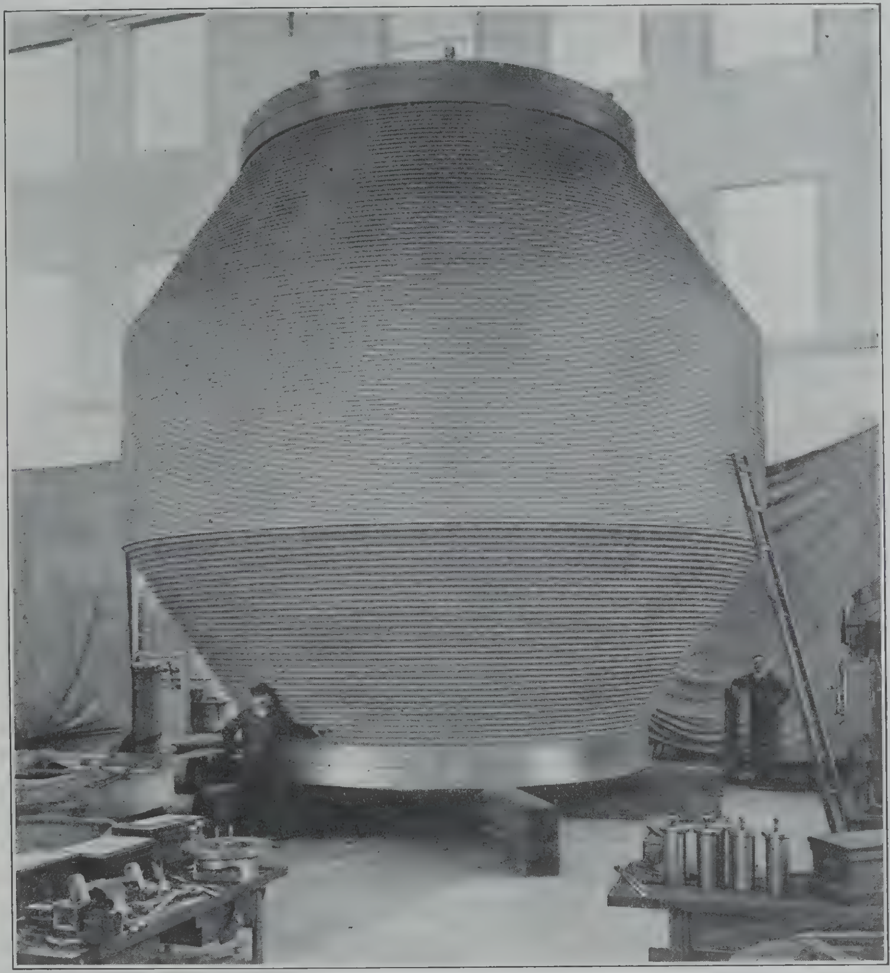

Fig. 1. Rope Drum as it looks Completed. Size, 25 feet Diameter; Length, 24 feet 6 inches. Two 1 1-2 inch Hoisting Ropes, each 6000 feet long, are operated by this Drum.

The rope drum of the first machine had cast grooves for the hoisting rope, but in the machine now building the drum was first turned, to produce a smooth surface like the face of a pulley, and the grooves were then turned out of the solid, making a thoroughly mechanical piece of work. The drum is 25 feet in diameter, 24 feet 6 inches long, and as it stands on end in the shop in the position in which it was photographed for the illustration, Fig. 1, it presents one of the most striking examples of machine work to be found. It is composed of 48 separate segments bolted together, besides the spiders, tension rods, etc., used in supporting it and attaching it to the shaft. The process of turning the grooves on so large a drum is of unusual interest. There are but few boring mills in the country which will take a piece 25 feet in diameter and these are not adapted to turning a spiral groove on the taper ends of a drum. The most feasible plan is to use a pit lathe, and here again much care and patience must be exercised in securing the segmental rings to the faceplate of the lathe in such a way that they may not only be rigid, but may be both turned on their circumferential surfaces and faced on both edges. The various views show how the job was accomplished and are sufficiently novel to warrant careful study.

Figs. 2 and 3 on the next page give an excellent idea of the pit lathe, the former being a side and the latter a front view. One of the conical ends of the drum is in position and the tool is at work grooving it. The lathe was constructed and formerly used at the old plant of the company and when the new works were erected was moved to its present location. It has a massive headstock, placed on a masonry foundation, with a faceplate 15 feet in diameter.

The lathe spindle is hollow, for the accommodation of a large boring bar, so that a pulley or gear may be bored while it is in position on the faceplate. This bar is driven independently of the lathe spindle, by a worm and worm wheel and pulley, to be seen plainly in Fig. 6. The feed mechanism is at the rear of the bar. The lathe spindle is driven by a variable speed motor, on the multiple voltage system. The wire connections and the controller box, together with the motor, appear plainly in Fig. 2. The motor is belted to a pulley at the base of the headstock, near its forward end, and the pulley shaft extends through to the other side of the headstock and drives the faceplate through a train of gears.

There are two carriages and tool blocks provided for the lathe, which slide on ways on top of a heavy cast iron bed shown in Fig. 2. This bed can be moved and clamped solidly in any desired position relative to the lathe. On each side of the pit are long, narrow floorplate castings, anchored to a foundation, which serve as baseplates for supporting the bed. The baseplates have T-slots running lengthwise so that the bed may be clamped in whatever position it is to be located. There are notches cast along the edges of the baseplates and a bar can be inserted in any one of them in order to pry the bed into its position. As it would be somewhat difficult to locate a casting of the size and weight of the slide base with any degree of quickness and precision, especially when turning the taper faces of band pulleys, a taper attachment is fitted to the base and may be employed with either or both carriages. The taper attachment is supported by brackets arranged to slide on ways on the side of the base casting, and it will be noted from Fig. 2 that the attachment proper consists of two long slotted plates, pivoted on the middle bracket, so that the outer ends of either may be moved horizontally one way or the other as required. When turning the face of a pulley, for example, the middle bracket of the taper attachment would be brought in line with the center of the pulley, and the two cam plates swung inward to conform to the taper of each side of the pulley face. Each tool carriage has three adjustments: one in a longitudinal direction along the top of the bed, and two transverse adjustments, by means of two cross-slides. One of the cross-slides has screw and handwheel adjustment and the other is controlled by a projection attached to the cross-slides, which fits in the slot of the taper attachment, the principle being the same as in an ordinary lathe fitted with a taper attachment.

When doing ordinary turning the longitudinal feed for the tools is accomplished by a ratchet mechanism operated by a gear and pinion back of the main headstock bearing, and clearly visible in Fig. 6. When grooving the drum, a coarse, regular feed is necessary and this is secured by means of a chain drive, appearing in Fig. 2. The chain is driven by a sprocket wheel on the lathe spindle, back of the faceplate. An intermediate overhead countershaft makes it possible to connect up to the sprocket wheel on the carriage slide when the latter is placed at an angle, as in Fig. 2. It also facilitates the use of different sprockets for securing different rates of feed.

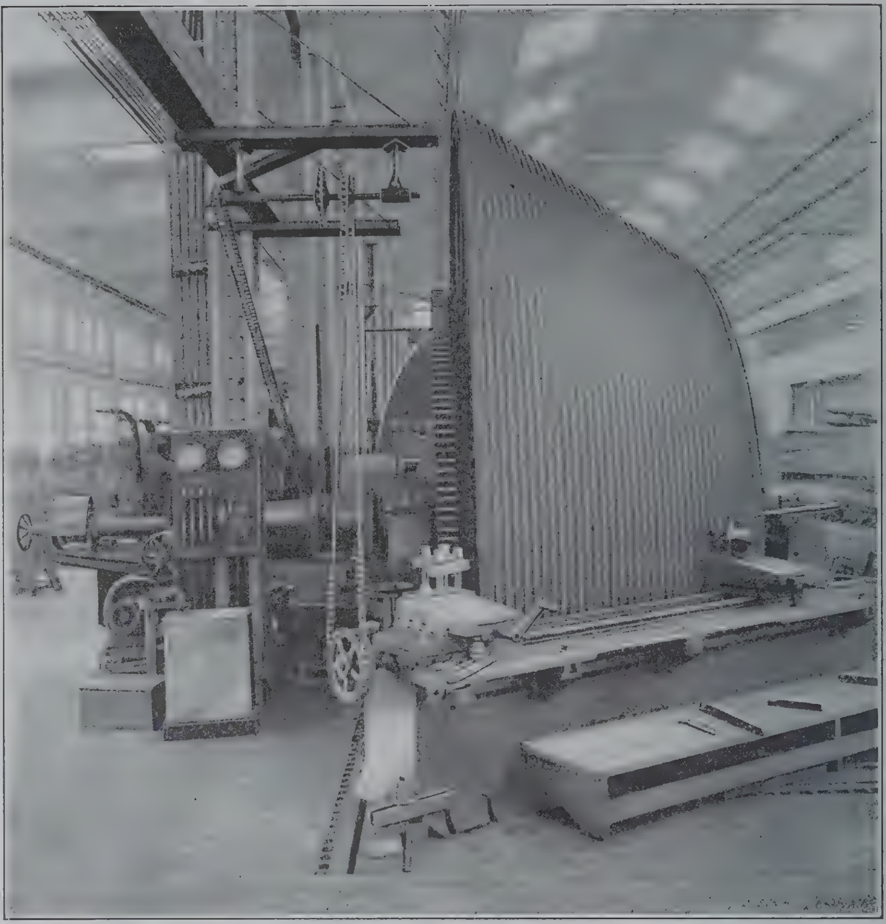

Fig. 2. Side View of Pit Lathe, with Taper End of Drum in position for Grooving.

When work was begun on the large hoisting drum, the lathe was in the old plant and views shown in Figs. 4 and 5 were taken before moving to the new quarters. Fig. 4 shows the lathe at work turning and facing the straight portion of the drum, preparatory to grooving the same, and Fig. 5 shows the grooving operation in process. The straight portion of the drum is built up of two annular rings bolted together side by side and each ring is composed of 12 segments. In Fig. 4 only one ring of segments is in the lathe, the parts of the other ring being piled up at the further side of the lathe. In Fig. 5 both rings are bolted together as one piece and the grooving is continuous from one side to the other.

The two taper sections of the drum are composed of 12 taper segments each, two of which appear in the foreground in Fig. 4, which will give an idea of their size and shape.

It is, of course, somewhat of a problem to properly support the parts of a drum of this size, and the method adopted is quite interesting. The different rings that go to make up the drum are in effect like the rim of a wheel and must be stiffened in practically the same way that a wheel rim is supported, viz., by spokes, which must not only give stiffness to the rim, but must be able to resist the torsional stresses due to the cutting force of the tools. Referring to Fig. 4, it will be seen that a supporting arbor was used, the outer end of which runs in an outboard bearing. There are two sets of spokes for the rim, one set composed of round wrought iron or steel bars like the tension spokes of a bicycle rim, and the

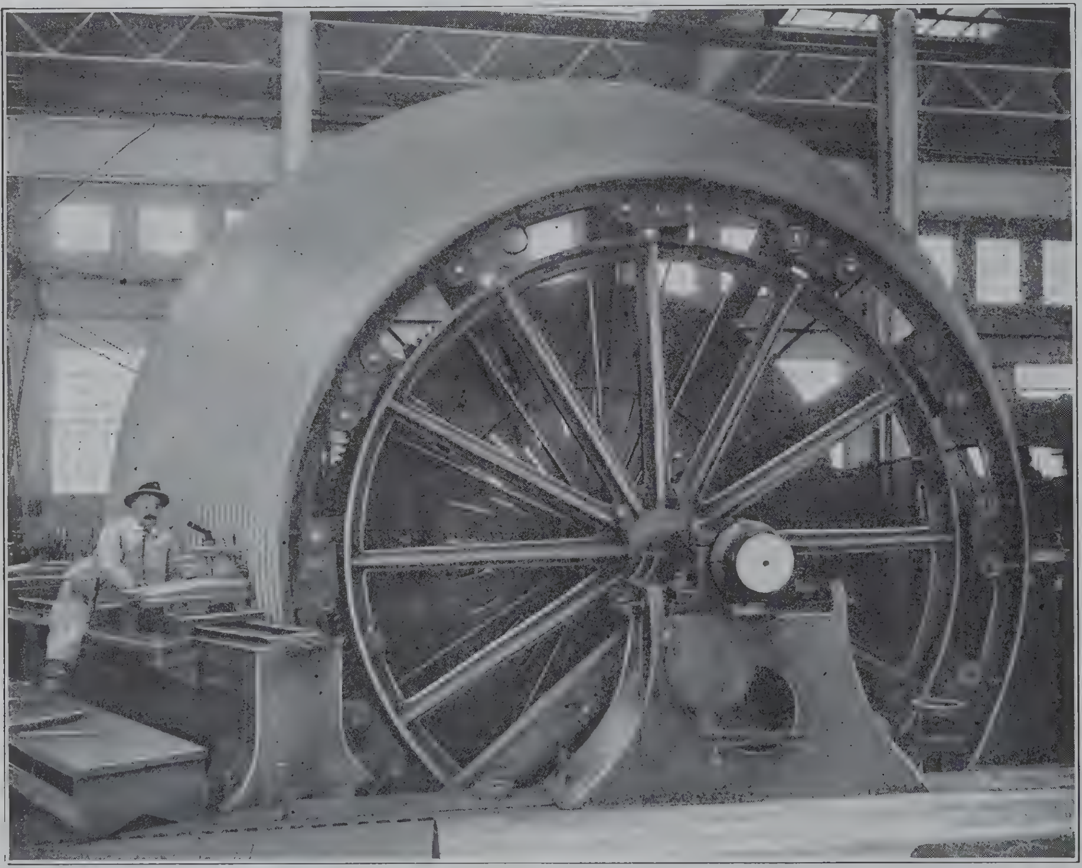

Fig. 3. Front View of Lathe, showing Method of securing the Taper Section of Drum.

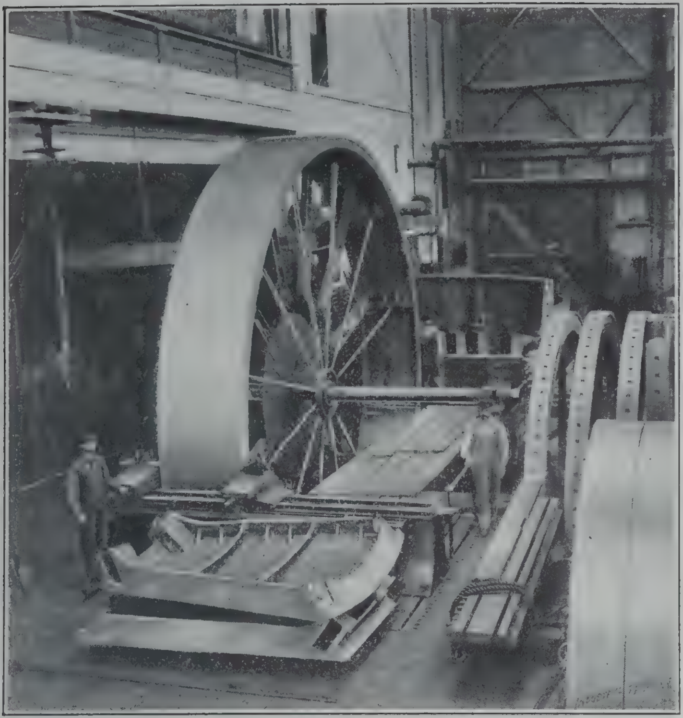

Fig. 4. Turning One-half of Straight Section of Drum.

other set of castings is bolted to the faceplate and made sufficiently heavy to both stiffen the rim and withstand the torsional force. When it came to supporting the wider section of the rim, however, as represented in Fig. 5, an outer spider was placed on the shaft and extension arms were bolted to it like those bolted to the faceplate.

The method of supporting the taper section was identical, except that the spider was of such a diameter that the lugs on its outer circumference could be bolted directly to the flanges on the smaller circumference of the drum.

As mentioned above, this drum is built up of small segments, bolted together, which, while it increases the cost for machining, reduces the labor in the foundry and pattern shop and makes it possible to secure practically perfect castings, an imperfect segment being easily replaced. The method of supporting the drum on its shaft, when in place on the engine bedplate, is different from that usually employed. The shaft itself would ordinarily be made the supporting element and several spiders placed side by side on the shaft would be employed for stiffening the shell and keeping it in position.

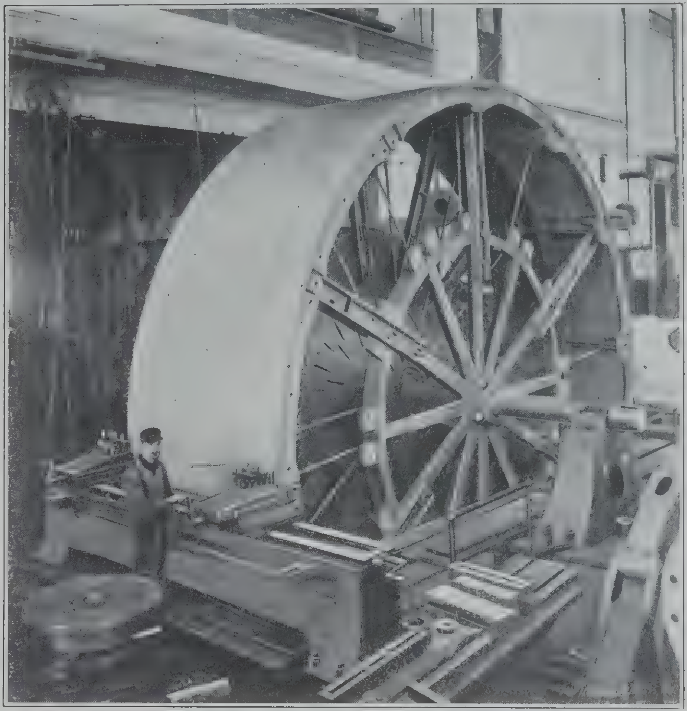

Fig. 5. Grooving Straight Section of Drum.

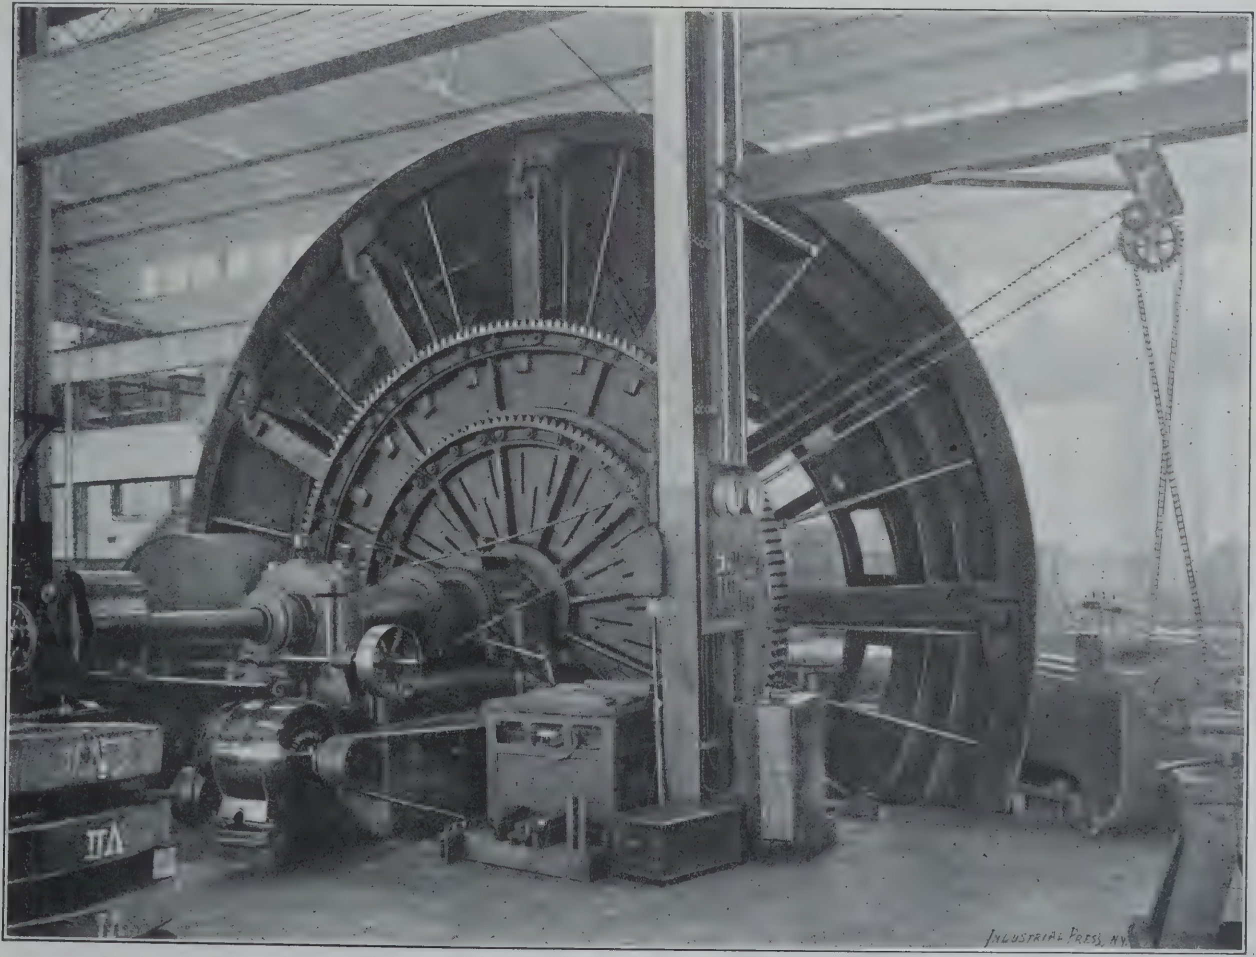

Fig. 6. Rear View of Lathe during Process of Turning one of the Taper Sections.

In the Nordberg drum the supporting element is the shell, which is very rigid, strengthened as it is by the bolt flanges of the different segments. Instead of a series of spiders two flanges or discs are used, one for each end of the drum. These are keyed to the shaft and before being mounted to the shell are brought into parallelism by means of through bolts passing from one disc to the other, thus stiffening the shaft and reducing any tendency to deflection. This being done, the shell segments are placed in position and tension rods are employed to further support the center of the shaft and to increase the rigidity of the drum itself.

It should be mentioned in connection with the drum that the shape in which it is made—taper at each end and straight at the center, as shown in Fig. 1—is a compromise usually adopted with large drums to secure compactness. The hoist is of the balanced type, two cages and two ropes being used, one rope unwinding as the other is wound up. The total weight of one rope when unwound is in this case over 20,000 pounds, or about equal to the combined weights of the cage, cars and ore which are hoisted at one time. When one cage is at the bottom of the shaft the other is at the top and the weight to be supported in one case is therefore double what it is in the other. As one car ascends, the load due to its rope becomes less and less, while the rope supporting the other cage is unwound and the weight due to its rope increases. To keep the cages in perfect balance, so far as the weight of the rope is concerned, and maintain a uniform turning moment for the engines, the drum should evidently be made in the form of two cones, placed base to base. When a cage was at the bottom of its shaft it would be suspended from the small end of its cone, while the other cage, at the top of the shaft, would hang from its cone at its large diameter. Such a design, however, would make necessary a drum of immense proportions, both larger in diameter and longer than the present one. In the compromise adopted the taper portions are carried only half way and each rope in turn winds over the whole width of the straight portion. By utilizing the straight portion for both ropes a substantial saving is made in the length of the drum; and the diameter, of course, is less than if the taper were carried out to the full extent of the rope's travel. When each rope is on the straight portion the ratio of the weight of its suspended part to the weight of the cage and ore is less than when on the tapered portion, and the effect of the compromise is thus not a serious matter.

* * *

LOCALIZATION OF INDUSTRIES.

In the census bulletin upon the localization of industries, issued this fall, is an extended discussion of the reasons that have led to the concentration of industries of a particular kind in certain localities. Numerous tables are given and the conclusion is drawn that there are seven principal causes for the localization of industries. These are: Nearness to materials, nearness to markets, water power, a favorable climate, a supply of labor, capital available for investment and the momentum of an early start.

One of the most important of the above is the nearness to materials, as shown, for example, by the establishment of the paper industry near the spruce and poplar forests, the tanning industry near the chief tanning materials, the manufacture of agricultural implements near the hardwood forests and iron-producing centers. As the location of the source of these materials has changed, so has the location of the industries changed. As for instance the transference of the manufacturing of agricultural implements to the West.

Of scarcely less importance is the nearness to markets although in general the proportion of the cost in transporting finished products on which labor has been expended is not as great as in transporting raw materials. Nearly 48 per cent. of the manufacturing is done in Massachusetts, Connecticut, Rhode Island, New York, New Jersey, and Pennsylvania—mainly because when the industries were started the greatest population was in the eastern states. As the center of population has moved westward, however, so has the center of manufacturing.

Nearness of materials and markets, however, mean more than mere geographical distance; they signify, rather, a general accessibility of the markets as effected by the means of transportation. Thus, the development of railroads, or good water power such as canals or rivers, have enabled industries to receive and ship materials cheaply for considerable distances. In the early history of the country, and to a certain extent to-day, industries tend to group near water power and this early tendency has caused them to continue in their original locations, even when otherwise disadvantageous. This is true of the cotton industry, in which power has been used for more than 100 years. At the beginning of the century water power was extensive, and the cotton factories were located along the rivers of New England, and the water supplied 31 per cent. of the power used by them. The desirability of locating near the raw materials, however, and the supposed desirability of cheap labor, have caused a recent movement in this field in favor of southern cities, where new cotton mills are being established.

It will be found that in most cases industries have been established in certain localities either through the habit of industrial imitation or else by chance. It is natural that when a workman has become familiar with a certain industry and is ambitious to go into business for himself he should follow the enterprise in which he has been trained. It is also natural that he should establish his plant where there are already workmen skilled in that particular branch; where he has acquaintance with moneyed men who would be likely to furnish backing; and where there has been a practical demonstration that his line of business can be made successful by proper management. Thus it is that an industry having been started in a particular locality becomes a nucleus about which other industries gather. This is well illustrated in the shoe industry which was established in Lynn, Mass., largely through chance. In the early days there was a settlement of cobblers at Lynn who repaired shoes for that region. In 1750 a skilled Welsh shoemaker came to this country and naturally located there, where he began to teach the art of fine shoemaking and this was the beginning of shoe manufacture, the fame of the place spreading gradually from year to year on this account. Machinery was not used in this industry, however, until the middle of the last century, when steam power was comparatively cheap; and so it is that less than 5 per cent. of our shoes are made by water power. It is interesting to note in this connection that of the industries most localized at the present time are those which require the least use of machinery. The introduction of machinery has tended to lessen the importance of any particular class of labor and has made more important the nearness of buying and selling markets.

Although not mentioned in the report, the shifting of the center of machine tool manufacturing from the east to the west is typical of the changes that have quite generally taken place. Formerly iron and steel came mainly from New Jersey and Pennsylvania, or from abroad. The selling market was in the east and the machine tool centers were at Fitchburg, Worcester, Newark, Philadelphia and other eastern cities. The large proportion of labor cost and the small proportion of material cost entering into such tools have made it possible for these centers to hold their own, and even to increase their output. But with the shifting of the population westward and the development of the iron and steel industries of the west has also come the shifting of the center of machine tool manufacturing to the west through the development of industries in Cincinnati, Cleveland and other western cities.

* * *

A writer quoted in the *American Shipbuilder* says that the fuel consumption of two steamships, one of, say, 8,000 tons displacement and the other of 26,000 tons, will be in the proportion of about 7 or 8 pounds per 100 ton mile for the former as against 5 pounds per 100 ton mile for the latter vessel. This comparison, of course, assumes that the engines are of equal efficiency. When it is considered that the chief item of expense in the operation of ocean vessels is the cost of the fuel, it will at once be understood why these vessels are more advantageous than the smaller ones provided the volume of freight is sufficient to give the large ones full lading. The personnel of the large ship is not much greater in number than that of the small one.

STEEL AND ITS TREATMENT.—5.

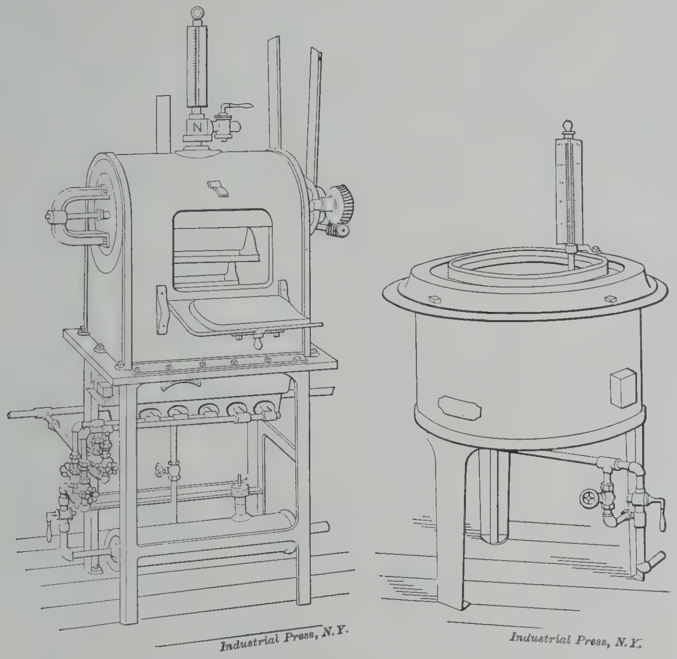
EXAMPLES OF HARDENING AND TEMPERING.

E. R. Markham.

Tool steel is hardened by heating red hot and plunging in some cooling bath; and as previously explained the nature of the bath depends on the character of the work to be hardened. It is necessary that steel used for cutting tools should be hard enough to do the work expected of them, and strong enough to stand up when subjected to the heaviest cuts and feeds they are to take. Now, tool steel suitable for cutting and similar tools, should be of a kind specially adapted for this class of work, and should harden at a *low* red heat.

When hardening, the amount of heat necessary for steel varies with steels of different makes, and with steels of various percentages of *carbon*. To accomplish certain results the steel maker puts other hardening elements into steel with carbon; these steels generally harden at a lower temperature than ordinary carbon steel. The lowest heat at which a piece of steel will harden in a satisfactory manner is called the *refining* heat, because when the piece is broken the grain shows it to have been refined. Steel hardened at this heat is very hard and strong and the grain is the finest possible.

Heating a piece of steel red hot and cooling quickly not only makes it *hard* but also makes it *brittle;* and the higher the heat when the piece was hardened the more brittle the steel will be. If steel is heated higher than at refining heat it is much more brittle. To reduce the amount of brittleness, the piece must be reheated, and this process of re-heating is termed tempering. The process of heating to temper is necessarily a softening one. Ordinarily it is desirable to leave cutting tools as hard as possible, but in this condition they are too brittle to stand up. It is evident that there is nothing gained in heating steel above the refining heat, and then drawing the temper to a degree that makes it much softer than when it came from the bath after quenching at the proper heat. Thus, it will be seen that the ability of a tool to stand up to the work depends greatly on the heat it receives when hardening.



Industrial Press, N.Y.
Industrial Press, N.Y.

Figs. 1 and 2.

To obtain good results steel must be uniformly heated. If one part of a piece is heated hotter than some other part violent strains are set up in the piece, and it is very liable to crack. Uneven heating is probably the cause of a large percentage of the steel cracked in hardening. Heats that are too high cause unnecessary brittleness and open grain.

The methods of heating steel and the baths used in quenching have been considered in former articles; we will now take up the methods ordinarily used in drawing the temper, before proceeding to the hardening and tempering of tools.

The more common way, when the article is taken from the hardening bath, is to brighten one or more of its surfaces with a buff stick. This is made by covering a stick with glue and then adding emery until the surfaces are covered; or a piece of emery cloth may be glued or tacked to the stick, or held on a file. When the steel is exposed to the action of heat various colors appear on the brightened surface. The colors furnish an unvarying guide as to the amount of heat absorbed by the steel. They do not necessarily show how hard the piece of steel may be; because a piece of soft tool steel, or even a piece of iron will show the same colors if brightened and exposed to the same amount of heat. But they do denote the amount of heat a hardened piece has received, and as a certain amount of heat is necessary to produce a desired result (provided the pieces are of an equal hardness to start with) it shows that the amount we reduce the brittleness may be very readily gaged by the temper colors. However, a piece of steel hardened at an extremely low red would not be in the same condition as a piece cut from the same bar and heated to a yellow, even if both pieces were reheated to the same temper color. Here, again, we see the necessity of hardening at the lowest possible heat, and as nearly as possible at the same heat.

The tempering heat may be applied by holding the article over the fire of an ordinary forge, turning it in order to insure uniform heating. Or if the shape of the piece makes it possible, it may be drawn by placing on a hot plate, moving it around and turning it occasionally to heat evenly. Or it may be placed in a pan of hot sand, keeping the sand and articles in motion by shaking the pan. But if the article has teeth or projections which would be injured by striking the other pieces, the pieces may be moved in the sand with a stick, care being taken not to strike them together.

A good method consists in placing them in the revolving pans of a furnace such as shown in Fig. 1. This furnace is provided with a thermometer for gaging the degree of heat in the furnace. The degree of heat registered in this way by the thermometer does not necessarily determine the amount of heat the steel has received; but if one observes the amount registered it serves as a guide, and when it is ascertained what results are obtained with a certain heat these results may be had at any time by heating the furnace so the thermometer registers the required amount. The temperature being no higher than necessary the heavy portions of a piece may be given the required temper without drawing the lighter portions too much.

A method of drawing the temper giving universal satisfaction consists in placing the articles in a kettle of oil, heated to the proper temperature, the heat being gaged by a thermometer, which in this case is partly immersed in the oil, the bulb being at the same height as the work being heated. Furnaces burning illuminating gas, of the pattern illustrated in Fig. 2, give excellent results. But one may be made on the premises at a low cost, that will burn hard coal as fuel. This method furnishes a very cheap means of drawing work done in large quantities, and of doing it very uniformly, as many thousand small pieces may be tempered in a day at a temperature varying not more than one or two degrees.

When very large pieces of steel are to be hardened, some means of heating should be provided for heating the article uniformly, for if the edges and corners are hotter than the balance of the block it is very liable to crack when quenched in the bath, owing to unequal contraction of the piece when cooling. When steel is heated red hot and plunged in a liquid, vapors are formed which have a tendency to keep the contents of the bath away from the work, thus preventing cooling. In order that the liquid may act quickly enough some means must be devised of getting rid of the steam or vapor. When small pieces are being hardened this may be accomplished by moving them up or down, or around in the bath; but, of course, with a heavy piece this would be impossible, so the water or other liquid must be forced against the piece with sufficient force to drive the vapors away and give the liquid a chance to absorb the heat in the steel.

For the hardening of large dies such as those used in drop forge work, a bath may be used having a jet coming up from the bottom, which should strike the face of the die with considerable force. When the die has cooled to the temperature of the bath it is taken out and subjected to heat to remove the tendency to crack from strain. On account of the immense amount of liquid needed for use when hardening work of this description, it is generally necessary to use clear water in the bath. For hardening dies used for punching blanks in punch presses, it is advisable to fill all screw, dowel-pin, and stop-pin holes with fire clay mixed with water to the consistency of dough. This prevents the contents of the bath acting at these points and causing cracks, especially in the holes having threads.

It is extremely important that a die of this kind be heated *very uniformly*, and *no hotter* than is necessary. Dies of this description harden at a lower heat than articles having no openings, even when made from the same bar of steel.

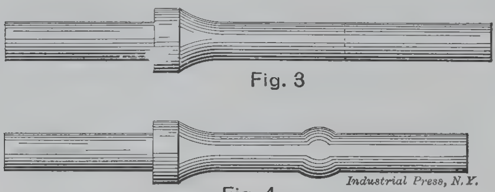


Fig. 3

Fig 4

Figs. 3 and 4. Punch Improperly Hardened.

It is well to dip the die in a bath which has been warmed somewhat, the temperature depending on the shape of the die and the percentage of carbon in the steel. If the die is of a shape that makes it liable to crack when hardened it should not be left in the bath of water until cold, but should be removed when it is hardened on the surface and immediately plunged in a tank of oil and left there till it has cooled to the temperature of the bath. Then it may be heated to remove the tendency to crack from internal strains.

There are various methods used when drawing the temper of dies and similar pieces. The one most commonly used consists in placing the die on a piece of flat iron or steel heated to a degree. Many hardeners heat the plate red hot and place the hardened die on this. It is, of course, necessary to brighten the face of the die previous to drawing the temper in order that the temper colors may be visible. It is also necessary to move the die on the plate and to turn it over occasionally to insure uniform heating, although most of the heat should be applied to the bottom of the die. The amount necessary to draw a die of this kind depends on the steel used in its construction, the shape of the die, the *amount* of heat given when hardening, and the nature of the work to be done by the die. If made of low carbon steel it must not be drawn as much as if high-carbon stock were used; if it were heated above a refining heat it would be more brittle than if properly heated, and consequently would require drawing lower, which would impair its usefulness. If the shape is such that portions of it are weak it must be drawn lower than if it were strong. If it is to receive very rough usage it must be drawn more than if not to be subjected to any great amount of strain.

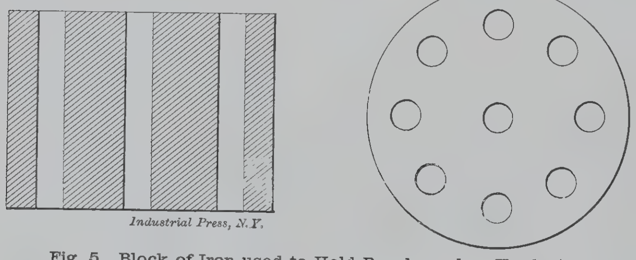

Fig. 5. Block of Iron used to Hold Punches when Hardening.

No given color or degree of temperature can be arbitrarily given as an indication of the proper amount a die should be drawn, as there are so many things to be considered. Sometimes all that is required is to heat them enough to remove the tendency to crack from internal strains, while at other times it may be necessary to draw until the surface is a deep brown with purple spots showing. For ordinary work, however, if hardened at the proper heat a full straw to a brown color will be found sufficient range. The punch to be used with the die should be drawn somewhat lower than the die. When hardening a punch it is necessary to take into consideration its shape and the nature of the work it is to do. If the punch is long and slender as shown in Fig. 3 it is, generally speaking, necessary to harden the entire length of the slender part, to make it as stiff as possible and do away with any tendency to spring. Then again if the punch was to be used in punching very hard stock—that is, heavy as compared to the diameter of the punch—it would be necessary to harden as described, to overcome any tendency of the stock to compress or "buckle." If a punch of the design shown in Fig. 3 were hardened to the point represented by the dotted line, and the balance left soft, it would, if used on stock as large in diameter as the punch, assume the shape shown in Fig. 4; whereas if it were hardened for a distance that made it possible for it to resist the immense pressure, it would remain straight.

When drawing the temper of punches having shanks as shown in sketch, it is customary in some shops to drill holes in a heavy piece of iron as indicated in Fig. 5, and to place the shanks of the punches in these holes having previously heated the block red hot. The heat starting from the shank end travels toward the cutting end. This answers very nicely if the punches are to be used on light or very soft material; but if the stock is heavy or hard, the punch must be about the same degree of hardness the entire length of the portion that must resist pressure. When drawing the temper it may be held in the flame of a gas jet, spirit lamp, Bunsen burner or anywhere that it will be subjected to a sufficient amount of heat to accomplish the purpose. However if there are many punches to be tempered this is costly as well as unsatisfactory, and the furnace shown in Fig. 1 will furnish a means of doing this work with very good results at a reasonable cost per piece. Probably the most satisfactory method consists in heating in a kettle of oil, gaging the heat by a thermometer as referred to under description of oil tempering furnaces, illustrated in cut Fig. 2. The amount of heat necessary to give the pieces when tempering depends on the conditions previously mentioned. It should be borne in mind that slender punches intended for piercing stock as thick as the diameter of the punch are necessarily subjected to immense strain, consequently the steel should be the strongest possible, and this can only be accomplished by careful heating when hardening. If the punch is heated above the refining heat it is more brittle than if properly heated.

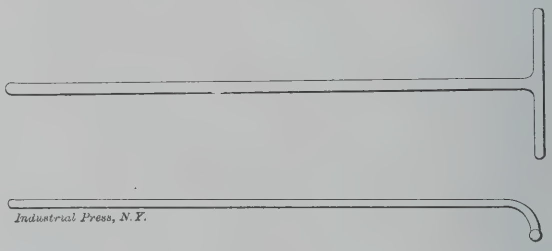

Fig. 6.

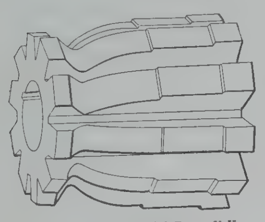
Articles that need to be toughened in order to resist strain should, if possible, be heated slowly when drawing the temper; it is advisable to let them cool off slowly also, that is they should not be quenched unless they show a disposition to become too soft, in which case they should be quenched in oil rather than water.

As previously explained, articles of irregular contour, or of a form that causes trouble when the piece is hardened, should, if possible, be annealed after blocking out to shape. Milling machine cutters, especially those of irregular shape, occasion a great deal of trouble in some shops. The teeth projecting from the main body of the stock are much more sensitive to the action of heat than the balance of the piece; consequently they are liable to become hotter than is necessary to obtain good results. If the teeth are hotter than the body of the cutter, then they are expanded more than the other portion, and when cooled in the bath they contract differently, and, as previously stated, unequal contraction is the cause of a large percentage of cracks in hardened steel. If the whole cutter is heated hotter than is necessary, but is heated uniformly, it may not crack, but it will not be as strong as it might be.

It is advisable to heat such tools to the lowest uniform heat possible. When properly heated place on a wire bent at one end in the form of a T as shown in Fig. 6; they should be plunged into a bath of luke-warm water or brine and left there until it ceases "singing," when they may be removed and instantly plunged into a tank of oil and left until cooled to the temperature of the bath. When brightening the teeth in order to readily observe the temper colors, it is advisable to brighten the backs rather than the faces, as in this way there is no danger of injuring the cutting edges.



Industrial Press, N.Y.

Fig. 7. Formed Milling Cutter.

It is the general custom in most shops to draw the temper of milling machine cutters by placing them on a plug somewhat smaller than the hole in the cutter, the plug having previously been heated red hot. The cutter should be constantly turned. When the proper temper color shows, the cutter may be removed from the plug and immersed in oil, to prevent its becoming too soft from the heat in the cutter near the hole which was exposed to the red hot iron. The necessary temper at which to draw the cutter depends on the nature of the stock to be milled; however, in most shops they are drawn to a temperature that varies from 430 degrees to 460 degrees, which is equivalent to from a faint straw to a full straw color.

When hardening *formed* mills, Fig. 7, it is not generally necessary to draw the temper, provided the cutter has been hardened at the refining heat. The tooth being heavy is strong enough to resist the strain incident to cutting the stock. Long articles such as reamers, etc., require extra care when heating for hardening. Their diameter not being in proportion to their length makes them especially liable to spring from unequal heating. They are also very liable to spring when dipped in the bath, unless held in as nearly a vertical position as possible. As stated in a former article, stock for tools of this description should never be straightened when cold as it is almost sure to spring when hardened. And the stock should be thoroughly annealed, after the outside surface has been removed. The bath for hardening tools of this description should be heated somewhat; cold baths are very liable to cause springing and cracking. If the articles are so long that uniform results seem impossible to obtain when drawing by the ordinary methods, place them in a pan of oil, heating the oil and gaging the heat by a thermometer as described.

Taps, on account of the weakness of the teeth (threads) which project from the body of the tool, should be heated in a manner that makes them as strong as possible. The teeth must not be overheated, because if overheated they become extremely brittle and break off when in use. After hardening, the flutes should be ground with an emery wheel of the proper shape. This grinding has the effect of giving the cutting portions a sharp edge; it will also break the burrs which form between the teeth from the action of the milling cutter used in cutting the flutes. It also brightens the stock sufficiently to enable one to readily observe the temper colors. If only a few taps are to be tempered they may be heated in a flame, applying the heat to the shank end. If there are many to draw it is best to use a kettle of oil. Taps are drawn to deep straw color for most work.

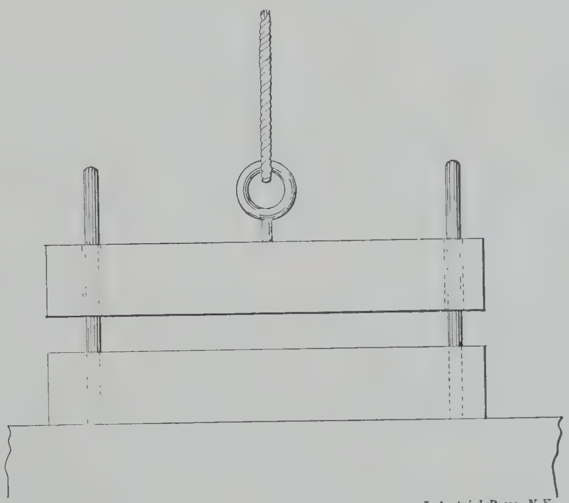
Hollow mills or similar tools having holes running *part way* through them, should be dipped in the bath with the cutting teeth uppermost, that the contents of the bath may readily enter the hole. Then again it is best to harden the frailest part of such a tool *last*, when possible, for if the weakest part is hardened first it would be rigid by the time the heavier portions were hardened, and the heavier and stronger parts would draw the lighter portions somewhat and these being hard and unyielding would crack.

When tempering these articles heat should be applied at the shank end, allowing it to run toward the cutting edges. If the tool is to cut hard metals a faint straw color will be satisfactory; if softer metals are to be machined it is best to draw to a full straw as they can be forced harder.

Thin saws for cutting metals are hardened by carefully heating and placing between plates whose surfaces are smeared with oil. A flat surface should be provided upon which to lay them when in the fire, which may be accomplished by using a flat plate, either of cast iron or machine steel, one surface of which has been machined flat. This precaution is taken to prevent the piece springing when heating. When it has reached a uniform red heat, which should be as low as possible, the saw may be taken from the fire and laid on the plate mentioned, putting the upper plate on the saw as soon as possible. To place the upper plate in position before the saw has become cooled enough to crook, it should be handled by a second operator. But where very many saws are hardened at a time by this method it is possible to make a fixture consisting of two plates. The lower one is located in a pan of oil and the upper one has a rope attached to it which runs over a pulley fixed overhead. It should then return and be attached to a treadle under the bench. By this means the upper plate can be raised sufficiently to allow the heated saw to be laid on the lower plate, and then the upper one may be lowered onto it. For a fixture of this description two rods, like those shown in Fig. 8 are needed. The lower ends of the rods are stationary with the lower plate. Holes somewhat larger are drilled in the upper one so that the plate may readily be moved up and down.

While it is possible to brighten such articles and draw the temper by observing the colors, if there is a quantity of them it is costly and unsatisfactory. For a large number place in a kettle of oil, drawing the temper to a degree that will adapt the saw to the work it is to do. If it is a metal-slitting saw for cutting tool steel and is to be used in a power milling machine, it may be drawn to 460 degrees; if to be used for general jobbing it should be drawn somewhat lower, say from 480 degrees to 500 degrees. Screw-slotting saws, if 1-16-inch thick or under, show good results when drawn to 525 degrees; if thicker than 1-16-inch they may be left.

When drawing the temper of these articles place them in the oil before it is very hot, as the sudden expansion of a hardened piece of the diameter of a saw used for ordinary machine shop work would cause it to crack. For this reason it is well to put them into comparatively cool oil, heating it to the desired degree, when the kettle may be removed and placed where the work and oil may cool off gradually.



Industrial Press, N.Y.

Fig. 8. Fixture Convenient for use when Hardening Saws.

For the instruction of any not familiar with the various degrees of heat necessary to produce given results when drawing the temper by heating in oil, the following table is given:

	Degrees.		Degrees.
Faint straw color	430	Dark purple	550
Straw color	460	Pale blue	610
Brown yellow	500	Clear blue	570
Light purple	530	Blue tinged with green	630

SUBSCRIPTIONS.

Shop Edition, $1.00 a Year. Ten Cents a Copy.
Engineering Edition, $2.00 a Year. Twenty Cents a Copy.
Foreign Edition, $3.00 a Year prepaid.

Lester G. French, Editor.
Fred E. Rogers and Geo. H. Hall, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to The Industrial Press, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

JANUARY, 1903.

NET CIRCULATION FOR DECEMBER, 1902,—27,423 COPIES.

The entire Engineering Edition is printed on coated paper, and a data sheet containing four 6x9 pages of notes, tables, charts, etc., for note-book use, is furnished with every copy—price $2.00 a year. The Shop Edition is printed on super-calendered paper—price $1.00 a year.

WHAT OF THE LARGE GAS ENGINE?

It is the purpose of Machinery to record from month to month the important steps in the mechanical progress of the times. The most significant event of the past month is the starting of the first of the large gas engines now being installed at the works of the Lackawanna Steel Co., Buffalo, as told in the first article of this number—an installation of exceptional interest in points of novelty, size and in the fact that the engines are to be operated by blast furnace gas.

A conservative estimate of the amount of energy available in blast furnace gas places the number of cubic feet of gas generated, per ton of pig iron produced, at 159,000. Of this, about 50 per cent. must be consumed in heating the blast, and by leakage. If we assume roughly, that 75,000 cubic feet are available for the blowing engines or other power purposes, at the rate of 100 cubic feet per horse-power hour, 750 horse power could be obtained per ton of pig iron. Figures given by W. H. Booth, the English engineer, make even a better showing. He estimates that 96,000 cubic feet of gas can be utilized per ton of pig, and that the engines will run on 91 cubic feet of gas per horse-power hour, giving an available horse power of over 1,000 per ton of iron. It is evident that the resources of a plant having several 400-ton blast furnaces would be very great.

The analysis of blast furnace gas shows it to be composed of the same constituents as producer gas, though in different proportions, the former being richer in carbonic oxide, the heat-giving element. The calorific power of blast furnace gas is only about one-tenth that of natural gas. This is partly because the former has a large percentage of nitrogen, the effect of which is negative, so far as combustion is concerned; and partly because natural gas is largely composed of Marsh gas, which has a calorific capacity of 23,000 B. T. U., as against 4,000 units per pound for the smaller amount of carbonic oxide in the blast furnace gas. The composition of blast furnace gas, however, is not entirely against it when compared with the richer gases, because it is less inflammable, permitting a higher degree of compression in the gas engine cylinder without danger of premature ignition. A larger charge of blast furnace gas can be safely used at each stroke than with natural gas, so that, in spite of the low calorific power of the former, the size of engine cylinder necessary to get the requisite power from the poorer gas need not be as great as would appear.

Statistics, recently quoted by Prof. J. J. Flatner, indicate to how great an extent Europe is ahead of us in large gas engine construction. A list of engines in use or building in the whole of Europe, neglecting those under 200 horse power, shows a total of 327 engines capable of supplying 182,000 horse power, an average of 560 horse power. In the United States in 1899 the total horse power constructed aggregated 165,000, but only nine horse power per engine. There is, however, a constant tendency toward larger work. Gas engines of 1,000 or more horse power each have already been made in this country by the Snow Steam Pump Works, Buffalo, and the De La Vergne Refrigerating Machine Co., New York, and engines of this power are in course of construction by the Westinghouse Machine Co., Pittsburg, and Struthers, Wells & Co., Warren, Pa. Other builders are also producing engines of several hundred horse power.

What are the prospects, then, for the more extended use of large-size engines? Blast furnace gas and natural gas are limited commodities, of course, and the large gas engine must be used with producer gas in most sections of the country. But the economy of the large gas engine with producer gas is not particularly better than the economy of the steam engine of corresponding power, at the present state of the art, reckoning in each case from the coal consumed. The original cost of the two plants—including the producer in one case and the boiler in the other—is nearly identical; and while each *may* develop a horse power on less than two pounds of coal per horse-power hour, we think neither is likely to go much below this figure in ordinary running. Under variable loads we believe the steam engine to be the more economical. In the case of small powers the gas engine, of course, easily leads, since the full economy of steam is not realized with small engines.

* * *

NOTES AND COMMENT.

"It is somewhat amoosin'" to note the attention that has been given by various publications, technical and otherwise, to John Jacob Astor's recent gift to the public of his steam turbine patents. While we do not wish to cast doubts on John Jacob's generosity, we somehow cannot help thinking that the dear public will never reap any great return from his munificence in this particular instance. The design of this turbine appears to one who has given the matter considerable consideration to be highly impracticable to say the least.

The day of small things seems to be fast fading away—at least in the minds of stock jobbers. Some years ago a needle was invented that can be threaded by drawing a loop of the thread along one side, opposite the eye, a narrow slot through the side being provided which makes threading in the ordinary manner unnecessary. Needles can be threaded with your eyes shut. It now appears that this simple scheme is worth an untold fortune and stock is being offered to the confiding public at $10 per share as a RARE investment. From the profits on needles sold in four months, it is calculated that a yearly profit of 60 per cent. will be netted on $1,000,000 capital. Investments *can be* made with your eyes shut, too.

Of course all boiler explosions are not preventable by the exercise of practicable methods of inspection and care, but, in the light of many subsequent investigations, it is quite safe to affirm that the great majority of them are. A city water supply pumping station boiler recently exploded with great violence in Queens Borough, Greater New York, that in all probability did so because of lax methods of inspection. The water used in the boilers was well-known to be of a corrosive nature, yet so lax were the inspection methods that the steel plates of the boiler, originally 3/8-inch thick, were allowed to be eaten away at the water line until they were less than 1-16 inch thick in places. Two men having large families were instantly killed.

Motive power for the machines in a wood-working establishment in Brooklyn is furnished by fourteen induction motors varying in capacity from 5 to 20 horse power. The majority of these motors are mounted overhead upon wooden sleepers bolted to the beams of the floor above. They require no care further than an occasional replenishing of the oil wells. Many of the motors operate in an atmosphere heavily laden with wood dust from the wood-working machinery and are completely covered with this oil-soaked dust but show no injury therefrom. The motors are belted to short line shafts which in turn drive various types of belted machinery, including turning and mounting lathes, circular and band saws, buffers, blowers, drill and machine-shop tools. The motors are started at a reduced voltage by means of starting coils and when near synchronous speed are thrown directly upon the 220 volt system. The power equipment has been in operation for over one year and has been thoroughly satisfactory in every respect.

LION TAMING.

Mr. George M. McCarthy, president of the Hudson County, N. J., Society for the Prevention of Cruelty to Animals, believes that lions come within his jurisdiction. Recently one of these animals has been taking part in a play called "The Lion's Bride" at a Jersey City theater. It was his duty to roar whenever the bride appeared because a Turkish Sultan, whose bride she would not be, had sentenced her to be eaten by the lion. The roar he emitted at sight of the girl frightened the audience, but an animal expert who saw the show informed President McCarthy that the lion's roars were caused by pain and not by anger or a desire to eat the heroine. He also said that he believed the pain was due to electricity. President McCarthy visited the theater and found that the bottom of the lion's cage, which was of iron, was connected with several electric wires that made the lion roar whenever the current was turned on. He notified the manager that the electricity must be omitted, even if the lion refused to roar without it. The order will be obeyed.—*Electrical World and Engineer.*

[Now that the electrician is knocked out in his effort to entertain the public, it remains for some enterprising mechanical genius to devise a roaring apparatus to accompany the lion in his act.—EDITOR.]

WHEREIN NEW JERSEY HAS BEEN FOREMOST.

New Jersey must be credited with influencing the industrial development of the country in other and more substantial ways than by the incorporation of gigantic combinations, by which means it is attracting attention at the present time. In the early history of the country, especially, her citizens figure prominently as leaders in scattering the seeds of future industrial growth.

The first steam engine in America was erected in 1753 at the Belleville copper mines, near Newark, N. J., by Hornblower, 16 years before Watt began his investigations.

The first steam boats driven by single and twin screw propellers were constructed by John Stevens, at Hoboken, in 1802 and 1804.

The Phœnix, the first steamboat to navigate the ocean, was designed, constructed and operated by Jerseymen—John Stevens and his son, Robt. L. Stevens, in 1807 and 1808.

The first charter for a railroad in America was granted by the Legislature of New Jersey in 1814, for a railway from Trenton to New Brunswick during the war of 1812.

The machinery of the Savannah, the first steamship to cross the ocean, was constructed at the Vail Works, Speedwell, near Morristown, N. J., in 1818.

The first locomotive in America to convey human beings on a railway track was constructed at Hoboken in 1825.

The first successful experiments with the electro-magnetic telegraph based on discoveries of Prof. Henry, of Princeton, were made by Vail & Morse, Speedwell Works, near Morristown, in 1838.

These facts were gathered by the curator of the National Museum, for the New Jersey Historical Society.

The *Engineering News* mentions a well-equipped boiler shop recently built in Alsace, Germany, in which the floor is made of clay mixed with cast iron turnings and borings, the mass being well tamped into place. In front of the workbenches pine flooring on oak joists, is laid.

THE USE OF A SURVEYING INSTRUMENT IN MACHINE SHOP PRACTICE.*

CHARLES C. TYLER.

Many machine shops now have floor surface plates upon which large work is laid out and various machining operations are performed by the use of portable machine tools secured to the plate. The quality of the work produced is largely determined by the accuracy of the laying out, the correctness of the portable tools, and the trueness of the surface plate.

For work having moderate dimensions, scales, squares, beam-compasses, and straight-edges can be purchased in the market sufficiently accurate, if used by careful workmen, to meet the average requirements in laying out the work and setting the portable tools; but for work having large dimensions the scales, squares, beam-compasses, and straight-edges, become quite special, are expensive, and require the utmost care in their manipulation to insure correct work. Ten-foot steel squares and beam-compasses spanning twenty five feet are not easy tools to make or handle, and the fear that errors might be made in some large work to be undertaken at East Pittsburg, led the writer to the consideration of doing away with these abnormal tools and substituting others more easy to manipulate and of a kind to insure accurate results.

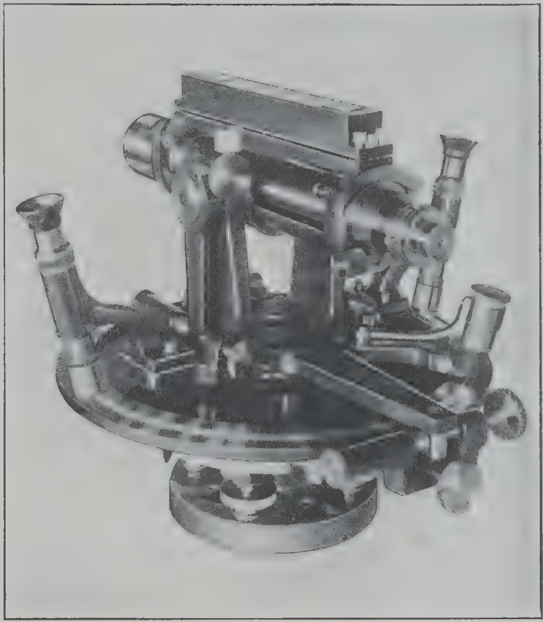

Fig. 1. Surveyor's Transit Designed by the Warner & Swasey Co. for Machine Shop Use.

To carry out the method adopted a dividing and leveling instrument was required, similar in principle to a surveyor's transit, but of special design, adapted to the needs of the machine shop in points of accuracy and convenience. The instrument in use was designed by the Warner and Swasey Co., Cleveland, O., and has a knurled base to be screwed to the cap of a tripod, or in this particular case to a supplementary base with a taper hole by which it can be readily centred on a suitably designed cast iron column which rests upon the floor plate. The knurled base of the instrument has four leveling screws by which, with the usual ball and socket joint and the use of accurate levels it can be adjusted and clamped in a level position. In the center of the instrument are two vertical spindles, one inside the other. The outer spindle carries a horizontal, graduated circle and the inner one a yoke supporting the telescope. The circle is provided with clamps and slow motions by which its O division can be brought to any position in azimuth and there clamped independently of the telescope. The graduations of the circle can be read to 1/10 degrees by two opposite microscopes.

The telescope has an objective one and one-half inches in diameter and is provided with the usual cross-hairs and focusing adjustment. The telescope rests in a cradle which can be revolved about its longitudinal or long axis and has trunnions supported by bearings in the yoke before mentioned. One of the trunnions carries a slow-motion arm which can be clamped at any position for accurate altitude setting. The yoke is provided with clamps and slow motions so that the telescope can be moved to any azimuth position relatively to the graduated circle and independently of it.

---

* Abstract from paper read before the December, 1902, meeting of the A. S. M. E., New York.

To illustrate the use of the instrument, let us assume that we have a floor plate, suitable portable vertical slotters or planers, and portable horizontal drilling and milling machines, and that we are to construct a cast-iron ring of over twenty feet outside diameter, properly proportioned. This ring is to be made of six similar sections suitably cored and ribbed, and the operations to be performed are the accurate planing of the joints, cutting the keyways, and drilling the holes for the clamping bolts.

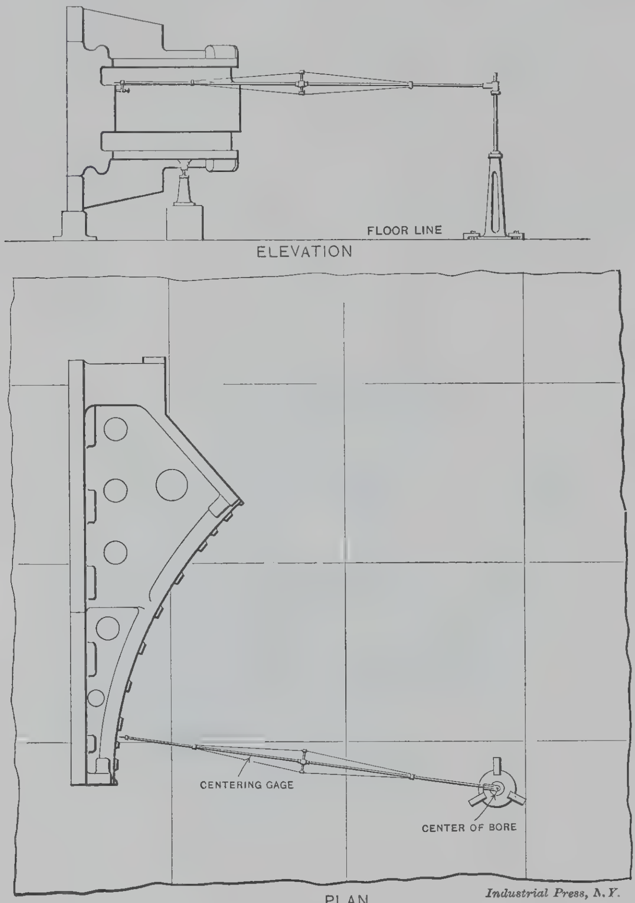

Fig. 2. Locating the Transit on the Floor Plate relative to the Large Casting.

Mount one section upon planed cast-iron blocks about two feet thick and fasten securely to the floor plate, being careful to equalize any warped surfaces found in the casting. The center column is to be moved about upon the floor plate until its exact position in relation to the section has been determined by the use of the centering gage, and the column is then to be securely fastened to the floor plate, where it should remain until all the operations upon the section have been completed. (See Fig. 2.)

Mount the dividing instrument upon the center column, and with the telescope determine the correct position for the zero division of the divided circle of the instrument, to insure equalizing the cut at each joint surface, and clamp the circle in this position. The next move is to secure a straight-edge or parallel to the floor plate in such a position that its front edge is in exact alignment with what is to be one finished joint surface. The location of the straight-edge is determined by the dividing instrument and by the use of a special target which rests upon the top of the straight-edge and has a zero line exactly in alignment with a shoulder which touches the front of the straight-edge. (See Fig. 3.) Another straight-edge is then to be secured to the floor plate under the other joint of the section, and its front edge must be set at exactly sixty degrees from the first straight-edge; its position being determined by the dividing instrument and the special target used in the previous case. The accuracy of the location of both straight-edges being demonstrated by proof surveys, we are ready for planing the joint surfaces.

Planing the Joint Surfaces.

For the joint planing operation let us use a portable vertical slotter or planer having the front edge of its base exactly parallel with the horizontal travel of the tool slide. Secure the portable slotter upon the floor plate with the front edge of its base exactly parallel to the front edge of the straight-edge; the accuracy of the setting being easily determined by a pin gage, and the fine adjustment being obtained by screw jacks bearing against the base and stop lugs inserted in the floor plate. While the roughing cuts are being made upon one joint surface, set a second portable slotter by the other straight-edge in the same manner and proceed with the roughing cuts at this end. In order that the workman may not cut beyond what should be the finished joint surface when roughing, it is advisable to scratch a finish line on the rim section at each joint, but the setting of the tool for its finishing cut is more easily and accurately made by the use of the telescope of the dividing instrument than by any other plan yet tried.

Before setting the tool for the final finishing cut it may be thought advisable to prove the surface of the last cut—a much simpler matter than at first appears. Let us suppose the last cut has left two-hundredths inch stock to be removed and that we have a target with a center line adjustable in a line parallel with one edge. By resting the edge of the target against the surface and adjusting its center line until it exactly cuts the center of the cross lines of the telescope when set at the correct angle, we can survey the joint surface and prove that it is or is not parallel with what is to be the finished joint surface. If the surface be found correct, the finishing cut can be made at once; if there be an error, proper adjustment of the portable slotter must be made and the joint surface again surveyed after taking a light cut. The accuracy of the finished joint surface can easily be determined by the dividing instrument with suitable targets.

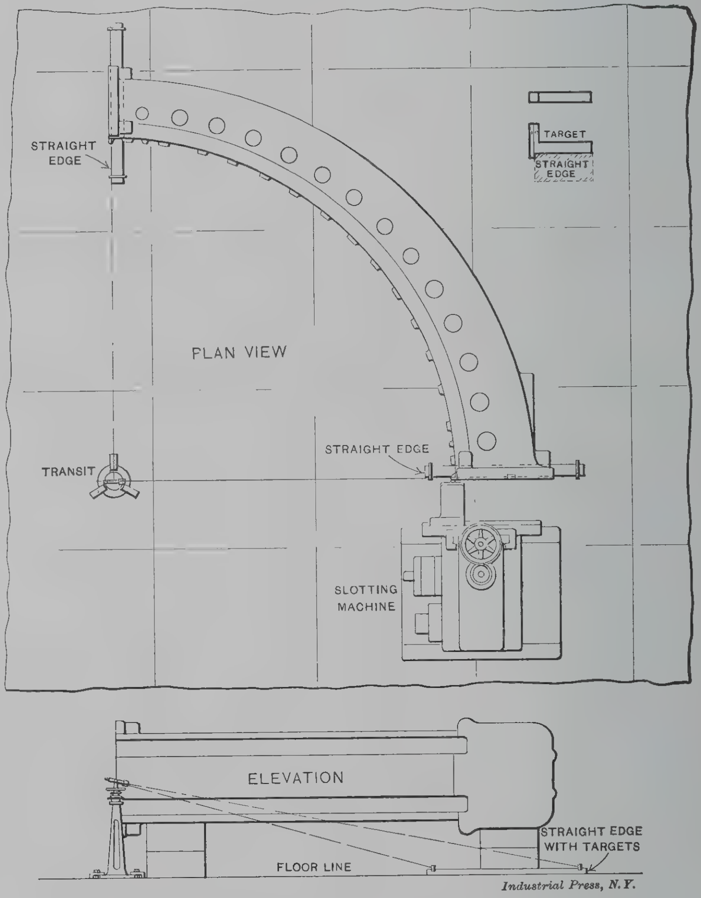

Fig. 3. Adjusting a Straight Edge on the Floor Plate by Aid of the Transit in order to Determine the True Plane for the Finished Surface of the Casting.

Cutting the Keyway and Drilling the Holes.

If the keyway is to be cut parallel with the face of the rim section, the operation can be performed by a portable horizontal milling machine or a portable slotter having a horizontal movement to the tool slide—the correct setting of either machine to be governed by the straight-edge attached to the floor plate, and the exact vertical location of the keyway determined by a surface gage.

If the keyway is to be cut parallel with the axis of the rim section, the portable slotter can be used advantageously and the exact distance of the keyway from the center of the ring determined by a pin gage calibrating from the tool to a pin inserted in the taper hole of the center column.

The axes of the bolt holes should be perpendicular to the joint surface, and they can easily be made so if the front edge of the portable horizontal drilling machine be perpendicular to the travel of the spindle and the base of the machine set parallel to the straight-edges attached to the floor plate. The exact position of each hole is better determined by a jig located by the keyway and a scratched center line; but if the jig is thought too expensive, the holes can be quite easily laid out in the usual way.

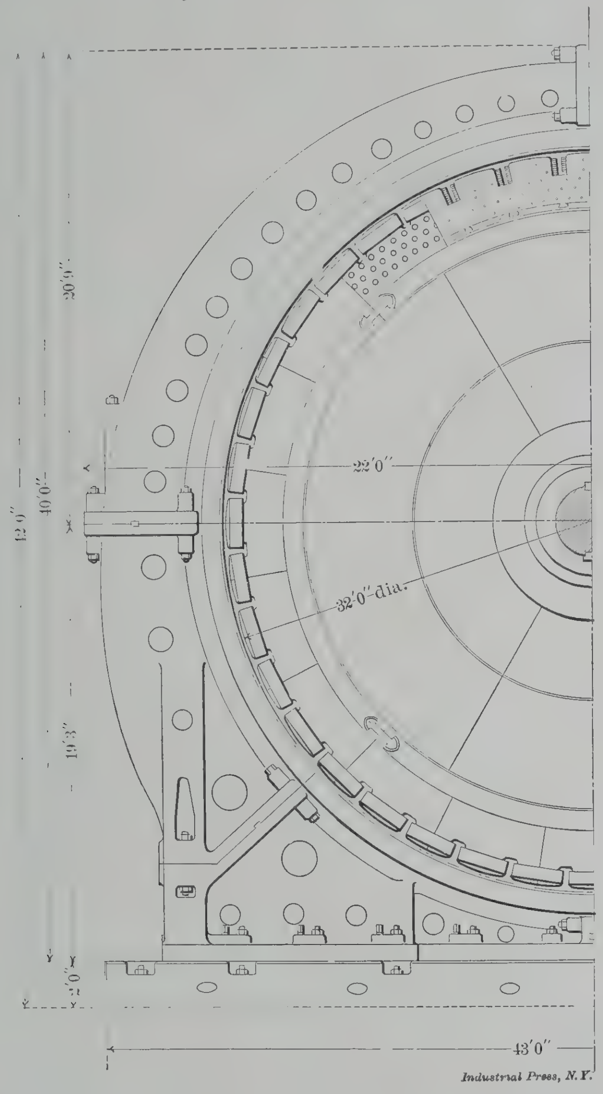

Fig. 4. Showing the Dimensions of a Large Field Frame to be Machined.

For each of the other five sections the same process should be gone through, and it will be found much easier to adjust the center column and straight-edges than to attempt to locate each section.

Testing Portable Machine Tools.

By the aid of the dividing and levelling instrument it is easy to test the accuracy of portable machine tools. In the case of a portable vertical slotter the vertical travel of the tool slide can be determined by setting the instrument so that the cross lines of the telescope exactly cut a line drawn upon the tool block when at its lowest position. Elevate the tool slide to its highest point, tip the instrument, and note the position of the line on the tool block in relation to the cross line of the telescope. If the tool travel is in a line perpendicular to the base, and the instrument has been properly levelled, there will be no variation in the reading. If the tool travel is not perpendicular, the instrument indicates the error, and correction can be made in the portable tool itself or shims can be used under the base to correct the error. To test the parallelism of the transverse travel of the tool slide with the front edge of the base of the machine, set the front edge of the base parallel with a straight-edge secured to the floor plate in a surveyed position—one edge of the straight-edge being approximately perpendicular to the tool slide. Adjust the tool slide until it is exactly perpendicular to the straight-edge by the scratched line as determined by the telescope. A transverse movement of the tool slide to its near and far position will indicate any error; if one be found, it is best to correct the machine by planing or scraping, as may be necessary.

To test the spindle travel of a portable horizontal drilling machine, set the instrument to cut the line of a target attached to the end of the spindle, and survey the spindle in its different horizontal positions. The vertical travel of the spindle slide can be determined by locking the spindle in one position and moving the slide up and down, the same as for testing the slotter. Other portable machines can be tested by similar means, and the result of the tests can be depended upon if the instrument is accurately made and the errors in the subdivisions of the circle are known.

Practical Application of the Method.

The method described has been practically applied to some of the mechanical operations incident to the manufacture of the eight 5,000 kilowatt, alternating current, engine type, 3-phase generators built for the Manhattan Railway Company by the Westinghouse Electric and Manufacturing Company.

The approximate dimensions of some of the principal pieces of one of these generators are shown in Fig. 4. The extreme height from the bottom of the bed to the top of the yoke is 42 feet, and the greatest horizontal distance over all is 44 feet. The bed plate, 43 feet long, has two parts, securely keyed and bolted together, each 21 feet 6 inches long by 10 feet 3 inches wide by 2 feet thick.

The stationary element, or armature, has six principal sections—two lower, two middle, and two upper—all securely keyed and bolted together; the bore being 34 feet, approximately.

The revolving element, or field, consists of many pieces, the principal ones being the cast-steel hub, the two web plates of six pieces each, and the four ring sections. The diameter of this element is 27 feet 8 inches over rim sections, and 32 feet over all.

The total weight of the stationary and revolving elements of this machine (without the shaft) exceeds 1,000,000 pounds, or 500 tons. It is evident from these figures, as well as from the general design of the parts, that very careful machining was necessary and unusual provisions were required to insure success. The principal portable tools used were vertical slotters or planers having a stroke of 8 feet, a small horizontal adjustment of the tool slide, a transverse tool travel of 4 feet —the column having a horizontal adjustment of 4 feet; horizontal drilling machines having a vertical adjustment of 8 feet, the column a horizontal adjustment of 4 feet, with spindle travel of 4 feet; vertical slot milling machines, radial drills, and small vertical slotters.

The principal stationary machine tools were a 14-foot planer, 8-foot open-side planer, radial drills with 10-foot arm, 16 to 24-foot and 16 to 36-foot extension vertical boring and turning mills, 28-foot vertical boring and turning mill, 122-inch engine lathe, a special floor-boring machine carrying portable heads, and several smaller machines.

Bed Plates and Bottom Section.

The bottom and top of bed plates were planed on the 14-foot planer; the joint surface and keyway on the open-side planer, and the joint bolt holes were drilled on the floor plate with portable horizontal drilling machines.

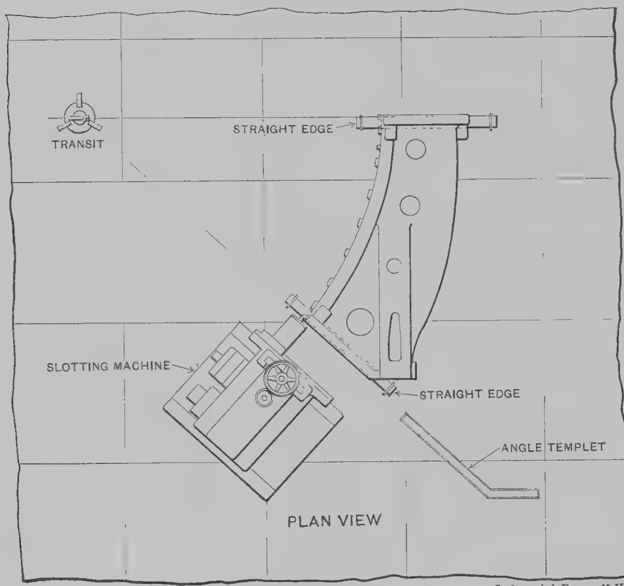
The bottom sections were the most difficult to machine, and a more detailed description of some of the operations on these pieces will make it unnecessary to outline so fully the operations on the other sections.

By referring to Fig. 4, it will be noticed that the lower or perpendicular joint is at right angles to, and the upper joint has a portion parallel to, the bottom or base—the remainder of the upper joint being at a definite angle from the lower joint. The rough casting was mounted on the floor plate, resting on cast-iron blocks, the bottom being set approximately perpendicular to the plate, as shown in Fig. 2.

The proper location of the section involved the making of numerous measurements to insure plenty of stock for finishing—this being particularly necessary for the slot lugs located in the bore. The center column was mounted on the floor plate and its position determined by the centering gage, as shown in Fig. 2, more or less proof testing being necessary to insure its exact location, after which it was securely clamped to the plate.

The perpendicularity of the faces of the slot lugs was determined by scribing lines upon the top surface of the slot lugs with the center gage at the proper elevation, and by lowering the center gage rest or support similar lines were scribed on the bottom surfaces of the slot lugs—scale measurements being accurate enough to prove this setting, after which the bottom section was bolted to the floor plate. The dividing instrument was then mounted upon the column, properly beveled, and finish lines scribed at each joint surface.

Straight-edges were then secured to the floor plate in their exact position—one edge of each being set exactly perpendicular to the desired finished joint surface, the position of these straight-edges being determined by the dividing instrument and a suitable target, as shown in Figs. 3 and 5.



Industrial Press, N.Y.

Fig, 5. Another Application of the Transit—Laying Out the Surfaces to be Planed by the Portable Shaper.

After proving the exact position of these straight-edges, the portable slotters were set in their correct location, secured to the plate, and the roughing cuts taken—slotters often working upon both joints at the same time. The accuracy of the rough planed joint surfaces was proved by the dividing instrument and an adjustable target, after which the cutting tool was set by the instrument for the final radial finishing cut. For that portion of the upper joint of this section parallel to the bottom, the slotter was set by the aid of the angle templet, shown in Fig. 5—a pin gage proving that the tool slide was parallel with the angle templet.

The joint bolt holes were drilled by portable drills, the position of the bolt holes being determined by the use of drill jigs located by keys and by a center line. The drill jigs were made reversible for drilling holes in the faces of the corresponding joint surfaces of the connection sections.

After completing the operations upon the joint surfaces, the lower sections were finished upon the bottom on a stationary planer. The next operation was the drilling of the bolt holes and the drilling and tapping of the adjusting screw holes in the bottom of the section under radial drills.

The operations upon the joint surfaces of the middle and upper sections were laid out and finished in substantially the same manner.

Large Boring Machine and Floor Plate.

The foregoing abstract covers the more important part of Mr. Tyler's paper and illustrates in a very clear manner the method followed in the use of the transit for laying out heavy machine work at the Westinghouse shops. Mr. Tyler next takes up the assembling of the various parts of the armature and field frame, showing how the alignment may be tested as the work proceeds. The frame was first erected in a vertical position on the floor plate and later re-assembled in a horizontal position on a special floor boring machine. The machine consists of a horizontal floor plate 48 feet square, at the center of which is a rotating table, level with the floor, 18 feet in diameter, which carries various tool heads. When boring large work these heads are carried on arms which have sufficient radial adjustment to bore up to 40 feet in diameter. When the frame was first assembled in a vertical position the inside horizontal and vertical diameters were measured; and then when the frame was assembled on the boring machine the same diameters were again measured to determine the extent of the deflection of the upper sections when in an upright position. It was found from the second measurements that the former vertical diameter had increased twelve-hundredths inch and that the horizontal diameter had not materially changed, showing that the deflection was mainly in a vertical direction. By numerous heavy braces and wedges the upper sections were sprung inward toward the center until the diameter corresponded with the diameter recorded during the first assembling, and the frames were then bored, faced and recessed to the required dimensions.

After the preliminary design of these large electrical machines had been determined upon, it was apparent that the buildings, traveling cranes, and machine tool equipment then in service at East Pittsburg were inadequate for the work. A new building was therefore erected, and electric traveling cranes were provided, having ample capacity and mounted on runways of sufficient height to give the crane-bridge the necessary clearance over the top of the generators.

For the operations to be performed by portable tools, and for the erection of the machines, a surface floor plate was considered a necessity, and the one provided is 48 feet wide by 176 feet long; weight, about 2,000,000 pounds. This floor plate consists of 132 cast-iron sections, each 8 feet square, of box section heavily ribbed, keyed, and bolted together—provision being made for the removal of any broken section, should such a mishap occur. The plate, well grouted, rests upon transverse brick piers 12 feet deep, built upon a solid bed of concrete, about 3 feet 6 inches thick. The brick piers are 4 feet apart, center to center, tied together at suitable distances by brick arches, and the space between the piers is filled in to within 5 feet of the under side of the cast-iron plates. The filling between the piers is covered by a layer of concrete, having enough pitch to properly drain into a longitudinal tunnel at one side of the plate. There are numerous rows of drilled and reamed holes for stop lugs, and tee slots extend the whole length of the floor plate, with numerous cored holes at the bottom of the slots to permit the chips to fall through into the transverse tunnels. The main tunnel has trap doors through which the chips can be taken out.

* * *

The American people have been prodigally wasteful of their timber resources, and now that lumber is becoming more and more expensive as the available supply decreases, means are just beginning to be employed to lengthen the life of wooden structures exposed to the weather, like telegraph poles, railroad ties, piles and similar work. Paint is, of course, of no value in preserving wood that is under ground or continually exposed to water action, as in the case of piles. The fiber must be impregnated with creosote or other chemicals of a similar preservative nature. A number of American railroads have recently installed timber preserving plants, some of which are of extensive proportions. The Great Northern Railway has a plant built by the Allis-Chalmers Co., at Flathead Lake, Montana, which has a capacity of 4,000 railroad ties per 24 hours. The three movement zinc-tannin process is used.

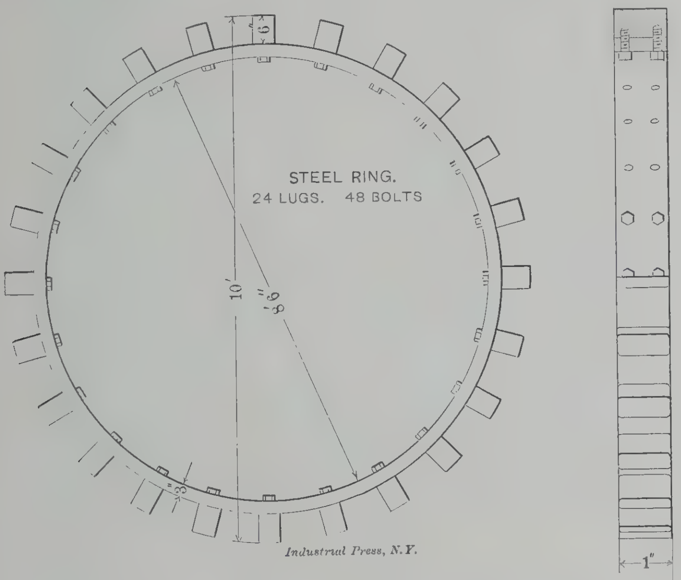
ROTATING RING WITH ATTACHED LUGS.

DESIGN WITH REGARD TO TENSION IN RING AND LUG BOLTS.

Forrest R. Jones.

The limiting speed at which a flywheel may run is generally determined by assuming the tensile stress that the material of which it is made can safely be subjected to, and then calculating either the linear velocity of the periphery, or the number of revolutions, that will cause the assumed amount of stress. In making the calculations for the limiting speed it is quite customary to deal with the rim as if it were free from the arms, thus neglecting their effect upon it. In other words, the rim is dealt with as if it were a plain ring, without attachments, lying on a horizontal table and rotating about a vertical axis coincident with that of the ring. While such an assumption neglects the pulling-in action of the arms and the consequent bending effect on the rim, as well as their tendency to reduce the pure tension in the rim, it is the best that can be applied, for the stresses as they actually exist are so complicated that they cannot be intelligibly dealt with in numerical calculations.

The ring of an electric generator that carries the lugs which form the cores of a rotating magnetic field may be dealt with for determining the tension in it in much the same manner as a flywheel. Such a ring, free from the supporting arms, is represented in the figure. The difference between this and the flywheel rim is that the lugs cause tension in the ring in addition to that induced by its own weight and rotation, and that there are bolts passing through radial holes which cut away part of the material.



Industrial Press, N.Y.

Steel Ring for a Rotating Magnetic Field for Electric Generator.

The speed of rotation that will induce a tensile stress of 14,500 pounds per square inch in the ring, and of 12,000 pounds per square inch in the lug bolts, using the form of ring and other parts shown in the figure, will be calculated. The ring is of forged steel 8 feet 6 inches internal diameter, 3 inches thick radially, and 1 foot wide. The lugs are 6 inches long radially and weigh 100 pounds each. Two lug-bolts are used to fasten each lug to the ring.

The following notation will be used:

C = centrifugal force of one lug, pounds;

$P = P' + P''$ = total tension in rotating ring due to the speed and weight of both itself and the attached lugs, pounds;

P' = total tension in the rotating ring due to its own speed and weight, pounds;

P'' = total tension, due to the speed and weight of the lugs, in the ring, pounds;

V = linear velocity of the rotating ring, feet per minute;

W = weight of the material of the ring, pounds per cubic foot;

a = effective area of bolts for resisting tension, square inches;

d = diameter of the body of the bolts used for attaching the lugs to the ring, inches;

g = 32.2 = force of gravity;

p' = tension, due to its own speed and weight, in a solid rotating ring of 1 square inch cross section;

r = distance from axis of ring to center of lugs, feet;

v = linear velocity of rotating ring at its mean radius, feet per second.

The tension in a ring that is as thin radially as the one now under consideration can be found, with sufficient accuracy for the purpose of designing, for any speed of rotation, by the following formula which gives pounds per square inch:

$$p' = \frac{W v^2}{144\, g}$$

The weight of steel forgings of this description is about 490 pounds per cubic foot. Substituting this value of W and that of g as 32.2 gives

$$p' = \frac{490\, v^2}{144 \times 32.2} = .1058\, v^2 \text{ lbs per square inch.}$$

The cross section of the ring is $3'' \times 12'' = 36$ square inches. The total tension in the ring due to its own weight is therefore

$$P' = 36 \times .1058\, v^2 = 3.81\, v^2 \text{ pounds.}$$

When the ring and lugs are rotating, a point in the middle of the length of the lug, measured radially, moves faster than one at the mean radius of the ring in the same proportion that its distance, 57 inches, from the axis of rotation is greater than the mean radius, 52.5 inches, of the ring. Therefore, the

$$\text{Mean linear velocity of lugs} = \frac{57\, v}{52.5} = 1.085\, v$$

The force necessary to prevent a lug weighing 100 pounds from the flying off the ring when both are in motion is expressed by the equation, in which v is the mean linear velocity of the ring, and r is the distance from the axis of the ring to the center of the lug,

$$C = \frac{100\,(1.085\, v)^2}{g\, r} = \frac{100 \times 1.177\, v^2}{32.2 \times 57 \div 12} = \frac{100 \times 1.177 \times 12 v^2}{32.2 \times 57} = .772\, v^2$$

The total radial pull of the 24 lugs if distributed uniformly around the entire circumference of the ring would induce an

$$\left.\begin{array}{l}\text{Average radial pull}\\ \text{per inch of cir-}\\ \text{cumference.}\end{array}\right\} = \frac{24 \times .772\, v^2}{\text{circum. of ring}} = \frac{18.528\, v^2}{105\, \pi} = .0562\, v^2 \text{ lbs.}$$

This radial pull of the lugs exerts a bursting force upon the ring which has practically the same effect as the internal pressure of confined steam, air or water in a thin shell cylinder, and may be dealt with in the same manner for determining the tension due to it in the ring. The formula applied to this case gives for the total tension in the ring due to the lugs:

P'' = radial force per inch of circumference × radius of ring $= .0562\, v^2 \times 52\ 5 = 2.96\, v^2$ lbs.

The total tension of the entire cross section of the ring is the sum of that due to the speed and weight of both the ring itself and the lugs. It is expressed by

$$P' = P' + P'' = 3.81\, v^2 + 2.96\, v^2 = 6.77\, v^2 \text{ pounds.}$$

Since a part of the material of the ring is cut away by the lug bolts, it is necessary to determine their diameter as the next step in the calculations. The effective sectional area of a bolt such as will be used to hold the lugs in place is that at the bottom of the thread. Since the diameter of these bolts is not yet determined, the exact ratio of the diameter at the root of the thread to that of the body of the bolt is not exactly known. It is on the safe side to assume that the diameter of the body is 1.18 times that of the root of the thread. This is a somewhat larger ratio than actually found for ordinary bolts from 1.75" to 3" diameter of body. Under this assumption a bolt in tension with a body diameter d has an

$$\text{Effective area of bolt} = \frac{\pi\, d^2}{4\,(1.18)^2}$$

Two bolts are to be used for each lug. Their combined tensile strength must be equal to the centrifugal force of one lug. This centrifugal force has been determined as $C = .772\ v^2$ pounds.

The equation between the bolt area and the centrifugal force of a lug, for two bolts in each lug, at a tensile stress of 12,000 pounds per square inch in the bolt, therefore, is

$$\frac{12000 \times 2\,\pi\, d^2}{4\,(1.18)^2} = .772\, v^2$$

Whence

$$d = 1.18\, v \times \sqrt{\frac{2 \times .772}{12000\ \pi}} = .00757\, v$$

The greatest tension per square inch in the ring is where the cross section is reduced by the two bolt holes for one lug. The solid sectional area is here decreased by an amount equal to the thickness of the ring multiplied by twice the diameter of a bolt. Therefore, for a tensile stress of 14,500 pounds per square inch in the material of the ring, the following equation can be written:

$$14500 = \frac{P' + P''}{\text{Effective area of ring}} = \frac{P' + P''}{(3 \times 12) - (3 \times 2\, d)}$$

It has already been found that $P' + P'' = 6.77\ v^2$. That of d may be expressed as $.00757\ v$. By making these substitutions in the last equation, it becomes

$$14500 = \frac{6.77\, v^2}{36 - (6 \times .00757\, v)} = \frac{6.77\, v^2}{36 - .0454\, v}$$

Whence

$$v^2 + \frac{14500 \times .0454}{6.77}\, v = \frac{14500 \times 36}{6.77}$$

$$v^2 + 97.2\, v = 77500$$

This equation can be put into form for extracting the square root by adding 2360 to each side so as to make the left-hand member a complete square. Thus

$$v^2 + 97.2\, v + 2360 = 77500 + 2360.$$

And by extracting the square root

$$v + 48.6 = \sqrt{79860} = 282.5$$

$$v = 234 \text{ feet per second.}$$

Or

$$V = 14040 \text{ feet per minute.}$$

The speed of rotation corresponding to this linear velocity can be found by dividing the linear velocity by the circumference of the ring, whence

$$\text{Speed of rotation} = \frac{14040}{9\,\pi} = 500 \text{ rev. per minute.}$$

The outer diameter of the ring is here used in order to roughly balance the error introduced by using the mean diameter of the ring and the radial distance to the center of the lugs, instead of the correct slightly larger values. The reason for not using these correct values is that it is difficult to determine them, and the error introduced by the method that has been followed is very slight in this case. With a ring thicker radially, or longer lugs, the error would increase rapidly.

The diameter of the bolts may now be determined by introducing the value of v just found into the equation for d developed earlier in the solution. Thus

$$d = .00757\, v = .00757 \times 234 = 1.77 \text{ inches.}$$

A body diameter of 1.75″ would naturally be used in practice.

As a check on the work that has been done, the values of the tensions in the ring and bolts may now be determined by introducing the speed of rotation and bolt diameter that have been found.

$$\text{Net sectional area of ring} = (3 \times 12) - (3 \times 2 \times 1.75)$$
$$= 36 - 10.5 = 25.5 \text{ square inches.}$$

$$\text{Tension in ring} = \frac{P' + P''}{\text{net section}} = \frac{6.77\, v^2}{25.5}$$
$$= \frac{6.77 \times (234)^2}{25.5} = 14600 \text{ lbs. per sq. inch.}$$

A bolt of 1.75″ body diameter has, according to tables of standard threads, an area at the root of the thread equal to 1.746 square inches. Therefore the

$$\text{Bolt tension} = \frac{.772\, v^2}{2 \times 1.746} = \frac{.772 \times (234)^2}{2 \times 1.746} = 12100 \text{ lbs per sq. inch.}$$

These values of tension are slightly higher than actually induced by a speed of 500 revolutions per minute, for this speed of rotation corresponds to a linear speed of the fastest moving point in the ring only as high as was determined for v at the mean radius of the ring by calculation. By making the speed of the mean radius of the ring as high as v was determined, the peripheral velocity would be increased.

There are, of course, bending stresses in the ring due to the localization of the radial pull of the lugs at the points where they are attached; also at the points where the arms of a spider for supporting and driving the ring are attached. As has already been stated, it is practically impossible to determine these stresses. There might be a gain in some cases by making the ring thicker radially where it is pierced by bolt holes, so as to make the cross section at these points as great as between the lugs. This is generally a source of considerable additional cost.

* * *

ANNUAL MEETING OF THE A. S. M. E.

The annual meeting of the American Society of Mechanical Engineers, which opened in New York on the evening of December second, was one of the most interesting in the history of the society; not because of the rare technical merit of the papers, nor of the great value of the discussions, but because mechanical engineers, like other human beings, enjoy a scrimmage, when it becomes animated enough to be interesting. The chief topic up for discussion was the metric system and the subject of the metric system permeated the meetings from beginning to end.

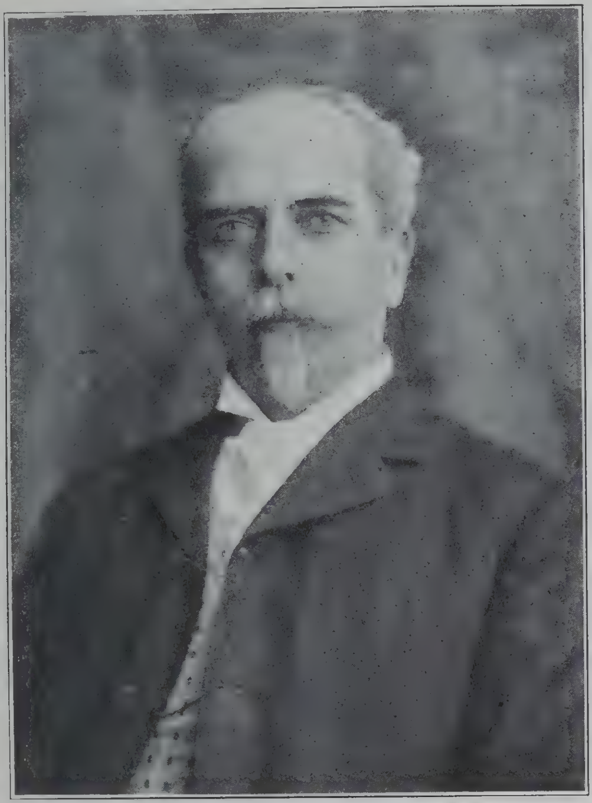
In the absence of President Reynolds, who, according to custom, should have delivered the annual address at the opening session, the first of the technical papers was read by Prof. Reeve, upon a duodecimal system of numeration. Such a system is interesting as a project, and has the advantage that its unit of 12 can be divided by 2, 4, and 3, all factors convenient to use.

On Wednesday and thereafter the sessions were held in the assembly hall at the Sturtevant house, an arrangement that was much appreciated by the members present, for it not only abolished the annoyance of the crowded lecture hall at the society rooms, but it gave much better facilities for serving lunch on the days of the meeting. The Wednesday morning session was devoted entirely to the transaction of business, with Vice-President Waitt as chairman, who showed rare ability in parliamentary matters. The business consisted principally of the report of the council, and the appointment and reports of committees. A committee of four was appointed to serve with four members from each of the other three leading engineering societies, for the award of the John Fritz medal, and committees were also announced for the consideration of standard machine screw threads and to co-operate with committees from other societies to establish specifications for testing materials.

The Committee on Rules and Methods submitted several questions, one being that of the dues and age limit for junior members of the society. This led to an extended debate which did not clarify matters much, until finally a resolution was passed voicing the sentiment that Juniors hereafter elected should not be allowed to remain Juniors after the age of 30, but should be required to become Associate or Regular members, according to their qualifications, and pay the increased rate of dues to such membership; or else be dropped from the rolls. A resolution was also passed calling for a letter ballot of all the members in the case of a change in the constitution or rules.

At the afternoon session the metric system discussion began. Mr. F. A. Halsey presented his paper upon the subject, which was the opening gun—one of large caliber—for he presented what are perhaps the strongest arguments ever brought together in one paper in opposition to the system. He went to the bottom of the subject and brought out a great mass of evidence to show that in the so-called metric countries, where the metric system has been used for many years, there are numerous other systems in vogue, which, by the inertia or preference of human nature, or both, will probably continue to be used by individuals and firms for years to come. He explained fully, by apt illustrations, why the same thing would happen here were the metric system to be introduced.

The heavy artillery on the other side was handled with telling effect by F. J. Miller, of the *American Machinist*, Director Stratton, of the National Bureau of Weights and Measures, and J. H. Southard, chairman of the Congressional Committee of Weights and Measures, the latter two attending the meeting and speaking by special invitation. Many letters were read for and against the system, those from Cincinnati manufacturers in particular being strongly against it.



James M. Dodge.

The discussion comes up at this time, primarily because of the bill pending before Congress to require all the departments of the government to use the metric system, and to make the system the legal standard of the country (which, by the way, it is now, so far as the measures of length are concerned). The chief objection to the bill seems to be not so much the use of the metric system by the government departments as the fear that the government may wish to make the system compulsory, and might in any case require machinery or other products sold them to have metric dimensions. That the first of these effects would be possible or the second probable was vigorously denied by Chairman Southard and he is, perhaps, in a position to give as unbiased judgment as anyone. It was contended that it would be impossible for the government to compel the use of the system outside of its own departments, and that in selling machinery practically the same conditions would hold as in supplying the metric countries at the present time, where but few if any changes in the machines are required.

The committee previously appointed by the society to consider the metric system presented a report strongly advocating the English system, and denouncing the metric system. At the time of its appointment it was known that this committee was adverse to the metric system, and for this reason it was moved that the report be laid on the table and the motion was carried.

The council was then instructed by a very close vote to confer with other societies with regard to the appointment of a committee composed of members from each, to investigate the matter further. At a later session, also, the Secretary was instructed to prepare blanks to be sent to each member for obtaining his individual opinion regarding the system—a very happy ending of the whole controversy.

Abstracts of several of the technical papers presented at the different sessions have been prepared for use elsewhere in this number and in the next number of MACHINERY.

The New President.

The new President of the society, Mr. James M. Dodge, was born June 30, 1852, at Waverly, New Jersey, on the farm of his grandfather, Prof. James J. Mapes, a noted chemist and scientist of his day. His mother is Mrs. Mary Mapes Dodge, Editor of *St. Nicholas* Magazine, the leading children's magazine. After three years at Cornell University, and one year at Rutgers College, New Jersey, at which place he took a special course in chemistry under the late Prof. George H. Cook, geologist, he served an apprenticeship at the Morgan Iron Works, New York, and spent a number of years of his earlier life at the shipyards of John Roach, Chester, Pennsylvania. Afterwards he went to Chicago and entered the employ of the Ewart Manufacturing Company in the manufacture of link-belting, in which business he has been ever since. He is now president of the Link-Belt Engineering Company, the Dodge Coal Storage Company, the Stair Lift Company of Philadelphia, and a director in a number of concerns. He has taken out considerably over one hundred patents, a number of which have proved to be commercially valuable.

COOLING RAILWAY MOTORS BY COMPRESSED AIR.

Patents have been granted to Messrs. Mailloux and Gotshall for two systems of cooling electric railway motors by means of compressed air. The size of electric motors is seriously restricted by the gage of the wheels between which the motors must be located. The compressed air cooling scheme is designed to increase the power factor for a certain size of motor which means that it could run at higher speed and develop greater power without overheating. The maximum permissible working temperature for the motor coils, is from 150 to 160 degrees and if this is exceeded the insulation soon chars and becomes defective. The efficiency of the motor also decreases with the increase of temperature. The compressed air is conveyed to the motors by pipes from the airbrake system or an independent air supply. Three systems of controlling the air flow are suggested: Hand control, in which the exhaust from the airbrakes is diverted into the motor cases instead of being allowed to escape into the atmosphere; automatic devices set to discharge air into the cases periodically; and thermostatic devices that would open the air valves when a certain temperature had been exceeded. One great advantage of the system, aside from that of increasing the motor capacity, is that it allows of electric braking. Electric braking is desirable for two reasons, but in the present overworked state of electric railway motors, is not generally feasible on account of overheating; it returns to the line a percentage of the energy required to get a car up to speed, and partly eliminates the wear of brake shoes.

* * *

While it is undoubtedly the case that kerosene oil is of a very penetrating nature and that it will leak through a very narrow crack, it is also the case that water is nearly if not quite as penetrating. One reason that leakage of water through a narrow crack is not so apparent as that of kerosene oil, is that it evaporates and leaves little or no trace of the leak. Again if there is any sediment or suspended mineral matter carried by the water, the evaporation soon leaves a deposit that effectually seals the crack and prevents further leakage. In the case of kerosene oil the leakage does not evaporate, or does so very slowly, and spreads over the outside of the vessel making its presence very apparent whereas the total leakage may be quite small. With the oil there is no tendency for a leak to seal itself, but on the contrary kerosene oil is of a highly solvent nature, and tends to remove all deposits clogging the crack.

SEMI-ROTARY STEAM AND COMPRESSED AIR HAMMER LIFTER.

E. W. Merrill, Jr., Brooklyn, N. Y., has taken up the manufacture in this country of the Brett semi-rotary drop hammer lifter, of English design, which is here illustrated. These lifters can be operated either by steam or compressed air and can be used to deliver one or a series of equal blows, or they will deliver variable light and heavy blows. These blows are of an elastic nature as the return of the hammer is instantaneous. Fifty to seventy blows per minute are ordinarily given with these lifters while at a low fall as high as one hundred blows per minute can be obtained.

Fig. 1 shows an automatic self-contained drop with a 600 pound hammer. The two levers at the right are connected by light rods to the valves controlling the throttle and the automatic trip. The lever controlling the automatic trip moves between two quadrants containing a series of notches which hold it in any desired position. When in its highest, lowest, or intermediate notch, the hammer will trip, automatically, at its corresponding high, low, or intermediate fall. The change of fall can be made in a few seconds either with the machine in operation or at rest. The drop is operated by releasing the latch with the aid of the treadle in the same manner as on a board drop, one or a repeated number of blows being given until the foot is removed. The variable light and heavy blows are obtained by operating the throttle lever as on a steam hammer.

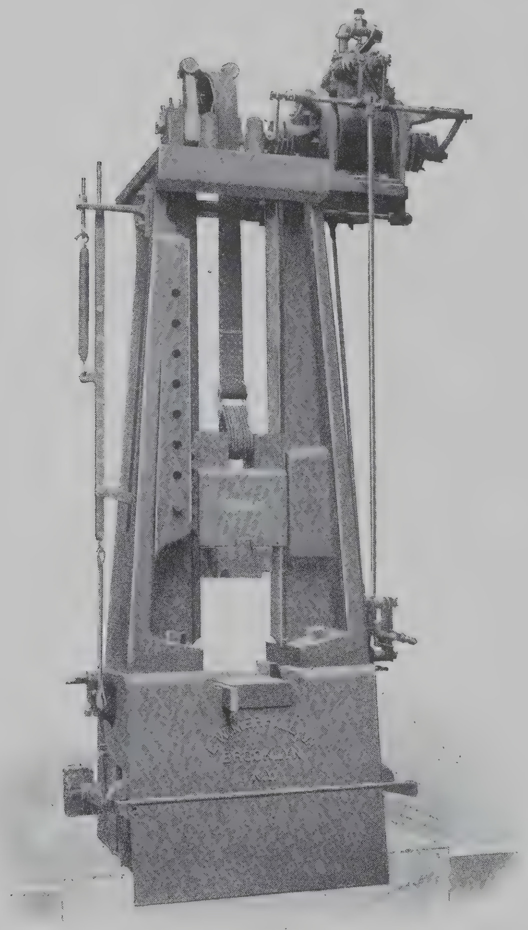

Fig. 1. Six hundred pound Drop Hammer with Merrill-Brett Hammer Lifter.

The method by which the hammer is raised will be clearly seen by reference to Fig. 2, which is a section through the cylinder with the piston, lifting arms and idler pulley in the positions which they would occupy when the hammer, which is fastened to the strap *I*, is down and at rest. In order to raise the hammer, steam enters the port A, presses against the wing B, and forces the piston to any desired position, say E. As the lifting arms F form a part of the piston shaft, when the piston revolves these arms are carried around to the position K carrying with them the strap *I*, and thus raising the hammer. When the piston has reached the position E, steam is cut off and that in the cylinder returns through the port A to the exhaust. This permits the piston to return to starting position and allows the hammer to fall. D is the division block and L the relief and safety vent.

This lifter may be applied to any style of drop hammer as the lifting mechanism can be mounted on any frame built over the hammer, or it may be located on the floor above. The scope of these machines is almost unlimited, drop forgings being now applied to all kinds of work. The size of work which can be handled in this way is constantly increasing, one case of recent practice being the forging, with these drop hammers, of mild steel locomotive pistons weighing 240 pounds each.

COMBINED STANDARD AND OPEN-SIDE PLANER.

In many shops there is a demand for the occasional use of an open-side planer but not enough to warrant the purchase of a machine made exclusively for that class of work, and as a standard type of planer is much better for all-round work, the occasional open-side work is done with an extension tool with a great deal of trouble and expense. To supply this demand, the Mark Flather Planer Co., of Nashua, N. H., have designed and put upon the market, the combined standard and open-side planer, which is here illustrated. The cuts are made from photographs of their 42-inch standard planer changed to the open-side. As shown in the photos, the far housing can be moved back and an extension piece placed

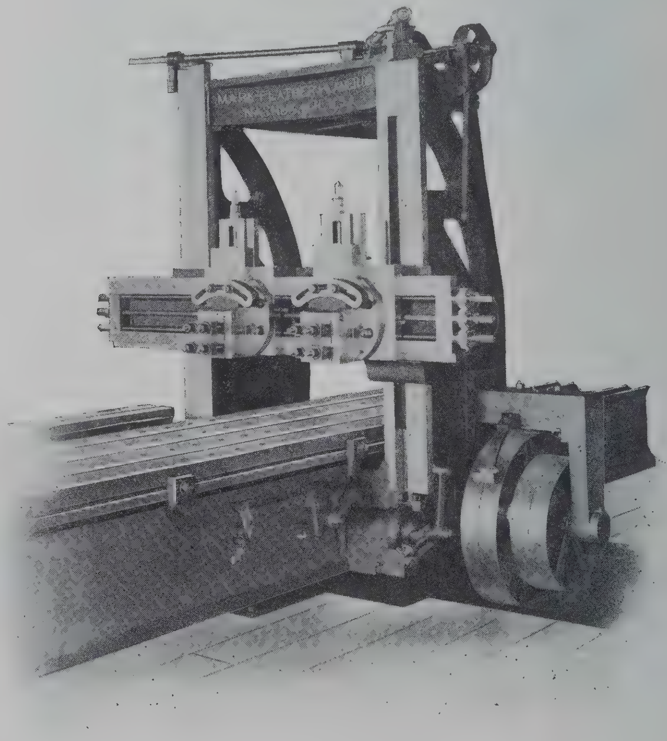

Fig. 1. Combined Planer arranged as Standard Machine.

between the cross-rail and the face of the housing. In the planer shown, the distance from the point of tool to face of housing is 63 inches, so that a piece 5 feet wide can be planed. The cross-rail, being the builder's regular standard 42-inch planer, with two heads on the rail, is long enough to square down work 63 inches wide with the far head, and by setting the head at an angle, several inches wider can be planed. A supplementary table to support the work, slides easily in a V-way, and gives a very secure outer support to which work can be bolted. A rolling table can be furnished instead of the above, if preferred.

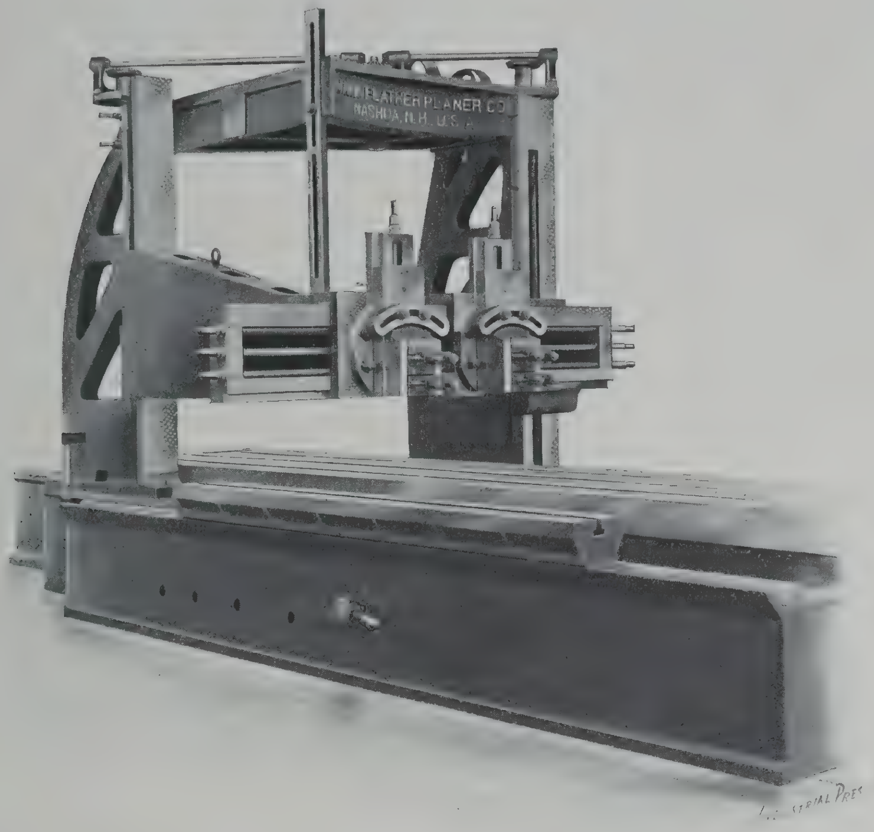

Fig. 2. Combined Planer arranged as an Open-side Planer.

The far housing is tongued into the top of bed, the cheek of which is made long enough to enable the housing to be moved back the required distance, with a rack pinion, so that the extension can be put into position and bolted to the cross-rail and housing, making a very rigid support for the rail. The face of the extension is made exactly like the face of the housing and is fastened to the rail by the same means as to the housing. The back part of the extension is made to fit over the two edges of the housing as well as to the face. The nut on the raising screw is disconnected from the rail and fastened to the extension and is made in such a way that the alignment of the rail is not changed by moving the housing. The rail is made to fit over the face and both edges of housings and is extended above and below the regular width of the cross-rail on the near housing, in order to give a greater bearing and support for the rail, so that when the far housing is removed, the rail will still be held rigidly in position. The change from a standard planer can be made in a very few minutes, and reversing mechanism can be operated from either side of the planer by hand and by the shipper dogs in front.

The power raising attachment for cross-rail, as shown in the drawing, is driven by two friction pulleys, similar to those used on countershafts for lathes. The bevel pinion on this shaft drives a double bevel gear in a central position on the tie which connects the two housings, the lower and larger one is driven by the pinion on the pulley shaft and the upper drives two cross shafts. One of these is rigidly connected with the near housing and the second one with the far housing and both are made to swivel round the central driving gear and also on the raising screw of the far housing. The shaft also telescopes through the bevel gear so that moving the housing from one position to another the shaft is free to slide through the gear as it moves around the circle of the central gear. As these gears revolve around the central gear, the relative positions of the raising screws are not altered since the bevel pinions revolve around the driving gear and also the bevel gear on the screw, consequently causing no change in the position of the screws. The driving gears are all contained inside the bed, which is double webbed around the gears and makes a stiff and powerful arrangement for driving the tables.

The feeding mechanism for the heads is driven by a new relief friction which has recently been brought out by the builders and is positive in its action in moving the feeds, but when released takes no power and does not heat. The reversing motion provides for one belt doing its work, then leaving the pulley before the other starts, preventing the disagreeable squealing of belts. The machine is entirely under the control of the operator at any part of the stroke and there is no unpleasant jar or jerk when the machine is reversed. In other features this machine is essentially the same as the standard planer built by this company.

* * *

Electrical traction has been found to be most satisfactory on the Manhattan Elevated Railway. The Second and Third Avenue lines are now completely equipped and 608 electric cars are in operation. It is expected that the Sixth and Ninth Avenue Lines will be completely equipped by April 1, 1903.

* * *

Brass is primarily an alloy of copper and zinc. Ordinary yellow brass consists of 2 parts copper to 1 of zinc. Lead is also used, a common mixture being copper 60, zinc 36, and lead 4. Bronze is an alloy of copper and tin. The standard ordnance bronze or gun metal, was formerly copper 90 and zinc 10, but the term "gun metal" is now a very elastic one. A gun metal alloy known as "steam metal" because of its common use for valves and fittings, is copper 87, tin 6, zinc 5, and lead 2.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

THE FIRST IRON BRIDGE.

After standing securely for upwards of 120 years the cast iron bridge which The Coalbrookdale Company erected over the Severn in the years 1777-1779 has failed by the sudden breaking of the girders. The structure is believed to be the first metallic bridge ever erected, and it possesses the further distinction of having given its name to the picturesquely situated riparian township of Ironbridge in Shropshire. The span of the arch is 100 feet, the width, exclusive of parapets, 26 feet, and the height from base-line to center, 40 feet, while the weight of iron in the bridge is about 380 tons. No details are at present available as to the cause of fracture, but it is surmised that "fatigue," due to long-continued vibration, may have some connection with the collapse. Cast iron for bridge building is no longer in favor, rolled iron or steel being the material generally used, but for all that, there are few wrought iron or steel structures now being erected that are likely to remain intact for such a prolonged period as has the famous cast iron bridge over the Severn.—*Ironmonger.*

FLOATING FIRE TRAPS.

The passenger steamers plying Long Island Sound are widely known as the most palatial inland-water boats afloat. The cabins and upper decks appear surprisingly spacious to one accustomed to the river or lake boats in other sections of the country. The upper works of the boats, however, while magnificent in appearance, are in reality mere tinder boxes, built with thin pine partitions. In the advent of a fire having a few minutes' start this inflammable material would be consumed in a much shorter time than it would take to tell the story. In 1888 the Fall River steamer *Bristol* burned while at the Newport wharf and although she was favorably located for fighting the fire and for the escape of the passengers, it was with the greatest difficulty that loss of life was prevented. Not profiting by this experience, the Fall River line has recently ordered another "floating palace," which, like its predecessors, will also be a floating fire trap. If it was impossible for the passengers and crew to escape from the comparatively slow-burning ocean-going steamers which were destroyed by fire at the Hoboken docks of the North German Lloyd line two years ago, how would it be in the case of a crowded Sound steamer a mile or two from land?

ANOTHER TOOL STEEL.

Another high-speed tool steel is said to have been produced by a new process at the Bismarck Furnace, in Silesia, Germany. The new material is claimed to greatly exceed in cutting power even the tool steel made by the Taylor-White process, and to have the added advantage that it will work successfully with much smaller cuts than the latter material. Thus it may be used on ordinary machine tools to increase their efficiency, whereas the Taylor-White steel can only develop its full efficiency on specially strong and powerful machines. This information is taken from the *Engineering News* which quotes the following from a German technical paper: "A certain steel shaft of hard steel (tensile strength 78,000 pounds per square inch) was given a cut of .024 inch with a feed of .12 inch. Using ordinary tool steel it took about 280 minutes to cover the surface of the shaft (about 775 square inches); with Taylor-White steel it took 140 minutes, whereas a tool made of the new material did the work in about one hour. It is stated that in working soft steel, with the new tool steel, taking a fine finishing cut, a peripheral velocity of 5½ feet per second could be reached, while other tool steels could not be made to cut at all at this speed."

FROM THE TECHNICAL SCHOOLS.

A short time ago we published an item regarding the new electrical laboratory of the Massachusetts Institute of Technology, Boston, which has been designed especially for research in the electrical field and has the equipment necessary for carrying on experiments similar to the advanced work conducted at the best German universities. These facilities for advanced study are now to be extended to other departments of the Institute, and beginning with the new year arrangements will be completed for several post-graduate courses, leading to the degree of Doctor of Engineering. To attain this degree students must be graduates of a technical school, or otherwise equipped for advanced work, and must carry on extended researches along original lines. They will be subjected to rigid examinations by the faculty, and in each case the degree will be conferred because of work completed rather than as an honorary degree frequently given to distinguished men by universities.

Another press dispatch of interest relative to educational matters is that several millions of dollars will be expended by the University of Chicago in establishing a technological department. It is expected that buildings for the new school will be begun next autumn and will cost, together with the equipment, at least $3,000,000.

ELECTRIC TRUCK FOR MACHINERY TRANSPORTATION.

In New York City the Niles-Bement-Pond Co. have taken the initiative among machinery dealers, by purchasing an electrically-driven truck built by the Vehicle Equipment Co., which concern is represented by the Rainier Co., 393 Broadway, New York. This truck is for use in New York city, and has a number of novel features. It has what is known as the pedestal running gear, the pedestal being a single steel casting fastened to the frame of the vehicle. The axle bearings are located in jaws in this pedestal and have absolute freedom vertically, but none laterally. The battery is below the wagon body, leaving the latter entirely clear, and is made of sectional trays which slide out at either side. The power is furnished by General Electric motors operating independently on the rear wheels. The tires are of 6-inch solid rubber. The controller has four speeds ahead and two for backing, and the battery has a radius of 25 miles on a single charge. The maximum speed of the truck is 5½ miles an hour. An electrical windlass is placed forward, under the seat, for loading freight, and is operated by an independent motor and controller.

A TEN-TON STEAM TRUCK.

This question of the use of motor trucks for the transportation either of raw materials or finished products is one that is being considered by many manufacturers. A few months ago we illustrated the details of the Morgan steam truck, manufactured by the Morgan Motor Co., of Worcester, Mass. Since then this company has brought out a 10-ton truck which is one of the most powerful automobiles ever constructed. It has a total length of over 22 feet and a width of 7 feet. A water-tube boiler is used, with burners using either fuel oil or kerosene. The engine is a double tandem compound, and the truck can always be started without reversing. Where unusual power is required live steam can be admitted to the low-pressure cylinders. There are two sets of driving gears, one in the ratio of 10 to 1, and the other of 20 to 1. The rear wheels, which do the driving, are fitted with steel tires, giving two inches of tire surface for every ton of load carried. The pulling strain of the engines is taken off from the rear springs by struts, which are braced against the supporting I-beams. The throttle is so made that when the lever is pulled back from the center, steam is admitted to the engine, but when the lever is thrown ahead of the center steam is admitted to a cylinder which actuates the brakes, and if for any reason they should fail to work the machine can be stopped by reversing the engine. On each end of an intermediate shaft connected with the engine is a capstan, and it is possible to throw the engine out of gear with the main transmission, so that it acts only on the shafts bearing these capstans. It is stated that by the use of these and of a hawser attached to a near-by tree or telegraph pole the machine can be pulled out of almost any difficulty and even backed down into the excavation and brought out again under its own power. There is also a crane on each side of the truck, by which the latter can be loaded or unloaded, heavy articles being picked up from the level of the ground. Another interesting feature planned by Mr. Morgan is to provide a truck with two or more bodies, which can be separated from the truck and loaded independently of it, thus saving the time usually lost in loading and unloading. The scheme would be to provide loading platforms in such a way that one truck body could be temporarily suspended for loading, while the truck backed against a second platform where the loaded body would be picked up and transported to its destination for unloading.

WIRELESS TELEGRAPHY.

As we go to press, dispatches announce the successful transmission of wireless messages by the Marconi system between the stations at Cape Breton, Canada, and Cornwall, England. While the transmission of these messages is apparently veiled in secrecy and may lead to some skepticism in the matter, there seems to be as good reason for believing the report as otherwise. In this connection the suits in this country now pending against the De Forest Wireless Telegraph Co., are of considerable interest, as the latter hold that Marconi is in no sense the inventor of wireless telegraphy. There have been a series of legal proceedings between the two companies. Among the claims of the De Forest Company is the one that the alleged inventions covered by Marconi patents were previously patented in England and the United States—the first being granted to Loomis as early as 1872, and one of the others in 1876 having been granted to Edison. It is also claimed that Marconi's patents were described in several papers in different countries before their date of issuance. By the De Forest system, messages can be sent at about the same speed as with any telegraphic system in which wires are used, 50 words a minute being possible; whereas it is said that 12 per minute is the greatest number that Marconi has succeeded in sending. However valuable the improvements in the De Forest system may be, we believe that Marconi will receive credit in the estimation of the public for persistently working upon wireless telegraphy until he succeeded in establishing its importance; and particularly since he himself does not claim complete originality, but admits that he has simply applied principles that have been understood by scientists for many years.

THE ECONOMY OF ELECTRIC TRANSMISSION.

In a paper, "Electricity in Railroad Shops," read before the November, 1902, meeting of the Central Railway Club, Mr. L. R. Pomeroy said that mere economy of power transmission by means of electricity as compared to other methods, is one of the least reasons for its adoption. The cost of fuel used to run the machinery of a manufacturing plant, is not usually over 3 per cent. of the cost of the article produced, labor and other items in which time is a factor representing about 47 per cent. and the material the remaining 50 per cent. But the obvious economy of electrical transmission is worthy of serious consideration. The friction load of line shafting remains constant, load or no load, while the transmission loss with electricity is always a percentage of the actual power used. If no power is being taken off by the machines, there is no transmission loss. The friction load of line shafting varies from 20 per cent. to 75 or 80 per cent. of the total power developed, and even more. It has been seriously stated that in a large cotton mill where the conditions were probably very unfavorable, as little as 1 per cent. of the power of the engine is applied to the cotton itself, the remaining 99 per cent. going into friction loss. The chief gain in machine shops, however, with electrical power transmission, is in the increased efficiency of the men and machines. In the matter of removing the wheels from a ten-wheel locomotive an electric crane will do in ten minutes what would require four men eight hours with common screw jacks, and four men one hour with pneumatic or hydraulic jacks. A list of 46 railroad shops was quoted in the paper, that have equipped with electricity or that are expected to do so in the near future.

SOLIDIFIED PETROLEUM FUEL.

A demonstration of the characteristics of a solidified petroleum fuel was given in Chicago recently, which apparently showed that the inventor, Mr. Austin Granville, has succeeded in overcoming the objectionable features that have hitherto accompanied solidified petroleum fuels made by other processes. The heat value of the briquettes is about 18,000 B. T. U. per pound, and they burn with a fierce white flame, leaving little or no ashes. The heat is so intense that for many purposes it is advisable to use coal dust, sawdust or other refuse of a carbonaceous nature to reduce the intensity of the flame. For steam making the preferable method of burning the briquettes is on a traveling chain grate, the air being admitted over the top and none through the grate. A plant having a capacity of 1,000 tons per day is being erected at Port Arthur, Texas, and another at San Raphael, California. The fuel can be delivered at tidewater from the Texas field at a cost of $1.20 per ton which, considering its greater calorific value, is equivalent to coal at about 90 cents per ton. The dangers attending crude oil in bulk are of so grave a nature that it is not probable that it can ever be used for many purposes where it would if the danger of fire was not so great. With the solidified product, however, the fire hazard disappears; also the difficulty of handling and transportation.

THE SUBMARINE BOAT.

A vast amount of money has been expended in this country upon the development of the submarine boat. From the time the United States *Housatonic* was destroyed by the Confederate submarine boat *David*, a great deal of attention has been paid to craft for navigating beneath the surface of the water, and, up to recently, the greatest progress has been made in France. But little public attention was drawn to the matter in this country until the creation of the first Holland submarine boat during the Spanish war. Mr. Holland has worked on the problem for many years and there is now a plant at New Suffolk, L. I., where there are several boats under construction for the United States Government. Recently experiments were conducted upon the two boats *Adder* and *Moccasin*, built at the above plant under the direction of a Government Board. The trials included a large number of runs—submerged, awash and floating on the surface of the water. The boats exceeded the contract speed, which called for seven knots per hour awash, eight knots per hour on the surface, and 5 knots submerged. For use when submerged there is an electric motor of 70 horse power, with storage batteries; while for running on the surface, gasoline engines are employed. The boat is fitted with tanks for compressed air, to provide fresh air for the crew; and a ventilating apparatus had to be devised, particularly since obnoxious gases are given out by the storage battery. The compressed air is also used for emptying water tanks when it is desired to shift the ballast. One of the chief difficulties in the operation of a submarine boat is its control in both vertical and horizontal planes. Apparently, these new boats can be as easily directed in one plane as in the other. It is generally admitted that the radius of action of submarine boats is not sufficient to enable them to operate at a great distance from the shore; but submarine propulsion has been so far improved that there is a good possibility of the submarine boat meeting with success in harbor and coast defense. It will at least have the effect of making an enemy uneasy.

DETERIORATION OF STEEL CAUSED BY "INTERNAL WEAR."

Iron and Machinery World. December, 1902, p. 19.

Charles H. Fitch in the course of an article on the deterioration of steel from internal wear, says that a boiler plate punch, especially a small punch, used to punch thick plates, soon loses its elastic strength. It may be as hard as ever it was, but some time it seems to break like glass. Now if we regard that bit of steel first and last as merely a hard solid body, the changes in that body will always remain blind mysteries. But if we recognize it in all its hardness and solidity as being what it is in fact—a collection of interwoven particles working together—then we can see how it is worn out by the interaction of these particles. This little punch which at the start will go through steel nearly as hard as itself, at the finish will break like glass because it is internally worn out. Though solid it is just as truly a spring as any spiral coil over a railway axle box. When it strikes the skin of the steel, which it pierces, it is driven back like a spring until the force of that spring's compression gives it power to drive through the steel. In going through a thick plate it may vibrate several times. It is in fact a spring battering ram, a little power machine. It has, therefore, the movement and friction of a power machine, and like a power machine it wears out. Then it breaks, not from some mysterious chemical re-formation of particles, not from anything like the crystallization which attends the passage of some bodies from the liquid to the solid state, but simply because it is internally worn out, and needs to be returned to the cupola or the melting pot to be made over from the inside.

MILLING CUTTERS WITH UNDERCUT TEETH.

Abstract from paper read by S. N. Brayshaw before the Manchester Association of Engineers, October 25, 1902.

A turning or planing tool for iron or steel has top rake, as well as clearance below, and milling cutters for many operations should have similar rake. A cutter, 3 inches diameter, 1¼ inch wide, with 10 teeth undercut 10 deg., was used on steel shafting in the works of L. Gardner & Sons, Ltd., the speed being 28 revolutions per minute, and the feed 1 inch per minute, with 9-16-inch depth of cut. This gives an approximate cutting speed of 27 feet per minute, and a feed of .036-inch per revolution. At this rate the cutter left a beautifully finished surface. It ran easily, and kept its edge well. It must not be assumed, however, that undercut teeth are necessarily advantageous. Frequently they are the reverse. Mr. E. G. Herbert, of Manchester, has recently made a series of tests with three cutters 6⅝ inches diameter, 9-32-inch thick, with 1 inch hole. In each case there were 30 teeth, which in one cutter were radial and in the other two were undercut 10 deg. and 15 deg. respectively. The cutters running at 20 revolutions per minute, or a cutting speed of 42 feet per minute, were fed separately into the vertical faces of heavy blocks, first of cast iron, and then of mild steel, until the machine stopped. The feeds varied from 1.4-inch per minute to .16 inch per minute, and there was no perceptible slip of the feed belt. The results of the tests were somewhat complicated, and the curves plotted therefrom were full of interest, but they failed to show any decided advantage of one tooth over another. The general indication seemed to be that the advantage rested with the undercut teeth with a big feed, and the radial teeth gave better results with a fine feed.

WELDING LOCOMOTIVE FRAMES IN SITU.

Railway and Engineering Review. December 6, 1902. P. 876.

Most practical railroad men are familiar with the process of straightening locomotive frames, *in situ*, that have been slightly bent by wrecks or other accidents, but there are few who would attempt to make a weld under such conditions. It appears, however, that where the use of liquid fuel is well understood, it is quite practicable to do this seemingly impossible job. A large number of broken locomotive frames have been welded in position at the West Oakland shops of the Southern Pacific Ry., 56 in all, and out of this number only five have since broken in the welds and this is attributed to the welds having been made at night when it was difficult to gage the heat. The first weld was made November 11, 1899, and the frame is still in service.

The plan followed is to strip the engine at the location of the break and to build up around the frame a temporary furnace of firebrick, after the plan usually followed when straightening bent frames. The furnace is built on a piece of sheet iron so that the whole affair can be quickly dropped into the pit when the welding heat has been reached. In practice, however, the first "setting up" blows are delivered before the furnace is torn down. Thus if the break is in a frame jaw, the lower end is driven up by a heavy pneumatic hammer weighing 30 or 40 pounds; if the break is in the top rail the tail piece is struck with a 1,000-pound ram a few times, with the furnace in place. Before the heat is taken it is the practice to jack the broken ends apart and to insert a piece of end-grain iron which is allowed to project all around about ¾ inch. This is, of course chipped off after the weld is made. The oil burner works under an air pressure of about 100 pounds. Kerosene, distillates or the lighter crude oils are found satisfactory fuels for this purpose. A 23 degree gravity crude oil is frequently used at the West Oakland shops with good success. It is stated that the adjustment of the burner as to the relative proportions of air and oil, is quite a delicate operation; also that the distance of the burner from the surface of the metal, the angle of the deflection and the location of the furnace bricks around the weld, are important. Considerable practice on the part of the smith is necessary to make satisfactory welds of this description, which is quite believable. It is recommended that preliminary experiments be made with bars of iron, iron axles, etc., before trying to weld a frame.

HEAVY STEAM PIPING.

New York Meeting Engine Builders' Association, Dec. 1-2, 1902.

At the last meeting of the Engine Builders' Association of the United States Mr. William Andrews read a paper upon "High-pressure Steam Piping," from which the following notes are taken:

"Up to the year 1900 the almost universal design for a piping system for power plants was to carry a pipe for each boiler into a large steam header, whose cross section was equal to the sum of all the areas of the feeding pipes. If the designing engineer wanted to be very grand he made it larger without knowing just why. From this header, pipes were carried to the various engines, of sizes called for by the engine builder. It was quite common to place steam separators in each line leading to an engine, but fashions change in steam piping, as well as in clothes, and with the advent of high-pressure and superheated steam, sizes of pipes have been very much reduced. In the four large power houses now built in New York city, with an ultimate capacity of from 60,000 to 100,000 horse power each, the largest steam mains are not over 20 inches in diameter, and these are used more as equalizing pipes or storage reservoirs. Some of our best plants have pipes which run from the header to the engine two sizes smaller than that called for by the engine builders. These pipes, before reaching the engine, are carried into a wrought-iron or steel receiver, which acts also as a separator. This receiver has a cubical capacity three times that of the high-pressure cylinder, and is placed as near as possible to the cylinder. The pipe from the receiver to the cylinder is of the full size called for by the engine builder. The object of this arrangement is, first to have a full supply of steam close to the throttle; second, to provide a cushion near the engine on which the blow caused by the cut-off in the steam chest may be spent, thereby preventing vibrations from being transmitted through the piping system, and, third, to produce a steady and rapid flow of steam in one direction only, by having a small pipe leading into the receiver. This steam flows rapidly enough to make good the loss caused during the first quarter of the stroke. Plants fitted up in this way are successfully running where the drop in steam pressure is not greater than 4 pounds, although the engines are 500 feet away from the boilers.

As to quality of material, in the earlier days of electric light and railroad plants, owing to the difficulty of keeping the screwed joints tight, some engineers tried flanged cast-iron pipe for steam mains, but it was heavy and clumsy and sometimes cracked on account of the unequal expansion. Then came copper, and this pipe, even when reinforced with steel wire wound around it, was found to be a treacherous metal. Flanged cast-steel pipe was tried, but the difficulty of obtaining this free from blow-holes barred it out. At present the material used is either wrought-steel or wrought-iron pipe, on which the flanges are either riveted, screwed or welded. In England and on the Continent they weld a light flange to the end of the pipe and face it; it is pulled together when in use by a heavy steel or cast-iron flange, which has previously been slipped over the pipe, very much as copper joints are made in marine piping.

In 1880 the New York Steam Co. installed about six miles of steam mains under the streets of the city of New York for power and heating purposes. All the joints in this pipe above 8 inches in diameter were made by expanding the pipe into recesses in the flanges, and then beading the ends of the pipe over the edges of the flanges. This was done by machinery, and was well done, and at the time was considered a great improvement over threading or riveting, but in five years every joint had to be taken out on account of leaks and threaded joints were substituted. These threaded joints lasted until 1895, when all the pipes were renewed with new mains having heavy wrought-steel flanges welded on the pipe. These welded flanges when turned true in the lathe make the most workmanlike and perfect steam joints in use at the present time, and their cost alone prevents their general use.

Corrugated-copper gaskets placed inside the bolts and well pulled up will make a joint which will last as long as the fittings. The softer gaskets containing rubber, asbestos, or lead alloys need constant attention, and when superheat is used they are rapidly destroyed. When the owner's bank account is strong enough ground joints without any gaskets are used. This makes a first-class job, but the price is all but prohibitive.

RESISTANCE OF AIR TO THE MOVEMENT OF FLYWHEELS.

Zeitschrift des Vereines Deutscher Ingenieure. 1902.

It has been ascertained by Herr Scholter, Manager of the Nuremberg-Further Trainways, that the resistance of flywheels is very far from being a negligible quantity. This resistance may be divided into two parts; that exerted by the friction of the air against the rim and that due to the displacement of the air by the arms; the latter being by far the more important of the two.

In the central station of the trainway there are two horizontal, tandem compound engines developing 450 horse power at a speed of 95 revolutions per minute. Each has a strong flywheel whose arms are formed of a double T with a central web set parallel to the center line of the shaft. The rotation of these flywheels produces a strong current of air which seemed to indicate the existence of a considerable resistance.

The suggestion was made to cover the two faces with a smooth protection of sheet metal, which was done. In order to determine the difference in the resistance under the two conditions, with and without the covering, one dynamo was made to serve as a motor to drive the unloaded engine. With the flywheel in its original condition, the work required was 13,300 watts, while, after the wheel was covered, only 9,874 watts were needed; a difference of 3,426 watts or about 5.7 horse power. The cost is then estimated, which may be reduced to American standards as follows:

Considering the engine to be running 17 hours per day for 365 days in the year on a consumption of 2 pounds of coal per horse power hour; the coal burned for the development of the power to overcome flywheel resistance will be about 35 tons, which at $2.00 per ton will be $70.00 per year. As the cost of covering the flywheels is an insignificant amount, the figures given above may be taken to represent a net annual saving.

As long ago as 1888 Prof. Brauer, of Darmstadt, called attention to the advisability of filling in the space between the arms of flywheels and cited an experiment made by Inglis on a 630 horse power engine in which indicator cards showed a saving of 30 horse power or 4.8 per cent. due to a reduction of flywheel resistances.—G. L. F.

FLYWHEEL EXPLOSIONS AND THEIR CAUSE.

Monthly Bulletin Fidelity and Casualty Co., December, 1902.

W. H. Boehm has received a letter from a cotton mill owner in which he says that his engineer has made a careful inspection of the flywheel driving his mill, and has reported that there are no defects or "buggers" in it. From this report the mill owner concludes that the wheel is safe and that danger from bursting is negligible. Mr. Boehm points out that flywheels do not often break from faults of construction or material, but from a sudden increase of speed due to some accident. Most flywheels that fail are really sound and safe under ordinary conditions. The fact that a defective wheel may run for years and then suddenly burst, shows that the immediate cause was not the defects, but some change from the normal condition under which the wheel had been running.

Wheels do not often fail from torsional stress or from twisting action in pulling their load, because enough material can be put in the wheel to resist successfully any load required of the engine. There is, however, no possible way to overcome the centrifugal force due to speed. Increasing the thickness of the rim of the wheel does not strengthen it so far as centrifugal force is concerned, because the weight added also increases the centrifugal force, leaving the wheel no stronger than before. There is, therefore, a definite speed at which any wheel, however sound, will explode, regardless of the amount of material it contains. For cast iron wheels sound theory borne out by good practice has fixed *a mile a minute* as the danger limit for the rim speed. Most wheels are run at or near this speed. The normal speed, however, is only of incidental consideration, as an accident may at any moment allow the speed to get beyond the normal. As the stress in the rim due to centrifugal force increases with the *square of the speed*, disruption quickly follows even a slight increase in speed. If the speed should be accidentally tripled, for example, the stress in the rim would become *nine times* as great as before, and the wheel would have exploded long before it had attained that speed. It is here that the "bugger" gets in his awful work.

In the case of the accident at the Amoskeag Cotton Mills, he got into the governor of the engine. Although he increased the speed only 20 per cent., the flywheel burst, wrecked the mill and killed two women and one man outright. In the case of the accident at the Griffin Manufacturing Co. a year ago, the "bugger" dropped a small washer in the port of the high-pressure cylinder, causing the slight increase in speed that precipitated a flywheel wreck in which the mill and an adjoining building were partially demolished.

As a matter of fact, the percentage of flywheels that explode is 33 per cent. greater than the percentage of boilers that explode, and the "bugger," by getting into the mechanism of the engine, is directly responsible for most of the trouble.

BRIQUETTING FINE ORES AND FLUE DUST.

Abstract from Paper read before the Engineers' Society of Western Pennsylvania, by Henry S. Mould.

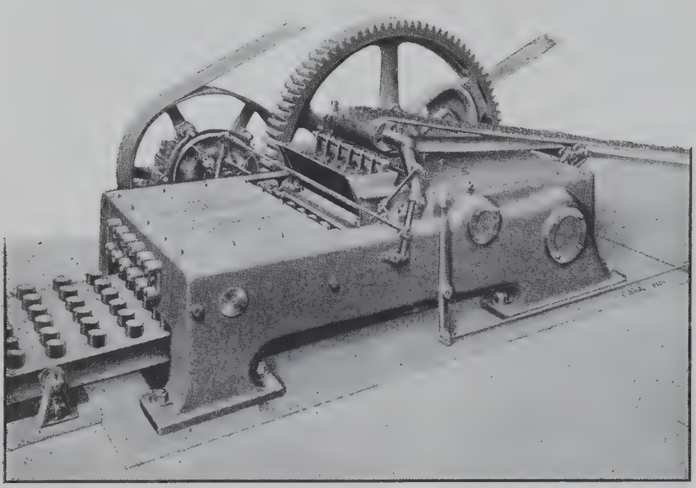
It is well known that in blast furnace operations metallic flue dust exists and that on this account there is a large loss to furnace owners. The scarcity and value of lump ore and the consequent necessity for using large quantities of fine material in the furnace increase the flue dust loss and give rise to other dangers and evils that sometimes entail heavy property loss and even the loss of human life.

It is to do away with these evils that briquetting this fine material has been resorted to, and progress has been made only through a long succession of failures, owing mainly to the difficulty in constructing suitable machinery, and the high cost of the bond. Conditions vary widely in different regions and with the materials that are to be put into block form. The bonding agent that can be successfully used with precious metal concentrates or flue dust from the smelters cannot be successfully used with anthracite culm, and the binder used in briquetting the latter cannot be used in briquetting iron flue dust or fine ores. Adjustability of pressure is also essential, as different materials require varying pressure, ranging from 2,000 to 18,000 pounds to the square inch.

About 1895 the most available machine for briquetting was what is known as an "eggette" machine, which is composed of two large rolls, each having an indentation in its face similar in shape to half an egg, so placed as to register accurately and so designed as to allow the eggette thus formed to drop onto a conveyor or belt. While the briquettes manufactured by this process were strong enough to stand up in the furnace, there were a number of other difficulties that made further experiment necessary before a successful process could be evolved. In the first place, using the "eggette" type of press, so large a percentage of binder was necessary that the cost of briquettes was too high. In addition to this, the machine as then constructed would not stand the wear essential in that class of work.

One of the more successful of the earlier machines was the White mineral press. This was of the disk type, the briquettes being formed in 48 molds, all in one piece known as the disk. It was found, however, that the briquettes were not hard enough to stand the pressure in the furnace without first drying; that special auxiliary machinery was required and that the cost for repairs was excessive. The gritty nature of the flue dust acted as coarse sand-paper or emery on the molds and necessitated the frequent purchase of new disks. The disks could not be re-ground or renewed; it took three men nearly half a day to replace one; a new disk weighed 1,500 pounds, was five feet in diameter, and cost about $150. This heavy repair cost feature had to be eliminated.

The second machine, patented in 1898, which was believed would do away with the faults shown by the mineral press, was an entirely new type. Instead of a disk arrangement to carry the molds to the point where the pressure was exerted, there were six molds placed in a reciprocating press-box, into which spring and compression plungers were thrust, capable of exerting enormous pressure. These molds are simple in design and can be removed and replaced at a nominal cost. As they sustained all of the wear, this did away with the enormous repair cost essential where an expensive disk was used.



No. 1. White Briquetting Press, Capacity 100 tons in ten hours.

A testing plant was fitted up, one of the plunger type presses was installed there and the experimenting went on for three years. Binder after binder was tested and careful records of each experiment were kept. During this time, the process of briquetting in a number of fields was perfected but the successful handling of iron flue dust was still beyond the grasp of the experimenters.

A little over a year ago another testing plant was fitted up, complete in every detail, with heating and drying apparatus so as to show the process of briquetting any fine material. The plunger press had been improved in many small details, although the principle of the machine remained the same. At last a binder was discovered that would hold iron flue dust, iron concentrates, or fine iron ores in hard and satisfactory briquettes, but it took 12 hours to dry them. After a little more experiment and investigation the point was reached where a binder and drying apparatus were perfected that gave a continuous process for the briquettes from the flue dust bins to the finished briquette in cars or storage bins, the whole operation taking approximately half an hour, and these are now used in the so-called Mould process.

In attempting to briquette the flue dust it was found that the solution of the problem was much more difficult than that of the handling of fines at precious metal smelting works. One main reason was the fact that the tiny particles of iron flue dust as they are whirled about by the blast are rounded until each particle, when seen through the microscope, appears as round as a marble. In addition to this, each little piece of ore is covered with a greasy carbon coating which seems to counteract the effect of a binder. For these reasons, it has been difficult to find a binder that would give a briquette with all the essential conditions. The difficulties may perhaps be better realized when it is known that the requirements call for a briquette that shall be hard and durable; waterproof; low in moisture; able to stand long transportation in open cars; not unduly refractory or liable to decrepitate or become dust again; and the binding agent must not injure either the lining of the furnace or the quality of the iron produced.

Many striking illustrations of the possibilities of briquetting processes can be derived from the statistics of ore production. In a blast furnace producing 600 tons of iron a day, the furnace burden approximates 540 tons of coke, 375 tons of limestone, and 1,085 tons of ore; a total of approximately 2,000 tons. Assuming that the furnace managers use 80 per cent. of Mesabi ore, or 868 tons, and lose 8 per cent. of the Mesabi burden in flue dust (and these are under the actual figures if anything) what does this mean in dollars and cents? It means that every 24 hours the furnace owners are absolutely throwing away 70 tons of ore. Estimating the value of Mesabi ore in Pittsburg at $3.50 per ton, this means that the loss in flue dust alone is $245 per day or $89,425 per year.

And this is not all. There are even greater things that can be accomplished by briquetting. In 1901 the total shipment of ore from the Lake Superior region was 20,589,237 tons, and of this the Pittsburg district received about 11,000,000 tons, of which about 44 per cent., or 4,840,000 tons came from the Mesabi range alone. Exact and careful analysis of ore cargoes, however, shows that the ores carry a heavy percentage of moisture. In 1901, from a tabulated list of these analyses compiled by the ore agents of the big steel companies, it was determined that the average amount of moisture in the Mesabi output from 52 mines for the year was 10.57 per cent. In other words, the manufacturers of iron and steel in the Pittsburg district are hauling from Lake Superior, and paying freight on 511,588 tons of water. The freight rate from the Mesabi range to Pittsburg is $2.35 a ton. On this basis, Pittsburg manufacturers are paying $1,202,231 a year for hauling water from the mines. With the use of briquetting machinery, this waste in freight can be saved to the manufacturers. It is quite possible to briquette the fine ores at the mines. After first drying the material by driving off the moisture and then pressing the fine ore into blocks, the raw material can be brought direct to the furnaces in this district as lump ore, in briquettes that are waterproof and that are abundantly able to withstand the rough usage inevitable in transportation. By this means all of the evils that must now be contended with, arising from the use of fine ores, can be absolutely done away with.

CONTINUOUS CURRENT MOTORS FOR MACHINE TOOLS.

Abstract from Paper read by F. O. Blackwell before the American Institute of Electrical Engineers. November 21, 1902.

Planers, slotters, milling cutters and many other tools need only a slight variation in speed, as the relation between the tool and its work is always the same, variation in speed only being required for different classes of work—that is, for hard or soft metal or for a roughing or a finishing cut. Such work does not require more than a 2 to 1 variation, while on the other hand, lathes, boring mills and other rotating tools may require an 8 to 10 or even 40 to 1 variation, necessitated by the varying diameters of the work. For instance, take a lathe in which is being turned a shaft six inches in diameter, to obtain a cutting speed of 50 feet per minute, it will require approximately 32 revolutions per minute of the main spindle, while if the flange of a 48-inch wheel was being turned, it would require only four revolutions per minute of the spindle to obtain the same cutting speed.

The common method in use for attaining variable speed by means of the electric drive, are rheostatic, field and multiple voltage control.

Rheostatic control is obtained by introducing resistance in series with the armature of an electric motor, the speed being reduced in proportion to the power consumed in the resistance. Therefore, if a constant horse power is desired at the tool, a motor when running at reduced speeds receives a reduced potential and requires an increased current. For example: If a motor is running at one-half its normal speed it receives but one-half the line potential and requires double current. From this it will be seen that as the rheostat is consuming practically one-half the power applied, the efficiency of the combination is less than 50 per cent. This method of control is undesirable, not only on account of its being very inefficient, but also from the fact that as the load decreases the speed increases; and should a man be working on a piece of material where the cut takes only part of a revolution, the speed will immediately increase, as the tool leaves the work, to such an extent that in all probability the tool will be burned or perhaps broken when it enters the work again.

By varying the current flowing in the field coils of the motor the strength of the magnetic field is changed, and the speed of the motor varied. With any setting of the field, however, the motor will give constant speed under changes of load, and this method therefore avoids the greatest objection of rheostatic control. A motor of ordinary design will not always permit of any considerable weakening of the field without sparking at the commutator; but with a motor having small armature reaction a variation in speed of 2 to 1, can readily be obtained, and when delivering a constant horse power the current will be approximately the same at all speeds, because the potential across the armature terminals is always the same. As the field current of a motor is only a small fraction of the total current, the efficiency of this method of control is practically the same at minimum and maximum speeds; it also allows the use of a much smaller controller and renders it possible to get a greater number of running speeds than can be economically arranged for with any other control.

Multiple-voltage control is obtained by having several different line potentials to work from. For instance, with the Edison three-wire system the potential from the neutral to the outside wires is one-half the potential between the outside wires. There are, therefore, two potentials available, and a motor connected between the neutral and one outside wire would run at one-half the speed it would when connected across the outside wires. A four-wire system may also be used in the same manner, giving various combinations of potentials, the minimum of which may be about one-fourth or one-sixth of the maximum potential.

Either of the above methods combined with the field control of the motor makes a very flexible system. For example, a motor having 100 per cent. field control used on the three-wire system will give a speed variation of 4 to 1, or a motor having 35 per cent. field control used on a four-wire system with potentials of 60, 80, 110, 140, 190 and 250 volts will give a speed variation of approximately 6 to 1, or with potentials of 40, 80, 130, 170, 210 and 250 an 8 to 1 speed variation, the gaps in speed between the various potentials being filled in by field control of the motor.

It has been demonstrated many times that it takes practically a constant horse power to remove a given amount of metal per minute, irrespective of the rotative speed of the tool. Therefore, the main spindle of a lathe taking a ⅜-inch cut on a 6-inch steel shaft with a feed of ⅛-inch and a cutting speed of fifty feet per minute makes 32 revolutions per minute, and takes a certain horse power to drive which we will assume to be 15 horse power, and the motor will be working on its highest potential or 250 volts. Now, if we are using the multi-voltage system with the last-named potentials above, and should put a 48-inch wheel in this same lathe and turn up its rim with the same cut, feed and cutting speed, the main spindle would run at about four revolutions per minute or one-eighth of the previous speed, but still require 15 horse power to drive. With this condition the driving motor would have to run on its lowest potential or 40 volts, and would be consuming fully six times the amount of current it did previously. A motor to be used on the multi-voltage system will have to be sufficiently large to carry its maximum horse power at the minimum potential, or, in other words, at, say, 40 volts on a 250-voltage system, the motor will have to be six times too large when working on its maximum potential. For this reason it is desirable that we keep the lowest potential employed as high as possible in order that the size and cost of the motor may be within reasonable limits. A potential of 40 or 60 volts requires such large conductors, if they are laid out for a small drop, that their cost is prohibitive in a plant of any size. If a large drop is used, the motor falls off in speed under load and its speed regulation under changes of load is little better than with the rheostatic control.

With the three-wire system and a 100 per cent. variation in the motor speed by field control, we can obtain a 4 to 1 total variation which, for general machine-shop work, is sufficient to cover a single operation on a given tool. The total range, however, on a tool can be increased greatly by having a few gear changes. For example, on a back-geared lathe with a gear ratio of 4 to 1 a total variation of 16 to 1 can be obtained. In the same manner on a double-geared lathe a variation of 64 to 1 might be obtained.

The reduction effected by different sets of back-gears on machine tools will be found to vary from 4 to 1 to 6 to 1. All tools can be arranged with 4 to 1 changes between back-gears without any difficulty. In many cases a single back-gear is sufficient for a tool. By putting a magnetic clutch on this back-gear and making the electrical connections in the controller, it is possible to get a 16 to 1 variation electrically and without increasing the cost of the motor more than would be required for a 4 to 1 variation.

With electrical control a man can keep his hand on the controller and his eyes on the tool, increasing the speed from time to time. Being limited only by the temperature of the tool, it has been found that much higher cutting speeds are unconsciously attained with a motor-driven tool than would be thought possible were any fixed rule followed. It is therefore apparent that this increased production in many cases is so great as to fully justify the installation of an electric system, even if there were no other advantages to be secured.

In conclusion, the author gave it as his opinion that it will generally be found best to use motors with field control, allowing a total speed variation of 2 to 1 with the two-wire system or 4 to 1 with the three-wire system, believing that the four-wire system is too expensive for general application if the plants employing it are properly designed and equipped with large enough electrical apparatus. For reciprocating tools a two-wire system will meet all requirements, and there are very few rotating tools where it is not better to mechanically vary the speed for all speed variations greater than 4 to 1.

The most important consideration in the electric driving of machine tools is to make the control of the tool as convenient as possible and arrange the system so as to permit small changes in speed, and consequently be able to always drive the tool at its highest possible speed and greatest output.

NEW OIL TESTING MACHINE AND SOME OF ITS RESULTS.

Abstract of paper read at the Annual Meeting of the A. S. M. E.

In this paper Mr. Albert Kingsbury describes a machine built by him for the purpose of making comparative tests of various kinds and grades of oils. There are two important properties in lubricating oils and greases on which their value depends—viscosity and body. Viscosity is the property by virtue of which the lubricants form comparatively thick films between rubbing surfaces, permitting perfect lubrication. The effect of the lubricant in reducing friction depends mainly upon the "body" or "oiliness."

The nature of this property, or combination of properties, is not well understood, but it appears probable that it is an intensified viscosity in that part of the fluid within the region of attraction of the surface molecules of the metal.

Experiments have shown that the effects of body and of viscosity are in nearly all respects diametrically opposite, and that it must necessarily be very difficult to derive reliable information regarding the lubricating values of oils from friction tests in which the effects of viscosity and those of body are not separately recognizable. Under this consideration, methods of testing which are described in this paper are arranged with special reference to the conditions under which the effects of either property may be investigated independently of the effects of the other.

In the machine with which these tests were made, the test journal has its axis vertical; it is suspended from the spindle by means of a flexible coupling and runs between two opposed bearings in a cylindrical cup or case, which may be filled with the oil to be tested if a "bath" is desired. The load on the bearings is provided, by means of a helical spring of 900 pounds capacity, with screw adjustment and with a device for quick application or removal of the load without disturbing the adjustment. In testing, the suspended parts turn freely to a position where the torsion of the suspension wire balances the friction at the test journal; and the angle of torsion, which may be as great as 270 degrees, is read from a graduated disk. The cup and the test journal contained in it may be heated as desired by a Bunsen flame. The revolutions of the journal are indicated by a counting device.

For tests involving perfect lubrication (friction due to viscosity only), the test journal used is 1⅜ inches in diameter, of tool steel, hardened, ground and polished. The brasses are sectors cut from a ring finished in the lathe, each having an arc of about 120 degrees and a length of 2 inches.

A number of curves have been plotted from tests made with this machine which seem to verify the deduction that the friction is proportional to the viscosity of the oil, and they also show the friction to vary roughly as the square root of the speed.

For tests for comparing oils with respect to body or oiliness the best results have been obtained by the use of a hardened and polished steel journal ¼ inch in diameter, running between two brass bearings about 1 inch long; on this small journal pressures up to 8,000 pounds per square inch may be applied if necessary. In making these tests the oil giving the less friction is assumed to have the greater body. The writer has not found the order of body values, as determined by this method, to vary with the speed or the pressure within a considerable range. A speed of 50 to 100 revolutions (3 to 6 feet per minute), with sufficient pressure to make the coefficient of friction only as great as .01 to .03, have been found most satisfactory; the pressures being from 500 to 5,000 pounds per square inch, according to the character of the oils.

The results of this method of testing for body agree thoroughly with the principal fact hitherto established with regard to body as distinguished from viscosity—namely, that the mineral oils as a class have much less body than the animal and vegetable oils. For example, in a body test of the mineral oil and the lard oil having viscosities 98.9 and 83.7 respectively, as determined by the Dudley pipette, the lard oil, although the less viscous, gives very decided evidence of greater body, by its much smaller friction. On the other hand, certain cylinder oils, wholly or largely mineral, and greatly exceeding lard oil in viscosity have also greater body than lard oil.

FLYWHEEL CAPACITY FOR ENGINE-DRIVEN ALTERNATORS.

Abstract of paper read at the Annual Meeting of the A. S. M. E.

Mr. Walter I. Slichter presented a paper which was written with the object of showing certain considerations which must be borne in mind when selecting a steam engine to drive an alternating current generator which is to run in multiple with another generator or which is to generate power for a system in which synchronous apparatus such as synchronous motors or rotary converters are to operate.

In a comprehensive manner he discussed the mechanical action of the engine when direct connected to the alternating current generator and also the allowable fluctuations in speed. A displacement of phase in the electric current of 2½ degrees from the mean will cause a cross current of about 10 per cent. of full load current to flow. This value has been more or less generally adopted by the builders of electrical machinery as the limit of displacement, if satisfactory running is to be expected. To determine a weight of flywheel which would limit the displacement to a value approximately equal to 2½ degrees the following formula has been determined, based on the unbalancing factors with a reasonable increase to allow for overloads:

$$W r^2 = \frac{K W \times C \times 10^9}{S^4}$$

where W = effective weight of wheel, KW = rating of generator, S = speed of engine in R. P. M., r = radius of gyration, C = a constant as follows:

	Horizontal Single-crank.	Vertical Cross-compound.	Horizontal Cross-compound.
25 cycles	315	275	250
40 "	505	440	400
50 "	630	550	500
60 "	755	660	600
125 "	1575	1380	1250

While not always giving the most desirable flywheel capacity, since it would be impossible to take into account all the irregularities of some engines, yet it gives a value suited to the various conditions (such as frequency of alternator, style of engine, etc.), such that if the engine is reasonably good we will get the results desired. If this weight of flywheel does not give satisfactory results it would be much better (for the electrical circuit) to make such changes in the engine itself as to give a better crank effort diagram than to increase the weight of flywheel, for a flywheel may easily give trouble by being too heavy.

As changes in the engine, the following are suggested:

First, as best though most difficult, changing the angle between the two cranks.

Second, changing the proportion of load taken by the different cylinders, and make the low pressure take more load.

Third, introduce compression at the end of the stroke to take up inertia, particularly in low-pressure cylinder.

* * *

TWO NOTABLE SPECIAL NUMBERS.

The November 6th issue of the *American Machinist* and the November issue of *Cassier's Magazine*, are notable examples of the special number scheme in trade journalism. The *American Machinist* special number was issued in commemoration of its twenty-fifth anniversary and is, of course, largely given over to an interesting historical review of mechanical progress that has taken place during its lifetime. The leading articles were contributed by men who have become eminent in various branches of engineering.

The November issue of *Cassier's Magazine* is a machine shop number, being entirely devoted to articles on various phases of this subject. There are 272 pages of reading matter and illustrations, and about 200 pages of advertising. Among the articles we note: The Multiplication of Cutting Tools by Joseph Horner, Electric Power in the Machine Shop by W. M. McFarland, Portable Machine Tools by Forrest R. Jones, Limit Gages in the Machine Shop by Wm. H. Booth, etc. It is needless for us to say that both of these special numbers are of great interest and worthy of the attention of every progressive mechanic.

A writer in the *Foundry* says that an alloy discovered by accident, which resists the action of strong sulphuric and hydrochloric acids, hot or cold, and which is only partially dissolved by hot nitric acid, has the following composition: Lead, 66.89; copper, 11.32; tin, 10.52; antimony, 3.70; iron, 0.75; silicon, 2.09, and sulphur, 0.53. We assume that parts and not percentages, are meant since the sum total is not 100. In general it seems best to give such formulas in percentages since typographical and copying errors in the figures may then be readily discovered.

* * *

In the notice given in the December issue of the death of Frederick Alfred Krupp, an obvious error was made in the statement of building property area covered by the Krupp Works in 1890. Instead of 11,700 acres, it should have been 117 acres.

PINS AND PIN MACHINES.

EXTRACT FROM UNITED STATES CENSUS REPORT, 1900.

The invention of the process of wire drawing marked the beginning of the modern pin manufacture. The process originated in France and Germany, and for two centuries these countries monopolized all industries dependent upon it. The first man to manufacture brass pins in England was John Tilsby, who, in 1626, established a plant in Gloucestershire, where he met with remarkable success, and his make of pins became famous. By 1636 the industry was so well established that the pin makers of London formed a corporation, and the trade soon found its way to Bristol and Birmingham, where, in connection with other ironwork manufacture, the industry became localized. In those cities pins were made for some time by hand labor. About 1800 William Bundy invented a method of heading pins which was the modern process in embryo.

In 1812 Bradbury and Weaver conceived the idea of heading "by means of an automatic machine." After the shanks were pointed and the heads prepared they were put into separate hoppers, where a mechanical device placed the shank and head into relation with each other. In this position the pins were pressed by screws against dies, which made the head and bound it to the shank, when they were withdrawn by hooks operated upon by parallels worked by the machine.

In 1817 Seth Hunt invented a machine to make the pin with head, shaft, and point from one piece, but his invention was not a success. In 1824 W. L. Wright, an American, a native of New Hampshire, invented the solid-headed pin-making machine, which entirely revolutionized the pin manufacture. He did not have his machine patented in America, but took it to England and put it into operation. He formed in London a company with a large capital, and built a good-sized factory in Lambeth. A plant was fitted up at great expense with 60 machines, but they were never put into successful operation, as they failed in pointing the pin. Although Wright remedied this defect by a supplemental machine, the company did not succeed, and suspended operations with a great loss to those interested in the enterprise. Fortunately, in the readjustment of the company's affairs the machinery fell into the hands of D. F. Taylor, who, by interesting capitalists in the enterprise, brought about the formation of a company known as D. F. Taylor & Co., which in 1833 put upon the market the first machine-made solid-headed pins sold anywhere in the world.

As early as 1812 the inventors of this country were using their energies to construct a machine for the manufacture of pins. The first machine made here, which was brought out by Moses L. Morse, of Boston, Mass., some time during the war of 1812, proved too delicate and intricate to be used to much advantage and was soon abandoned. The man who did more than any other individual to place the manufacture of pins by automatic machinery on a practical and successful basis in this country was Dr. J. I. Howe. In 1830 he began his labor in this direction, spending some of his time in Europe studying the methods employed there, and by the year 1832 he had patented in this country, France, and England, a machine designed to make pins similar to the English diamond pins, with heads formed of coils of small wire fastened upon the shank by pressure between dies. He brought the business to a successful issue in 1836, when the Howe Manufacturing Company was formed in New York and began operations at Birmingham, Conn. At first automatic spun-head machines were used, but in 1840 they were converted into solid-headed machines. These latter machines at first made from 40 to 50 pins per minute. They were later improved so that they made from 60 to 70 per minute.

About 1835 Samuel Slocum, an American, obtained a patent in England for a machine to make solid-headed pins. In 1838 he began with this machine the manufacture of pins in Poughkeepsie, N. Y. As he never had the machine patented here, it was operated secretly for a number of years. Until 1842 the industry made little progress because of discriminating tariffs. In this year, however, a new tariff law went into effect which was more favorable to this industry than the previous tariff act, and the above-named companies did a very profitable business. Led by exaggerated ideas which became prevalent as to the extent of the business and the profit made in it, many persons in different parts of the country invented machinery for the construction of pins. Attempts in this direction met with varying success but the articles turned out were, with a few exceptions, inferior, and the market became overstocked. In consequence of this over-production, by 1848 all parties engaged in pin making, except the two old companies at Poughkeepsie and Birmingham, suspended operation. In the year 1850 there were four establishments engaged in this industry, and the success attending them led to further improvements in the machines. A Mr. Fowler and a Mr. Atwood perfected machines to make 160 to 170 pins a minute which, on account of their capacity, soon replaced the early machines.

Following the successful introduction of a machine for making the pins, the next important step was to invent a machine that would stick them on paper. Howe and Slocum gave their attention to this matter as early as 1840. Dr. Howe invented the device for crimping the paper, and this was followed by the distributer of Mr. Slocum. The two inventions were combined and effected a great increase in the number of pins that could be stuck on a paper in a day. These devices were improved upon by Mr. De Grasse Fowler, who invented the "goose neck" or "runway." For many years the sticking machines consisted of a combination of these three devices, but more recently machines of various styles have come into use that will stick from 500 to 600 packages a day, far more than the early combined machine of Howe, Slocum, and Fowler.

The old process of pin manufacture by manual labor was very slow and tedious, since each pin passed through the hands of from 14 to 18 individuals. The modern pin is made in the United States by the improved Atwood or Fowler machines. The process of pin manufacture by modern machines may be briefly described as follows: Coils of wire are placed upon a reel, whence the wire is drawn automatically by a pair of pincers between fixed studs that straighten it. A pin length is then seized by a pair of lateral jaws, from which a portion of the wire is left projecting, when a snaphead die advances and partially shapes the head. The blank is then released and pushed forward about one-twentieth of an inch, when the head is given another squeeze by the same die. By this repetition of the motion the head is completed and the blank is cut off the wire in the length desired. About one-eighth of an inch of wire is required to make a pin head. If the attempt were made to upset this with a head in one motion the wire would be more likely to double up than to thicken as desired.

The headed blanks then drop into a receptacle and arrange themselves in the line of a slot formed by two inclined and bevel-edged bars. The opening between the bars is just large enough to permit the shank of the pin to fall through, so that the pins are suspended in a row along the slot. When the blanks reach the lower end of the inclined bar in their suspended position they are seized between two parts of the machine and passed along, rotating as they move, in front of a cylindrical cutter, with sharp grooves on its surface, that points the pins. They are then thrown from the machine properly shaped, and if they are brass pins they are cleaned by being boiled in weak, sour beer. After they are cleaned they are coated with tin. This is done by placing alternate layers of pins and grain tin in a copper can and adding water, along with some bitartrate of potash. Heat applied to this produces a solution of tin which is deposited on the surface of the pins. The pins are then taken from this solution and brightened by being shaken in a revolving barrel of bran or sawdust. Lastly the operation of "papering" takes place. This process is performed now by an automatic papering machine something in the following manner: The pins to be stuck are placed in a hopper, in connection with which a steel plate is used, with longitudinal slits corresponding to the number of pins which form a row in the paper. The pins in the hopper are stirred up by a comb-like tool, the shanks drop through the slits in the steel plate, and the pins are suspended by their heads. Long narrow sheets of paper are presented by the operator to the action of the machine, by which two raised folds are crimped, and the row of pins collected in the slit steel plate is then, by being subjected to the same action, pressed through the two crimped folds. These operations are repeated until the requisite rows of pins are stuck in each paper.

LETTERS UPON PRACTICAL SUBJECTS.

A SUGGESTION TO THE APPRENTICE.

Editor MACHINERY:

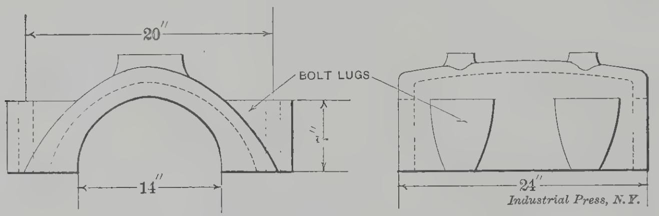
I wish to make a simple suggestion to the apprentice, which, if followed, will be sure to be appreciated in after years. It is an almost daily occurrence to hear old journeymen, during the noon hour, discussing their various tools, where they were purchased and what they paid for them. During one of these discussions one of the men was noticed to be the center of interest among his shop mates. He had traveled over the United States and the Old Country quite extensively and one of the men asked him some questions concerning some of the places which he had visited. He took from his tool chest a small note book which contained notes from the time that he started to learn his trade, each place in which he had worked, the name of the firm, location, superintendent, general foreman, etc. Also the date of entering and leaving the place, the wages received, tools purchased, where, when, and their cost. It was interesting to see the men gather around him and ask him to read some of the notes from this book.

Nothing would please me more than to have one of these books of my own but it is a little late in life to start now, so I will suggest to the young man starting out, that he keep a note book in his tool chest. MACHINIST.

HOW SHOULD THIS PATTERN BE MADE?

Editor MACHINERY:

Considerable discussion has taken place in our shop regarding the way in which the pattern shown in the sketch should be made. When I came to work in this shop my first job was to make a pattern of a cap for a 14-inch journal box. The principal dimensions of this cap are given in the drawing and it will be seen that while the inside is semicircular the outside is elliptical. After carefully studying the drawing I decided to saw around the elliptical outside, leaving as little hand work as possible, afterwards sawing out the bolt lugs and fitting them to the cap. One of the patternmakers thought that this was wrong, in fact was not in keeping with good patternmaking. He contends that the lugs should have been worked from the solid and claims that all patterns previously made in this shop have been made in this way. Small bearing caps are, of course, often made from the solid but it seems to me that for making so large a cap my method was the better. I wish that some of my fellow craftsmen would give their ideas on this subject.



The Pattern in Question.

PATTERNMAKER.

ONE OF KRUPP'S ECONOMIES.

Editor MACHINERY:

The recent death of Frederick Alfred Krupp reminds me of some of the things I have been told by a German mechanic who worked in the great Krupp works at Essen in his younger days. At that time, of course, Alfred Krupp was in authority.

One of the economies then practiced, was of such a novel character that I will describe it so far as I know. At that time muzzle-loading cannon were being made. They were bored from solid forgings, leaving the breech solid with the rest of the gun. Instead of boring them out in the ordinary way and converting all the metal removed into chips, a solid core was taken out and afterward converted into an axle or similar forging. The boring tool was similar to a long hollow mill, and cut an annular groove in the gun to the required depth of bore. This in itself seems like an incredible operation, but the cutting off of the core at the breech seems still more so. That it was accomplished without serious difficulty, I was assured by my German friend. How the tool was constructed he could not or would not tell.

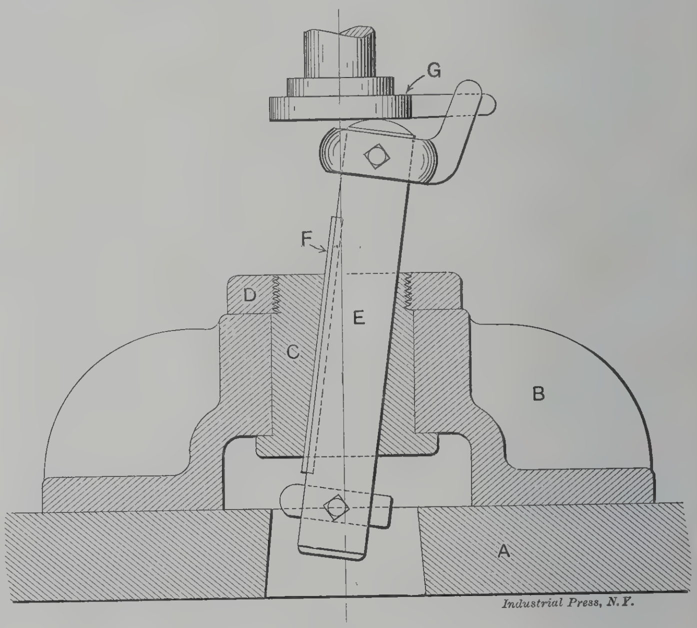
Now, it would scarcely be considered good practice to use the metal from the center of a forging or steel casting for any important purpose, but then conditions were different, and possibly Krupp knew how to insure the integrity of such product. At any rate it indicates something of the wonderful powers of the man chiefly responsible for the development of the greatest European industry. F. EMERSON.

Newark, N. J.

DRILLING TAPERED HOLES ON THE RADIAL DRILL.

Editor MACHINERY:

Some time ago a job of drilling came to my notice which I think will interest some of the readers of MACHINERY. In a large disk, which formed a part of a machine for making mineral briquettes, it was necessary to drill a series of tapering holes that increased in diameter as they receded from the face of the plate. In the figure, *A* represents the plate and the section shows the taper of the holes which were about four inches in diameter at the top. These holes were drilled under a radial drill by the aid of the jig shown in the cut. The cast iron frame *B* was firmly clamped to the face of the disk so that the center line of the jig coincided with the hole to be drilled. The bronze bushing *C* was held by the nut *D* so that it made a smooth running fit in the body of the casting. Through this bushing was drilled a hole making the same angle with the axis of the bushing that the sides of the hole were to make with its axis. The boring bar *E* was free to slide up and down in this hole, but the key *F* caused the bar and bushing to revolve together. On the end of the radial drill spindle was clamped the driving dog, *G*, the arm of which engaged an ordinary lathe dog clamped to the upper end of the boring bar. It will be apparent from the sketch that as the bar was fed downward the hole would be bored to the required taper.



Jig for Drilling Tapered Holes.

Providence, R. I. J. W. PRELL.

SCREW ARBOR FOR TURNING COLLARS.

Editor MACHINERY:

We have as a regular job a large number of threaded collars to be made on the turret lathe. Considerable trouble was experienced in turning these on a solid arbor, owing to the difficulty of removing them when finished. To overcome this trouble, the arbor shown on next page was designed combining, as it does, the stiffness of the solid arbor and the quick action of a split arbor. By the first operation the hole is drilled and threaded and one side of the collar is faced, then it is ready to be finished on this arbor. The shank of the arbor fits the turret and the front end is threaded to a good fit in the collar. Directly beyond this thread is a second threaded section, somewhat coarser than the first and left-handed. This second thread is sufficiently large to allow the hexagon nut to be passed over the first thread. This nut is turned on its front end to a diameter slightly below that of the collar, in order to give clearance in turning the top. As will be seen, the collar butts up against the nut with the left-hand thread and remains secure no matter how heavy the strain put upon it. When, however, the collar is finished, a slight turn of the nut will release all pressure and the collar may be unscrewed with the fingers. Before another collar is placed on the arbor the nut is returned to its first position by bringing the pin *F*, in the nut, against the screw *D*, in the arbor. This arrangement is necessary in order to use the automatic stops on the turret and insure getting all the collars of the same thickness.

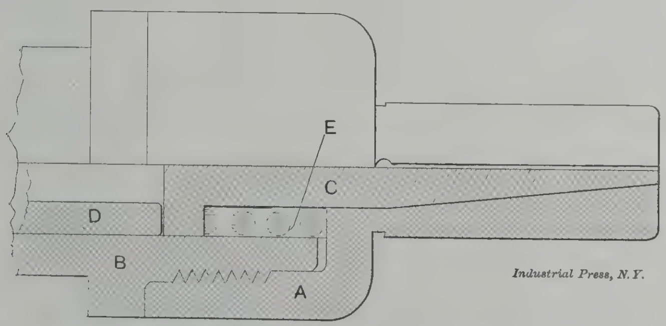
Arbor for Turning Collars.

Lawrence, Mass. CHARLES P. THIEL.

AN EXPANSION CHUCK FOR THE SCREW MACHINE.

Editor MACHINERY:

We were making hundreds of shells 2⅛ inches outside diameter and 1 15-16 inside, on the outside of which it was necessary to perform several operations and make them perfectly true with the hole. We were at first perplexed to find a way to hold these shells but finally solved our difficulty by the adoption of the spring chuck, here shown, which was simple and can be used on any screw machine that is provided with a wire feed. The body of the chuck, *A*, is made of machine steel and four longitudinal slots extend the full length of the portion on which the work is held. When the chuck was made these slots were stopped a little way short of the forward end, leaving a small tie which held the piece in shape while it was being hardened. This was afterward cut through with a circular lap. After these fins were cut away the taper portion and the part that fits the spindle were lapped out so as to be perfectly in line with each other. I then made an arbor to fit these holes and ground off the back of the chuck.



Industrial Press, N.Y.

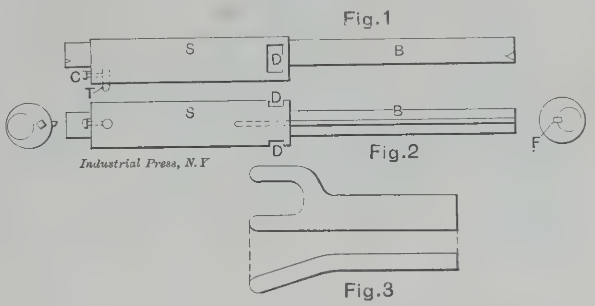
Expansion Screw Machine Chuck.

The plunger, *C*, is made of tool steel, hardened and ground, the length being governed by the wire feed so that the quill of the machine will act the same upon it as it does on ordinary collets. The taper on our chuck was 11 degrees on a side and it was afterward found that this taper was sufficient to cause the chuck to release itself, so that the spring was not needed. Should the taper be made less, however, the spring would be necessary. *B* is the spindle of the machine and *D* the quill which forces the plunger into the chuck. After the parts were assembled the chuck was put in the machine and by the use of a grinding attachment, held in the turret, the portion upon which the work fits was ground and then lapped to a good close fit in the holes in the work. As these holes were all made to plug gage the chuck worked very nicely. In each of the four slots was fitted a piece of fiber which kept out all chips and dirt. J. M. S.

BORING BARS.

Editor MACHINERY:

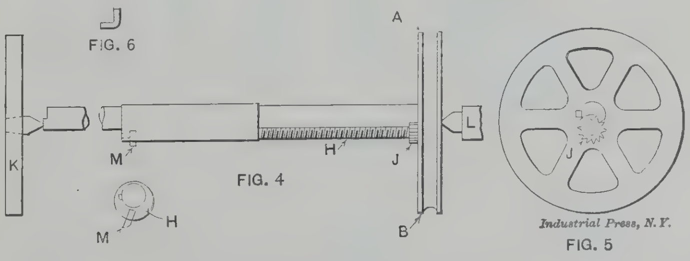
Fig. 1 shows the plan and Fig. 2 the side view of a boring bar that I have used with success for both straight and tapered work. It consists of a bar, *B*, whose centers are offset enough to bring the eccentric sleeve, *S*, central with the lathe centers. The object in making this sleeve eccentric is to make more room for fastening the cutting tool. The bar is splined for about three-fifths of its length and a feather, *F*, fitting tight in the sleeve and sliding in the spline, keeps the sleeve from turning on the bar. The cutting tool, *T*, is held in place by means of the set screw, *C*. Fig. 3 shows the form of driver that is used. The jaws are placed in the slots, *DD*, Fig. 2, and the straight end is fastened in the tool post, like an ordinary lathe tool. The carriage feed is used to feed the sleeve along the bar while the tailstock is set over to get tapers the same as in turning work held on the centers.



Industrial Press, N.Y.

A Convenient Form of Boring Bar.

I also submit a sketch of a rig for re-boring lathe headstock boxes which "Connecticut" asks for in the September number of MACHINERY; this is shown in Figs. 4, 5 and 6. The headstock is left in its normal position on the lathe bed and the plate, *K*, which is supplied with a center, is clamped to the back end of the headstock with its center true with the lathe spindle, thus forming a bearing for one end of the bar, while the other end runs on the tailstock center, *L*. The sheave is securely keyed to the bar and is driven, by means of a rope drive, from any convenient line of shafting. If desired a pulley and belt may be substituted for the sheave and rope. The bar is provided with an eccentric sleeve which carries the cutting tool and is prevented from turning on the bar by a feather the same as shown in Fig. 2. The sleeve is threaded to fit the feed screw for about one and one-half inches on the end that the screw enters, and a clearance hole is drilled the rest of the way through. Fig. 5, which is a section on the line, *A B*, shows how the toothed wheel, *J*, is let into the bar. The toothed wheel is rigid on the feed screw and is turned slightly at every revolution by coming in contact with a bar held in the toolpost for that purpose. The headstock end of the bar is made as shown, for boxes that are tapped out on the back end to receive an adjusting screw, the reduced size entering the tapped hole. By using a cutting tool as shown in Fig. 6, which projects a little beyond the end of the sleeve such a box can be bored and also faced.



Industrial Press, N.Y.

Bar for Boring Lathe Boxes.

Watervliet, N. Y. M. H. BALL.

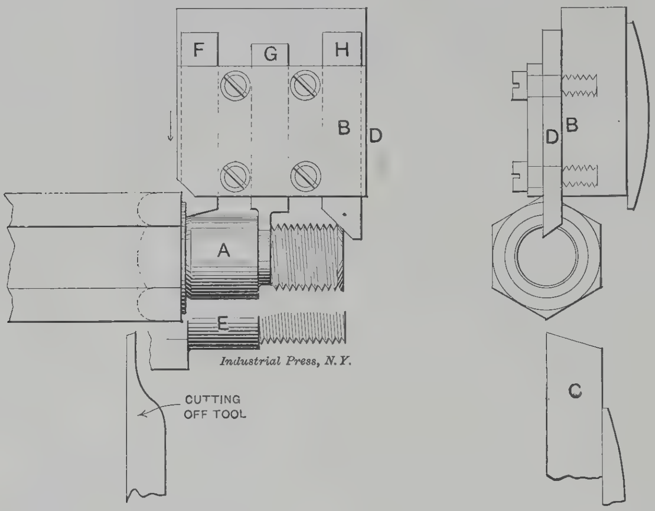
SCREW MACHINE TOOLS FOR MAKING BOLTS.

Editor MACHINERY:

I had several thousands of the bolts shown at *A* to make from hexagon stock on the screw machine. Three turning tools were used and it was found very difficult to keep them set so as to always make the corners square and of the correct length. So I adopted the method shown in the sketch.

This method, which is described here, worked very successfully. The bolts were first turned, nearly to finished size, with the regular turning tools, as shown at *E*. On the back toolpost of the cut-off slide was mounted the tool holder, *B*, in which are set the tools *F*, *G* and *H*. When the bolt had been rough turned, as previously described, these tools were then run up to a stop and the bolt finished as at *A*. As these tools have but little stock to remove they seldom require grinding and therefore save a great deal of time and insure accurate work. After the body of the bolt has been finished as described it is cut from the bar with the cutting-off tool shown at *C*, which while cutting chamfers the corners, at the same time, thus completing the bolt. JAMES P. HAYES.

Meriden, Conn.



Screw Machine Tools for Bolt Making.

A HANDY JIG TO HAVE AROUND THE SHOP.

Editor MACHINERY:

The photograph shows a tool that we made two or three years ago, which does not seem to be generally known or used. It has proved of so much convenience to us that we think a description may be appreciated by others who have similar work to do. As will be seen, it consists of an angle plate which is capable of holding studs of different diameters horizontally or at an angle. It is used for drilling setscrew and oil holes in pulleys, gears and other similar work. The studs, five of which are shown in the photographs, range in size from ¼-inch to 2 inches in diameter. The smaller sizes, up to ⅝-inch, are driven into the backs of the larger ones, thus saving the expense of making complete studs for these sizes.

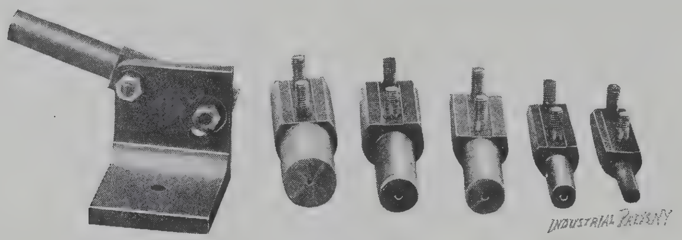


Fig. 1. Jig for Drilling Set Screw and Oil Holes.

As with nearly all new tools, if a second one were to be made it would be different in some respects from the original. The objection to the present tool is that the movement of the studs is somewhat limited, so if another were being built it should be as shown in Fig. 2, in which it will be seen that the studs may be set horizontally, vertically or at any angle between. Fig. 3 is a dimensioned drawing of one of the studs, which will give a general idea of their size, although, of course, the dimensions are varied for the different sizes of studs. They are made from stock somewhat larger than the diameter of the stud required and are turned with as much eccentricity as possible in order to obtain a sufficiently large flat surface for clamping to the angle plate. For work that requires to be held rigidly the studs could be made to expand on the same principle that is employed for expanding arbors or reamers. CORNEIL RIDDERHOF.

Grand Rapids, Mich.

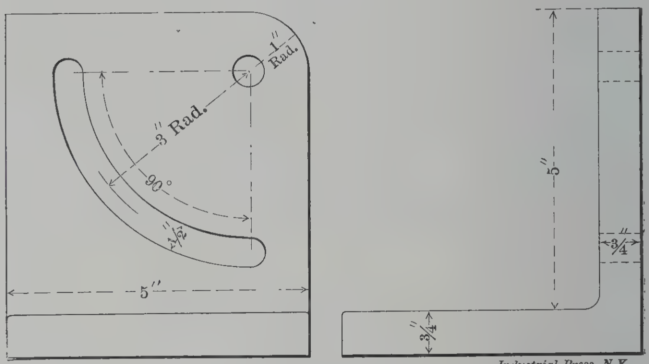

Fig. 2. Base of the Drilling Jig.

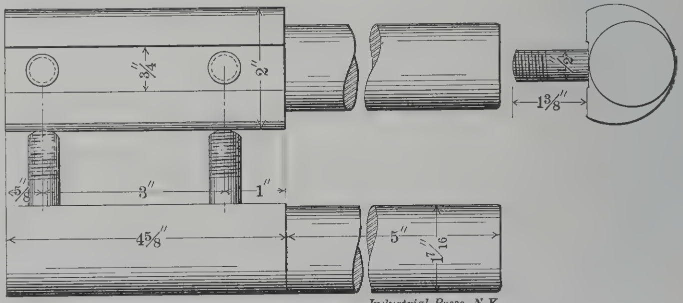

Fig. 3. One of the Drilling Studs.

REGARDING LARGE OIL TANKS.

Editor MACHINERY:

In your publication Vol. 9, No. 1 for September last, under "Notes and Comments" (Engineering Edition) we see it stated that what is said to be the largest steel tank in the world has been completed at Boston for the Atlantic Refining Co., and measures 36 feet high, with a diameter of 90 feet. We, in this country, are specialists in the oil tank line, and think that you will find the following particulars of current contracts which we are executing, of sufficient interest to your readers to merit notice in an early issue of your journal.

Catalogue page 79 enclosed, shows a view of tanks, 58 feet 6 inches diameter, by 30 feet high, built and erected for the Burma Oil Co., Ltd., also tanks, 64 feet diameter, by 34 feet 10 inches high, built and erected for the Standard Oil Co., of New York. These were installed at Budge Budge, the great oil depot for this side of India, and are typical of similar contracts carried out by us in other parts of the country.

Our most important contract at present in progress of execution is for the Standard Oil Co., of New York, and consists of two steel tanks each 90 feet diameter, by 38 feet 6 inches high to top of roof. The capacity of each tank is considerably over 1,250,000 gallons. The bottom, which is double-riveted, weighs 46 tons and is composed of 67 plates ⅜-inch thick, maximum sizes rolled being used. In this part of the work there are 15,200 rivets. The maximum size of plates has also been used for side of tanks, there being 13 plates in circumference; the bottom strake is 9-16-inch thick, each plate weighing 3,360 pounds. There are 240 ⅛-inch plates and 12,500 rivets in each roof, the net weight of rivets in a tank being 15,680 pounds.

For the above and for other oil companies we have, in the aggregate, close on 100 smaller tanks actually in hand at present, for erection all over India. Each tank is built up from the imported raw material. Our works, we may say, have an area of 35 acres—exclusive of our drydocks and saw mills.

Howrah, India. BURN & Co.

[The item referred to, is in error as regards capacity and as being the largest, even in this country. The maximum capacity of a tank 90 feet in diameter and 36 feet high, is about 34,260 barrels of 50 U. S. gallons, capacity. Mr. H. C. Folger, Jr., of the Standard Oil Co., informs us that a number of oil tanks have been constructed in the United States to hold 50,000 barrels and some even larger. The very large tanks are in the Texas oil fields.—EDITOR.]

METHOD OF MACHINING SLIDE VALVES.

Editor MACHINERY:

The economy of milling over most planing operations is pretty generally understood, and we are very much in favor of the duplex face or butt mill type of machine. The machining of an ordinary slide valve is one of the operations for which we have lately used the miller. The work was for many years done by planing, and as large numbers were made, suitable fixtures were used so that several could be machined at once. They were also done at piece work, so we may infer that the planing was accomplished in a reasonable time, one and one-half hours being the average.

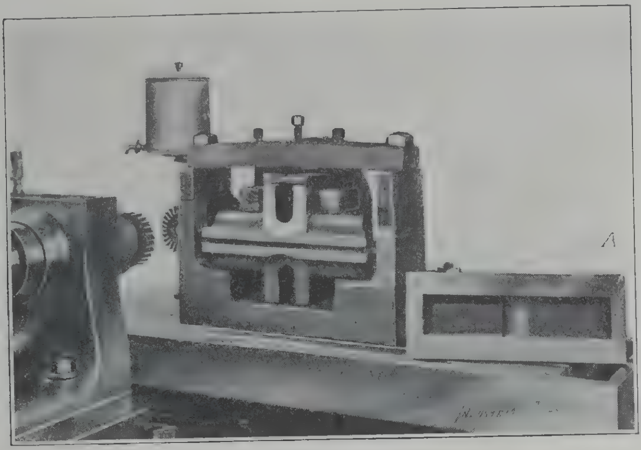

Fig. 1. Machining Slide Valves, First Operation.

The first operation, illustrated in Fig. 1, is to mill the edges of the valves at *A*, it being essential that the edges shall be parallel with the exhaust port. To accomplish this the valves are placed, one on the top and one on the bottom, of the steel plate on which are bosses the same length and width as the exhaust ports into which they fit. This plate, bearing the two valves, is then fitted into grooves in the milling fixture so that the valves are held with the exhaust port parallel with the travel of the machine. In this way the first operation is performed on both sides of two valves simultaneously.

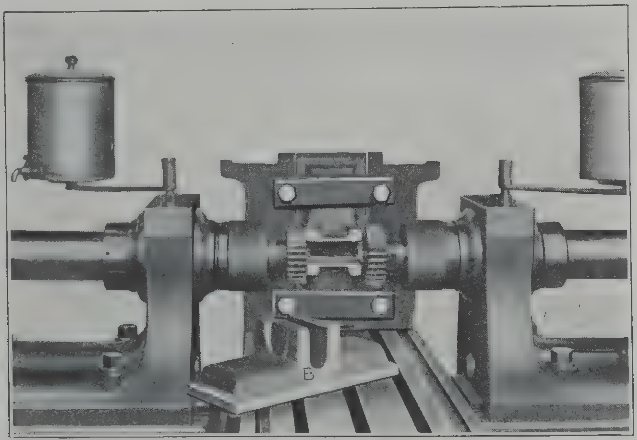

Fig. 2. Machining Slide Valves, Second Operation.

The second operation is to mill the valve stem lug *B*, Fig. 2. The fixture in which this operation is performed is simply an angle plate with a groove planed in its face the same width as the valve. In this plate the valve is held by a pair of latch clamps which have a spring under them, holding them up in position so that but a single turn of the clamping nut is required to clamp or release the work.

The next operation, which is to mill the face, is performed in the fixture shown in Fig. 3. This fixture is an I-shaped chuck having a row of setscrews on top, along its two edges, by which the work is securely held. This is the most particular part of the job and the cutters need to be in best condition and the feed must not be forced too much, but in this operation eight minutes only is consumed in finishing the face of the two valves.

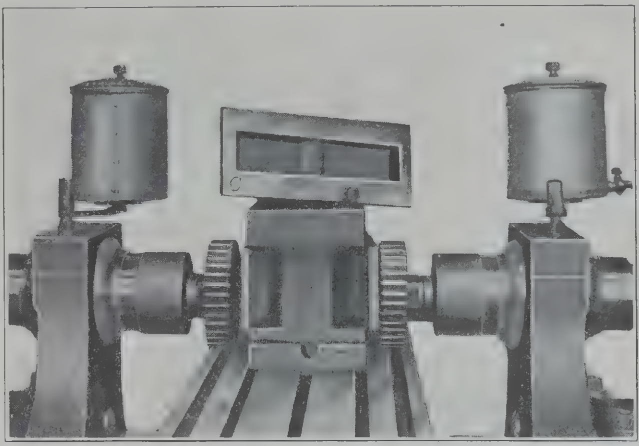

Fig. 3. Machining Slide Valves, Third Operation.

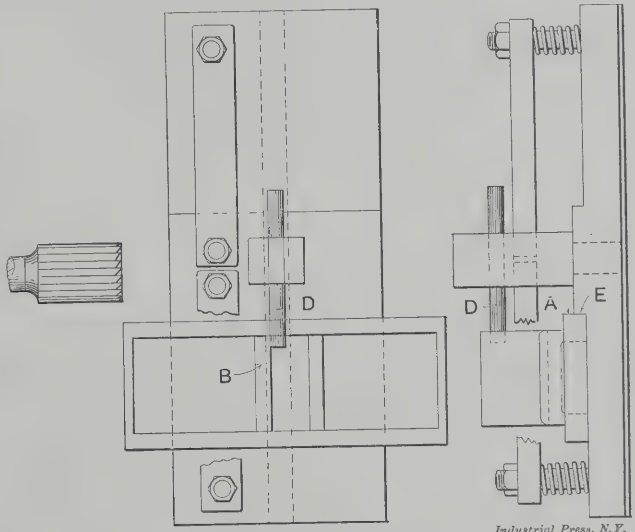
The fourth operation, which completes the work, is to mill each end at a given distance from the center. This is performed with an end mill, on an ordinary plain miller, the valve being held in the fixture shown in Fig. 4. One valve is shown in position, the valve stem lug *B* being held against the stop pin *D*, while the edge *A* is held squarely against the planed shoulder *E*. The second valve is held in the other half of the fixture in the same manner, so that while one piece is being milled another piece is being jigged and the machine need not be stopped until the entire lot is completed.



Industrial Press, N.Y.

Fig. 4. Machining Slide Valves, Fourth Operation.

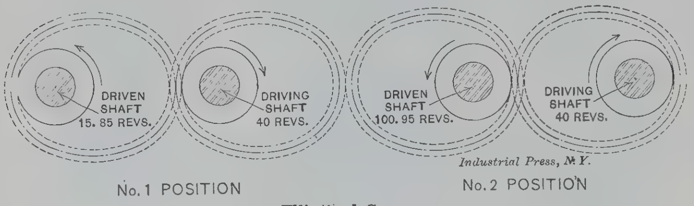
The operators on the machines were apprentices in their first year, at $1.00 per day, and they completed the lot of valves in twenty-nine minutes each. Of course the writer regulated the speeds and feeds of the machine, as well as the speed of the boy. A. A. AVERY.

Warren, Pa.

ELLIPTICAL GEARING.

Editor MACHINERY:

The builders of presses and other machines for the press working of metals do not seem to place much value on what is called the element of time in the construction of their machines. Forming tools, punches and other tools that are used in changing the form of metals, have in most cases the chopping movement, going down to the work as fast as they go up, advancing at the same speed as they recede. A slow movement of the punch or forming tool is valuable in several ways. It prevents sudden strains from injuring the press, favors the punches and dies, allows them to be run longer without having to be ground or replaced, and in a great many cases permits the use of a less expensive metal for the tools. During an experience of many years in using and building presses, the writer has become strongly attached to the use of the elliptical gear. These, while giving the powerful alternating leverage, the slow advance and the quick return, are capable, when properly designed, of furnishing as much or as little of the element of time as may be desired.



Elliptical Gears.

The sketches show a pair of elliptical gears in the two effective positions and illustrate the slowness with which the tool is forced through the work and rapidity with which it returns to position for the next stroke. These gears have a leverage of about 2½ to 1. The large end describes a circle, the diameter of which is equal to that of a 53 tooth gear, while the small end moves in a circle whose diameter is that of a 21 tooth pinion. No. 1 position shows the relation of the gears when the punch or tool is being driven down at a rate of 15.85 revolutions per minute. No. 2 position, when the tool is being withdrawn from the work at the rate of 100.95 revolutions per minute.
E. M. Lehman.

Chicago, Ill.

A HOME-MADE T-SQUARE ATTACHMENT.

Editor Machinery:

In every draftsman's daily work he has continually to use his triangle at angles other than those found on the regular 30-60 and 45 degree triangles. For this purpose I have made the attachment shown in Fig. 1, which has proved very useful in a great number of cases. The base *A* is made of a piece of wood about one-quarter of an inch thick and ten inches long. In the center of this base is firmly fastened a thin strip of steel carrying at its top the thumb tack *B*, which serves as a pivot for the triangle *C*. About this pivot the triangle is swung into any desired position, after which it is held in place by means of the retaining strip *D*. This strip is pivoted to the triangle at *E* and is held down to the base of the attachment by a thumb tack passed through one of the holes *F*, *F*, *F*. In this way the triangle may be held firmly in any position desired, and it may be easily set at any required angle by the use of a protractor. A few of the useful applications of this attachment are shown in Fig. 2 and many others will suggest themselves to the draftsman as he becomes familiar with the use of the instrument.

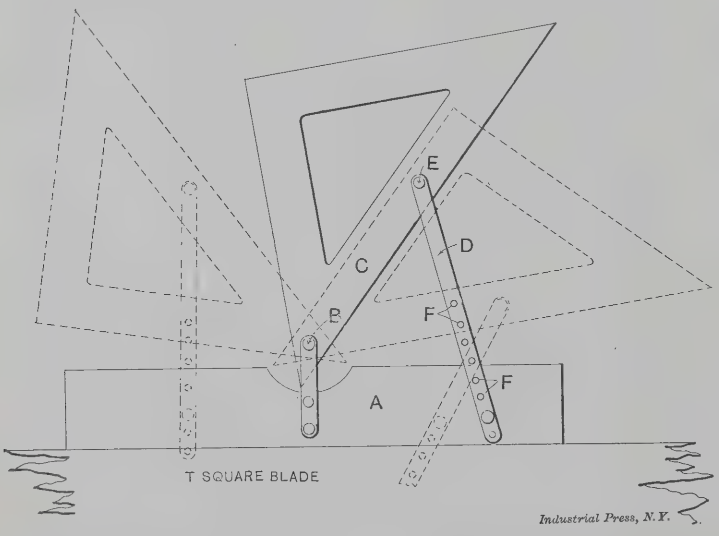


Fig. 1. A Handy Attachment for the T-square.

In constructing this arrangement any 45 or 30-60 triangle can be used and for the strips I employed pieces of an old hack saw, but strips of brass or other metal will, of course, answer the purpose equally well.

RIGHT AND WRONG WAYS.

Editor Machinery:

While working in different shops in this country, in England and France, various examples of the right and the wrong way to do a job have come to my notice and I think that some of these cases may be of interest and possibly benefit to the readers of Machinery.

An order came into the shop one day for a lot of screws, about three feet long by two and a half inches in diameter, having six threads (or a sextuple thread). The turners were on piece work and started cutting them in the usual way, by dividing the change wheel into six equal parts and cutting thread by thread. One, however, more enterprising than the rest, made a gage which was as long as the lead, and had six equally divided spaces in it, which were equal to the spaces between the threads. Next he got six tools forged and ground to the right dimensions and fixed these on the rest so that each one would just go into a space in the gage and were all in line; then putting in the change wheels, he started the lathe and cut *the six threads all at once.*

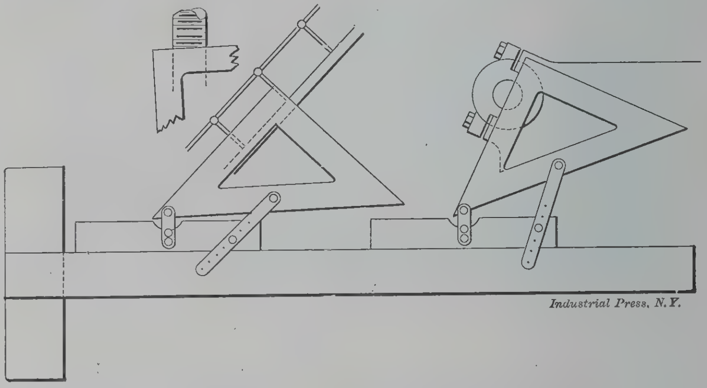

Fig. 2. Some of the Uses for the T-square Attachment.

I remember a lot of bolts being made about 12 inches long by two inches diameter, threaded at one end, with a hexagon head at the other. These were faced up and the centers thereby turned off. It was then found best to turn them down a little in the middle as they fitted too tightly in the holes. It looked as though all those bolts would have to be centered again before the turning could be done, so they were taken to the lathe man and he was told to go ahead—and go ahead he did. He found a short box spanner which would fit the bolt head and this he put in the chuck jaws, setting it to run true. Next he got a steady rest with two semicircular wooden blocks which just fitted the threaded part; these were lined with tin to prevent the threads from cutting the wood out. Having everything ready he picked up a bolt, put the head in the box spanner, and the screwed end in the steady rest, started the lathe and put the cut on at once. The tool traveling toward the headstock pressed the bolt into the box spanner, and so prevented it from working out. One cut across was enough to take off the required quantity of metal and he finished those bolts in such short time that the foreman would hardly believe his eyes when he saw them turned and yet uncentered.

He was a bit different from the man who, when given some left-hand screws to cut, set to work and rigged up the lathe to run backwards, turned the tool upside down, and proceeded to cut what he thought would be a left-handed screw. He must have been considerably astonished at the result.

A few years ago a hydraulic press had to be moved—it was a large one of about 800 tons pressure. The ram was in the bottom casting, and the top was held up by four large columns. The man who had charge of the job went to a lot of trouble to get it apart; he got derricks, ropes, blocks, etc., had a regular gang of laborers and, in time, with a lot of shouting and bossing he got it to pieces. It was then erected in the new place. Lately it was taken down to make room for a more powerful machine and a young mechanic was put in charge. He didn't cut off the water pressure first of all, then get derricks, etc. No! he took the four nuts off the top of the press, put a lot of packing on the press table, opened the valve and as the ram went up it lifted the top casting clear of the columns. This top was then barred through 90 degrees and the ram lowered, which let it down between the columns. The ram next brought it down to the level of the floor and it was rolled away to the crane. Next a crosspiece was fixed to the ram table and to the two opposite columns, the lower nuts were taken off, the ram sent up, and it pulled out the two columns which were allowed to fall to the ground, being guided by ropes. In the same way the other two were removed. The ram was next lifted up as far as safe and secured from toppling over by four ropes, after which it was pumped completely out of the hole, the ropes slowly slackened allowing it to fall to the ground. The water pipes were now disconnected and the bottom casting lifted by hydraulic jacks. All this took the mighty force of the mechanic and his laborer; no derricks, blocks or special tackle were used; only a few ropes, and it was done in about one-sixth of the time it took the other man, who had worked hard but did not think.

That reminds me of a man I knew who had to repair a double cylinder engine, and after taking it to pieces and doing the necessary repairs carefully put it together, gathered up his tools, just started the engine to make sure it was all right, and I think he was the most surprised man in that State when he saw the engine run—well, but the wrong way. After using up a lot of brain energy it dawned on him that the crankshaft and cranks were turned end for end. He was in a nasty temper for the rest of the day.

In placing a steam valve, remember there is a right and a wrong way to connect it up. I have known many cases where they have been placed upside down. The valve should always be placed so as to close against the in-flowing steam, that will cut off the steam from the side of the valve where the handwheel and stuffing box is located, so when the packing gets worn it is only necessary to close the valve and repack. If the valve is put in the other way it is impossible to pack it without shutting off the steam at another valve, which is generally inconvenient.

There was once a steam pump, pumping water to a high tank with the inlet pipe at the bottom of the tank. The pump did not work well, and the boss, after long consideration, decided that there was too much *weight* of water to pump against. So he had the inlet pipe removed from the bottom, another length joined on, and turned over the top of the tank. Thus the water would be pumped over the top and run into it. He could never understand why the pump instead of being better was worse, if anything, after *easing*(?) the load so much. It was a pity he never studied elementary hydraulics.

I have noticed lately there has been a lot of discussion about making things theoretically and not practically correct. I have seen many cases of this; one was where a draftsman, after using his slide rule and table of "Strengths of Materials," designed a cast iron hydraulic cylinder for low water pressure to be cast with the wall three-sixteenths of an inch thick by twenty inches in diameter. It was quite strong enough theoretically and did not (or would not, for it was cast five-eighths) use much metal. But for all that, he fell a good deal in the chief's estimation.

He was nearly as bad as the draftsman who was preparing drawings for some machinery. A brick wall which was to be two and a half bricks thick, came between some of the parts. A brick is nine inches long and nine inches multiplied by two and a half equals twenty-two and a half inches. This he put down as the thickness of the wall. *He forgot the mortar*, and when the wall was built it was twenty-four inches thick, which made such a difference to the machinery that a lot of alterations were necessary.

Mistakes like these are, in my opinion, due to the draftsman not having enough practical experience. The great majority only just rush through the shops doing patternmaking, machining, and fitting (no molding as a rule) in about a year, then they think they have had a good, varied, practical experience.

GEO. P. PEARCE.

Williamsport, Pa.

A FRICTION CLUTCH PULLEY AND THE JIG FOR TURNING THE FRICTION SHOES.

Editor MACHINERY:

The photograph, Fig. 1, shows a special chuck that is used for turning clutch shoes and Fig. 2 shows the friction pulley in which these shoes are used. When the clutch was designed these shoes were fortunately made to take up a little less than 90 degrees, making it possible to place four in a circle. I say "fortunately" because it was not done with that purpose in view, as we expected to build a revolving fixture for the milling machine and mill them as we are doing with the shoes for a smaller size of these clutches. But as there was already more milling than our capacity conveniently allowed we were compelled to resort to the lathe and, although it is not possible to tell whether or not the miller would have done the work quicker, it is sure that we are well satisfied with the amount of work turned out with this chuck. It is fitted to the faceplate with eight dowels, and four capscrews tapped into it from the back hold it fast.

Here let me say a word about dowelling special chucks to a faceplate. Some do not like the practice because it impairs the "looks" of the faceplate. This is true, in one sense, but it is also true that "handsome is that handsome does" and the time saved by dowelling as many as possible of the special chucks to the faceplate would pay for another if one were bound to have one not perforated with dowel holes. When a number of chucks have been dowelled to a faceplate it is often difficult to find the right holes, even if they have been numbered. This is usually caused by numbering too many of the holes and using the same number more than once. It is neither necessary nor desirable to number more than two of the dowels and corresponding holes for each fixture, as when these are found the rest of them will, of course, drop in. When the first fixture is dowelled to a faceplate two of its dowels should be marked 0 and 1, two of the next one 2 and 3, etc.; there will then be no trouble in finding the right holes and the faceplate will look at its best when a large number of holes indicate that it has been made "good and useful." The foregoing relates only to that class of chuck that cannot very well be made to screw onto the spindle nose in place of the faceplate.

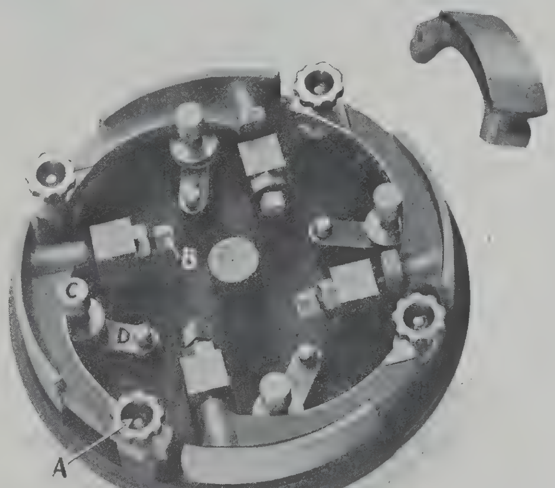

Fig. 1. Jig for Turning Clutch Pulley Shoe.

To return to the chuck in question, it is principally different from many others in that neither wrenches nor measuring tools are needed in its use. As the four quarters of the chuck are identical, but one needs be considered in describing it. The fulcrum end of the shoe, having been previously milled with straddle mills and drilled, is placed on the stud in the chuck and the nut, *A*, tightened by hand while the other end of the shoe is left some distance away from screw *B;* then, pressing the shoe down onto this screw the nut *A* is "helped along" tightening it firmly. Screw *B* was adjusted when the chuck was made and is not again disturbed. Collarscrew *C* is now unscrewed till its collar touches the back side of the rib on the shoe and levernut *D* is tightened to lock it. This supports the shoe against the side pressure of the tool, which is fed toward the faceplate. The clutchshoe is now firmly held and the tool being adjusted to a setpiece on the chuck, a roughing and then a finishing cut are taken. The force of the cut presses the piece firmly down on screw *B* and there is no tendency to tear away. Although these shoes are to be faced with leather it is essential that the outer surface conform as nearly as possible to the clutch rim on the pulley. Should it fail to fit the rim the leather would engage it at one end only and the pulley would be crowded to one side on its sleeve and, less surface being in contact, the clutch would not drive so well.

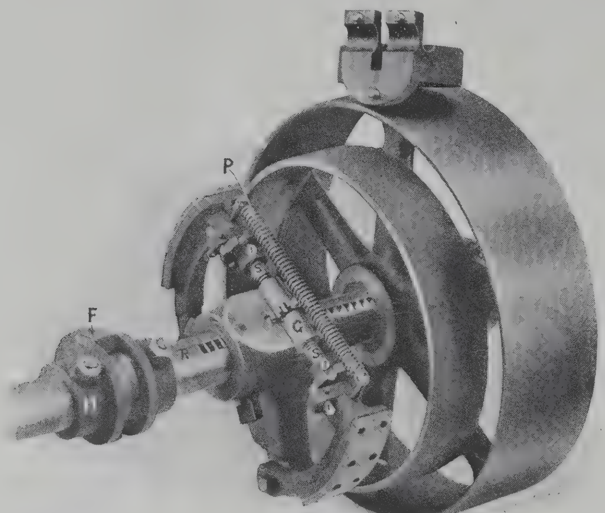

Fig. 2. Clutch Pulley.

The construction and action of the clutch in which these shoes are used is so different from any other that a brief description of it may be of interest. In the photograph, Fig. 2, the pulley has been slipped back on the shaft and the cap removed from over the gear to expose the working parts to view. A rectangular groove is milled in the shaft and therein slides a toothed rack *R* meshing with gear *G*. The rack is attached to a grooved sliding hub *H*, which is moved laterally in the usual manner by fork *F* on the shifter rod. Gear *G* has a long hub, one end of which is threaded right and the other left hand. The screws *SS* are held from turning by the lockpins *II*, each engaged in a notch of the disks *DD*, which are fast on the screws. When the gear rotates the screws the shoes will be either forced outward or allowed to be drawn inward by the spring *P*, according to the direction of rotation. When the leather wears away so sliding hub *H* will reach the hub of the clutch before the shoes are expanded sufficiently, the cotterpins passing through lockpins *II* are withdrawn, and the expanding screws *SS* may be turned to another notch and again locked. This adjustment is readily made without the aid of any tools. It, however, needs be made but very seldom as the latter is very durable when in contact with metal and the old story of a rawhide lace-leather hanging over a line-shaft and wearing it in two is not entirely without foundation.

When these clutches were first designed there were some doubts concerning the enduring powers of leather, so, as I preferred leather to wood or fiber, a preliminary test seemed advisable. A countershaft for a lathe being equipped with a pair of clutchpulleys its shifter rod was connected through a bellcrank to an improvised crankpin on the faceplate of another lathe and when it had been reversed considerably over one hundred thousand times under a heavy load the leather was found to be reduced one-hundredth inch in thickness. This was some eighteen months ago; the countershaft has been in daily use since and there appears to be several years of service left in the leathers. The principal beauty of this clutch is the very small effort required to operate it, as the clutchshoes are actually *screwed* into contact with the clutch rim so that with the tip of the little finger at the shifter lever the clutch may be engaged tight enough to slip the belts.

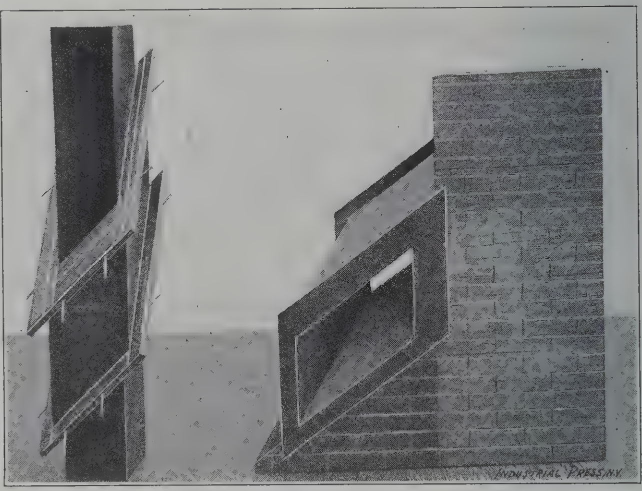
Although designed primarily for use on friction countershafts for machine tools its good points have introduced it in other establishments and even in woodworking shops it is preferred to the common tight and loose pulleys. Some of them used at woodworking shops are running at 800 to 1,100 turns per minute, a speed reached successfully by very few friction clutches. CORNEIL RIDDERHOF.

PATTERN FOR AN OBLIQUE CHUTE.

Editor MACHINERY:

Pattern makers occasionally meet with problems that are exceedingly perplexing, especially to those who have neglected the study of geometry; moreover such problems are often by no means easy to solve even by those fairly informed in that science. Fig. 1 shows the pattern which is the subject of one of those problems. A cast iron chute rectangular in section is required to pass in an oblique direction through a brick wall 17½ inches thick. It passes through at an angle of 35 degrees with the perpendicular and 45 degrees with the face of the wall. As the illustration shows, the chute emerges from the wall with its sides parallel with the vertical joints of the brick work, but its top and bottom are oblique to the horizontal joints of the wall. This obliquity results from the combination of angles and the rectangular section of the chute. There are several ways of determining the length of the pattern and the angle of its ends in such a case, and two of these ways will be described.

In order to obtain the proper dimensions and angles of the pattern it is advisable to lay down full size the necessary views, as illustrated in Fig. 2. First draw the plan *A*, making *a* equal to the thickness of the wall and *b* equal to the base of the required triangle horizontally. In this case the horizontal angle being 45 degrees makes both sides of the triangle 17½ inches. Draw the line *d* parallel with the hypotenuse *c* and make the perpendicular distance between the two lines equal to the external width of the chute, 14 inches, and extend *d* to *e*. Draw the side elevation *B* equal to the thickness of the wall, making the line *f* 35 degrees with the perpendicular. Project a line from *g* toward *h* and extend it indefinitely. Project the point *i* toward *k* and extend it indefinitely. Project the point *l* and intersect *i k* at *k;* connect *k m*, this line will give the angle of the chute through the wall when viewed in front elevation. Project the point *e*, and intersect the line *g h* at *h*. Project the point *n* toward *o* and extend it indefinitely. From the point *h* draw the line *h p* parallel with *m k* intersecting *n o* at *o*, connect *k o* and the length of the line so formed will equal the length of the angular side on the top and bottom of the chute at its ends. So far while we have arrived at the width of the chute, also the angle of the ends on the top and bottom, there is no line that gives the actual length of the chute, because to obtain that it is necessary to have a view from a point perpendicular to the side; the side being obliquely viewed in



INDUSTRIAL PRESS, N.Y.

Fig. 1. Pattern for an Oblique Chute.

that which has been drawn. The actual length of the chute through the wall is the diagonal line, or hypotenuse of the angle whose sides are the line *f* and the length of the thickness of the wall *q*. Draw *q* perpendicular to the end of *f* making the length equal to the thickness of the wall, connect the extremities of *f* and *q* and the hypotenuse *r* will equal the actual length through the wall, and between the flanges of the chute; this line also furnishes the basis for obtaining the angle of the ends of the chute on its sides. With the length of the line *r* intersect *g h* at *s* and *i k* at *t*, and draw *t u* parallel with *n o*. Draw *v* parallel with *r* making the perpendicular distance between the two lines equal to the external thickness or depth of the chute. Let *v* intersect *t u* at *u*, the length *t u* will then equal the depth of the end of the chute where it emerges from the wall, and the angle so formed will be the angle of the ends on the side of the chute. Project and make *k w* equal to *t u;* from *w* draw *x* parallel with *o k* intersecting *n o* at *y*, and the rhomboid so formed by *k o* and *w y* will be the figure of the end of the chute, minus the flange, when viewed perpendicular to the end, as it emerges from the wall. Having determined the most important part of the problem, and proper length and angles for the pattern, its construction is not difficult. The pattern complete except the core box, which is a plain rectangular one, is shown at the left in Fig. 1.

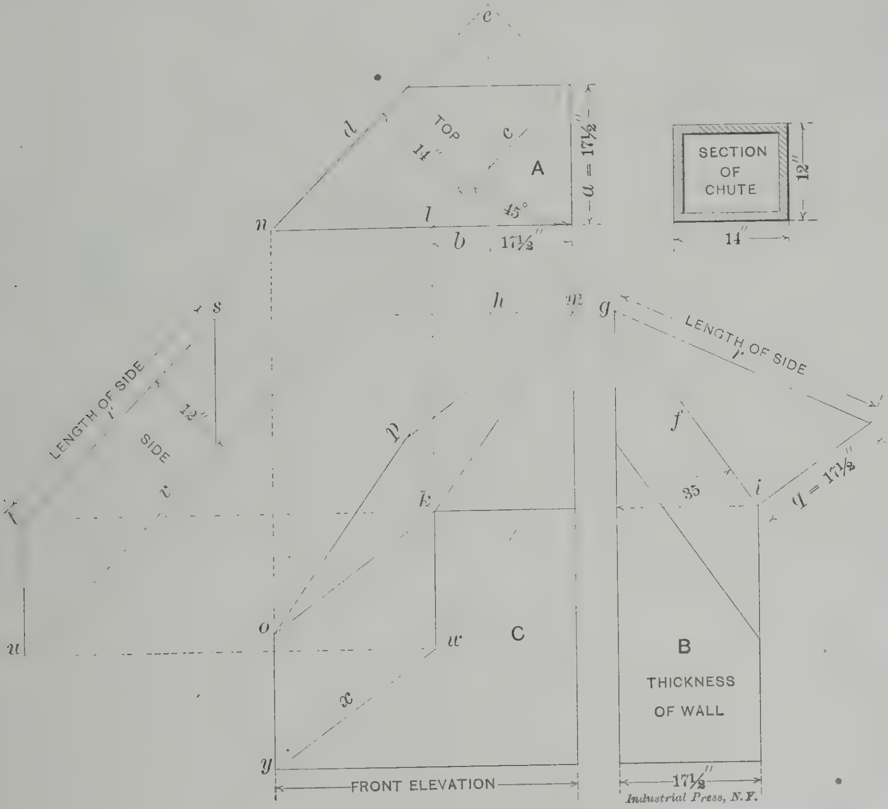


Fig. 2. Development of Pattern for Oblique Chute.

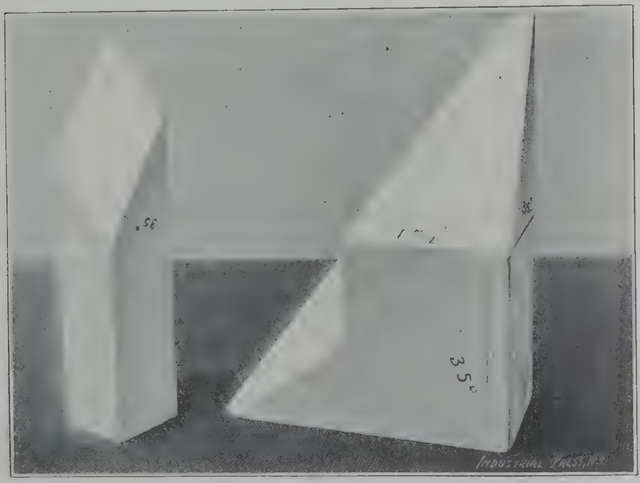

Fig. 3. Wooden Model for Oblique Chute Pattern.

To begin the pattern a box or core print whose cross section equals that of the interior of the chute, is built up of one inch material; the length of the print is sufficient to allow bearings for the core beyond the flanges at each end. Upon the print the length and angles of the pattern are lined off and the thickness for the metal planted on in conformity with the lines. Where the thickness forms undercuts, as at one end of the sides, the undercut pieces are made to be drawn separately from the body of the pattern; they are secured in place by draw pins. After the thickness is completed the flanges at the end are fitted to the pattern and secured by draw pins; they remain in the sand and are drawn after the body of the pattern has been lifted from the sand.

Another way which the writer has often used with great advantage and unvarying success in working out difficult problems of this character, is to make a wood model to a convenient scale and develop the object from it. He would especially recommend this method where a number of different angles are involved, because it enables one to comprehend the problem more readily by having the chief features of the object under view, thereby impressing them more deeply on the mind and making mistakes less liable.

Fig. 3 shows a model of all that is necessary to solve the present problem, and in making the pattern it would save tenfold time spent in making the model. It is not necessary that such models should be very elaborate, but accuracy is absolutely essential. It so happens in this case that the angles of the ends of the chute agree with those with which it passes through the wall, 35 degrees and 45 degrees, or so near to them that they answer practical purposes; but this result does not follow as a rule for any combination of angles.

A problem of the foregoing character was once submitted to the writer after its solution had baffled the efforts of several excellent draftsmen for a number of days, and he solved it with the aid of a model, which required less than two hours to make.

Washington, D. C. I. McKim Chase.

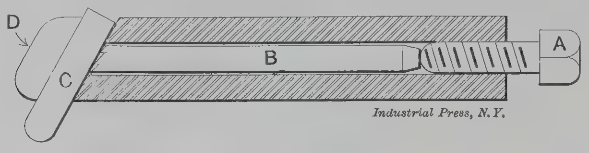
* * *

British engineers quite properly take pride in the durability of their machinery. They intimate that the American habit of scrapping machinery long before it is worn out, is a trick to deceive, and that such machinery is scrapped because it actually had to be, to prevent deterioration of the product. This is, of course, untrue, but it is true in many cases that American design is not as durable as it should be. This fault, however, is being generally corrected without going to the British extreme. A great ado has recently been made in England over the record of a Stephenson locomotive that was put in commission in 1822, and, at last reports, was still running. Such durability is of an extremely expensive kind, as we have time and time again demonstrated in the operation of American railroads—railroads that have the cheapest freight rates in the world. The old engine had been rebuilt so that little if any of the original remains. As to durability, which appeals to the practical American engineer, any mentioned by Mr. J. Davidson in a paper read before the Liverpool Engineering Society, is a good type. He referred to a Willans engine that had run five years in which time its crankshaft had made 535,000,000 revolutions. The crosshead pin was found to be worn in one part only .002 inch, and the connecting rod brasses had worn only .02 in the five years of service. Such a condition indicates good design, first-class fitting and excellent care on the part of the operating engineer.

CONTRIBUTED NOTES AND SHOP KINKS.

BORING TOOL HOLDER.

E. M. Burgess, Springfield, Ohio, sends a sketch of a holder for inserted cutters to be used in boring in such close quarters that a setscrew placed on the end or side of the holder would be in the way. This holder has a hole running from the back end into the tool channel, the hole being tapped at its outer end for the setscrew *A*. A piece of tool steel *B* with its end beveled and toothed extends from the setscrew up to the tool which it clamps firmly. The end *D* being solid can be made considerably thinner than if it was drilled and tapped for a setscrew.



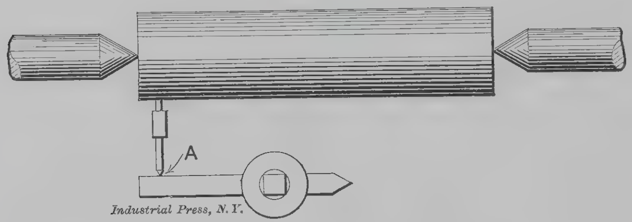
CENTER REST KINK.

Referring to the "kink" in the October MACHINERY, relative to setting work in the center rest, A. C. Muff, Los Angeles, Cal., writes: My method of doing this is to bore out the center rest to the nearest even dimension, using a boring bar held on the lathe centers. Then, when a shaft or other piece of work is placed in the rest a pair of inside calipers is set to the difference between the diameter of the shaft and the bore of the steady rest, and by measuring from the bore the work is very readily brought to a central position.

At our shop we have eight lathes, ranging in size from 8 to 48 inches, and on none of these was the center rest bored out when it was received from the factory. Within a short time I have bored out center rests made by several different lathe builders, and each time I was surprised to see how universally negligent builders are in the construction of this part of the lathe. Not only were these rests left in the rough, but some of them were about a quarter of an inch eccentric. Also the guides for the jaws were not milled accurately and the jaws, when set for small sizes, presented different faces to the work than when set at their largest capacity.

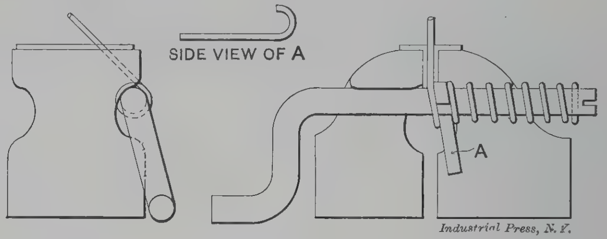
LINING UP THE TAILSTOCK.

E. M. B. sends a "kink" for lining up a tailstock after it has been set over for taper turning. Select a perfectly straight and true arbor and put it in the centers of the lathe. Then put a punch mark in the side of a lathe tool, near the back end as at *A*. This tool is put in the tool post so that it is approximately parallel with the arbor and so that the punch mark is about on a level with the centers. Placing one end of an inside micrometer caliper in the punch mark, measure the distance from the tool to the arbor when the carriage is close to the headstock. Run the carriage down to the other end of the arbor and adjust the tailstock to the micrometer. By repeating this operation two or three times the centers can be lined up in a very few minutes.



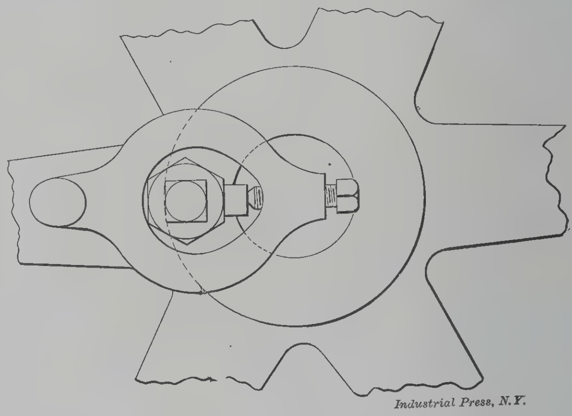
WINDING SMALL SPRINGS.

A. C. Muff, Los Angeles, Cal., describes an ingenious and simple way for winding small springs in a vise. In the first place a rod of the diameter of the inside of the spring is bent to form a crank and a small hole drilled in one end to hold the wire while being wound. This rod is placed at one side of the vise, as shown in the sketch, and one end of the wire passed through the hole in the end while the other is led up through the copper jaws of the vise, which are set so as to make an easy fit for it. To get the proper pitches a piece of metal, *A*, the width of which equals the required distance between two coils of the spring, is bent to a half circle at one end while the other is left long, forming a tail. This is hooked over the mandrel at the point of bending and feeds it along at the desired pitch while the tail strikes against the vise and is thus prevented from turning. When no drill is at hand for drilling the hole in the end, a slot may be filed to answer the same purpose. In this manner the writer has been able to wind all kinds and pitches of springs when doing repair work miles away from a lathe or any tools other than a vise and file.



PULLING A TIGHT KEY.

James F. Willey, Jeffersonville, Ind., in sending in a "kink" says: An aged blacksmith once told me that the best "kinks" could be learned from workmen of very ordinary ability. Whether this be so or not, the one which is here illustrated I saw used by a man whose reputation for quick wit greatly exceeded his skill as a mechanic. He wished to remove a tight key for a pulley on the end of a shaft and the way he did it is shown in the sketch. With a lathe dog a hexagon nut was clamped tightly against the projecting end of the key and a setscrew was then turned through the nut. The end of this screw bore against the hub of the pulley and as it was turned it raised the nut and consequently drew the key with it.



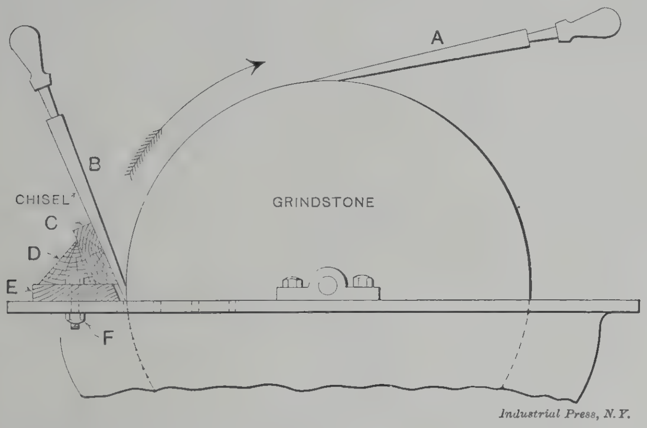
A REAMER KINK.

Charles F. Brandon, Hartford, Conn., sends the following reamer kinks regarding which he says: They would probably be out of place for a first-class tool job but for ordinary work they are frequently very handy. It is often required to ream a hole slightly larger than the size of the reamer at hand. To do this we employ a piece of drill rod about 1-64 inch larger in diameter than the depth of the reamer flutes and long enough to extend through the hole and project a few inches on either side. This rod is thoroughly lubricated and inserted with the reamer in the hole. The reamer is operated in the ordinary manner and the rod crowds it to one side sufficiently to cause it to cut the hole slightly large. Should the enlargement not be sufficient a larger rod may be used or two rods may be put in flutes near together.

A reamer that has become slightly dulled may be sharpened without grinding by the use of a piece of Stubs' drill rod ⅛ to ¼-inch in diameter, depending on the size of the reamer. One end of this rod is hardened as hard as possible and this is inserted in the flutes with the side pressed firmly against the cutting edge of the blade. This is slid up and down a few times against each blade and has the effect of raising a slight burr on the blade which causes it to take hold well and to cut a smooth hole.

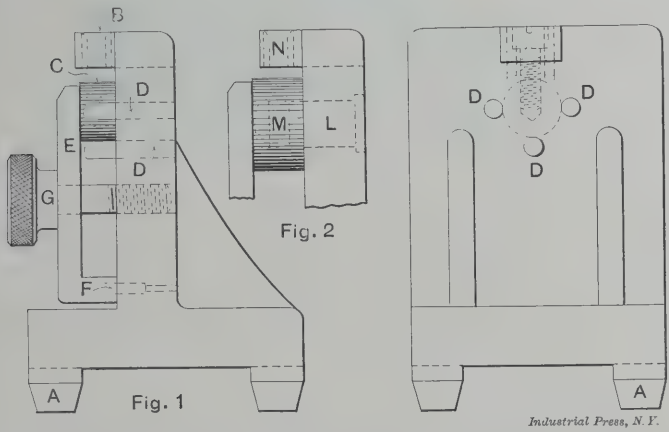
JIG FOR GRINDING A CHISEL.

Woodworker writes: Patternmakers and woodworkers who grind chisels, plane irons, etc., in the old way by holding them on the stone as shown at *A* will find the little jig, for holding them as at *B*, to be a great convenience. The two pieces, *C* and *D*, are screwed or nailed together and braced by the bracket *E*. Then the piece *C* is beveled to give the proper angle to the edge of the tool. The fixture is fastened to each side of the grindstone trough by the bolts *F* and a series of bolt holes is drilled through each flange of the trough so that the jig may be moved in as the wheel is worn down. With this attachment the writer has ground trimming knives as accurately as could have been done on a special emery grinder.



JIG FOR DRILLING COLLARS.

C. H. Rowe, Lynn, Mass., sends the sketch of a jig which he has used with much satisfaction for drilling setscrew holes in collars. The collar *C* is held in position by means of the three locating pins *D*, *D*, *D*, and the swinging clamp *E*. In order to place a collar in position for drilling, the strap is swung to one side about the hand screw *G*. When the collar has been put in place the clamp is swung back and in doing so its motion is limited by the pin *F*, which brings it to a stop directly over the collar. At the top of the jig is a bushing *B* through which the drill is guided. When the outside diameter of the collars is likely to vary, the pins *D*, *D*, *D*, may be replaced by a central pin, *L*, Fig. 2, and the collar held on this while it is being drilled.



* * *

The great Forth cantilever bridge in Scotland with its two spans of 1,710 feet each, has the longest single spans in the world. It is one of the world's long bridges, being 9,000 feet long. The Tay bridge is the longest great bridge, having a total length of 10,780 and following that is the Ohio River bridge at Cairo, Ill., with a total length of 10,560 feet. The new Manhattan bridge now building across the East River will come next with a length of 9,230 feet. The distinction of having the longest span will soon be taken from the Forth bridge, however. A bridge is to be constructed across the Strait of Canso between the mainland of Nova Scotia and Cape Breton, which will have a clear span of 1,800 feet. Its estimated cost is $5,000,000.

DIFFERENTIAL INDEXING.

METHOD OF INDEXING EMPLOYED ON BROWN & SHARPE MFG. CO.'S UNIVERSAL MILLING MACHINES.

This method of indexing is much simpler than the compound method heretofore employed for obtaining divisions that are prime numbers and others not obtainable with the regular index plates. The indexing is obtained in the same manner as for plain indexing excepting that the spiral head spindle is geared to the index plate. It differs from compound indexing in that the movement of the crank at each indexing is positively modified by the plate, which is geared to the spiral head spindle and moves whenever the crank is moved. The differential motion is thus obtained, allowing the indexing to be made with one circle of holes and the index crank turned in one direction the same as in plain indexing. This enables spacings to be made that cannot be obtained with an index plate locked in the usual way with the stop pin. In the compound method, it is necessary to exercise great care, as two circles are employed and it must be constantly kept in mind as to the direction in which the crank is to be moved, right or left. In the differential method, however, there is little opportunity for error, as the index crank is moved the same as in plain indexing, it being only necessary to place the proper gears in position, as indicated by the table which accompanies the machine. This table is made up to include both plain and differential indexing and avoids the necessity of two separate circles. It gives all divisions from 1 to 360 and the proper change gears and instructions as to placing them.*

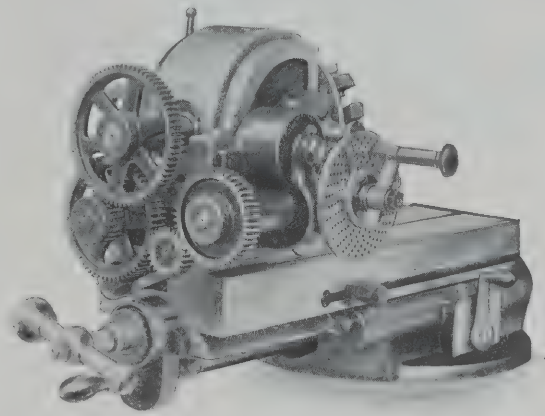


Fig. 1. Indexing for 319 Divisions.

As an illustration of the principle of the differential method of indexing, assume the index plate and spindle to be geared together in the ratio of one to one. The plate will then turn once while the spindle turns once. Therefore, if the plate turns in the same direction as the crank, and the crank is turned enough more than a complete revolution at each indexing to have the crank pin go into the same index plate hole, it will be readily seen that one turn of the crank will be in consequence of having followed the plate while the spindle has made one turn. Hence, the worm will have turned 40 turns in 39 indexings, which is equivalent to obtaining 39 divisions with equal gears and using only one hole in the index plate, the regular spacing number being 40 turns of the worm to one of the spindle. If the regular spacing number were 60, it would be possible to obtain 59 divisions with the equal gears.

The use of two idlers with the equal gears will rotate the index plate in an opposite direction to the crank. In this case, the crank, in making 40 complete revolutions, will meet the same hole in the index plate 41 times, thus obtaining 41 divisions by bringing the crank to the same hole in the plate at each indexing. It will, therefore, be readily seen that with only one hole in an index plate, it is possible, by gearing the index plate to the spindle in a ratio of one to one, to obtain 39 divisions with one idler and 41 with two idlers. With one idler, the spacing number is changed to 39 and it is possible to obtain divisions equal to 3 x 39 with a circle of 3 holes, or 4 x 39 with a circle of 4 holes, etc. With the same gearing and two idlers, the spacing number is changed to 41. Any division not obtainable with the index plate can, therefore, be made up with proper gearing.

---

* This table is reproduced in the data sheet accompanying the Engineering Edition of this month.—EDITOR.

To explain this method further, the following examples are given:

Required: 59 divisions, no index plate with 59 hole circle being at hand. First, set the indexing for 60 divisions, which is 2-3 turn of the crank at every indexing. With 59 indexings, therefore, there will be obtained 39 1-3 revolutions of the worm, lacking 2-3 turn of the 40 required for one complete revolution of the spindle. With the proper gearing, 2-3 turn can be made up, the gears in this case being 48 on the worm and 32 on the spindle, with one idler. This will give the 59 divisions required, or with two idlers, 61 divisions can be obtained.

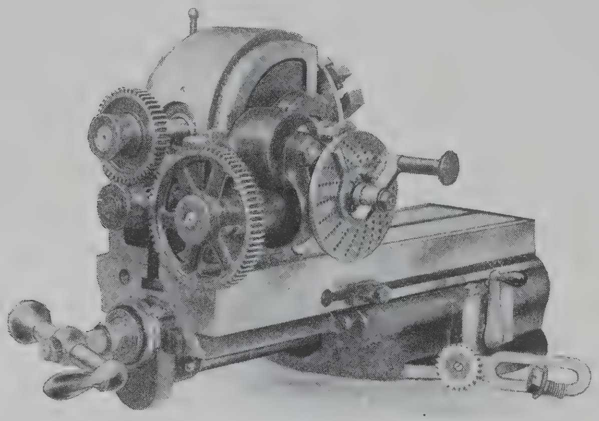

Fig. 2. Indexing for 177 Divisions.

In gearing the index plate to the work spindle, it is necessary sometimes to employ compound gearing, Fig. 1. As an illustration of this method of gearing, take 319 as the number of divisions required. First, select some number of divisions that can be obtained with any index plate furnished with machine; for example, 290, which would require a plate with 29 hole circle, using 4 holes at each indexing, 4/29 turn of the index crank. Indexing 319 times, 4/29, the worm will be turned 44 times, this being 4 turns more than the 40 required for one complete revolution of the spindle. 4 = the number of turns that the plate should make to one turn of the spindle. It can be expressed in the form, $\frac{3 \times 4}{1 \times 3}$; and multiplying the first turn, $\frac{3}{1} \times \frac{24}{24}$, and the second, $\frac{4}{3} \times \frac{16}{16}$, the expression becomes $\frac{72 \times 64}{24 \times 48}$. The terms of this fraction represent the teeth of available gears, the gears, 72 and 64, being drivers, 24 and 48 driven gears. The proper arrangement of these gears is found by referring to the table. Gear on spindle, driver; gear on worm, driven, or the follower. The first gear on the stud is a driver, which drives the worm gear. The second gear on the stud is a follower, being driven by the spindle gear. A collar is provided for use on the spindle to locate spindle gear. In some arrangements of the gearing, this collar is placed outside of the gear next to the nut and in others, back of the gear. For example: in compound gearing, it is placed back of the gear, bringing the gear out against the nut; and in simple gearing, many times it is necessary to place this collar back of the gear, for the reason that the gear may be so large that it will interfere with the gear of the worm sleeve. An example of this is shown in the gearing for 176 teeth. In this case there are two 24 tooth gears on the stud, making the gearing appear as if it were compound; but the two 24 tooth gears really act as a single idler, as they are on the same stud.

Spacing for One-Quarter Degree.—To space for ¼ deg., or 1,440 divisions, first try an indexing of 1/33, which will give a spacing of 1,320. It is sometimes found convenient to multiply the difference between the spacing required and the assumed number of spaces by the assumed indexing, which gives the gear ratio direct. Thus, the difference between 1,440 and 1,320 is 120, which, multiplied by 1/33, equals $\frac{120}{33}$ the required gear ratio; that is, there are 120 spaces to gain. One spacing being 1/33 of a turn of the index crank and 120 spacings required, $\frac{120}{33}$ is the number of turns of the index crank to one turn of the spindle. $\frac{120}{33}$ equals $\frac{40}{11}$. In order to express this ratio in a form that will permit the use of available gears, it is necessary to reduce it as follows: $\frac{40}{11}$ equals $\frac{200}{55}$, which can be compounded into $\frac{8 \times 25}{5 \times 11}$. Multiplying the first term, $\frac{8}{5} \times \frac{8}{8}$, the result is $\frac{64}{40}$; and the second term, $\frac{25}{11} \times \frac{4}{4} = \frac{100}{44}$; and the ratio, or train of gears, becomes $\frac{64 \times 100}{40 \times 44}$. In order to gain the required number of indexings, one idler is required to reverse the index plate in relation to the movement of the crank, which, combined with the compound gear stud, gives the effect of two idlers, for the reason that the gears on the stud act as one idler. The gears, 64 and 100, are drivers, and those with 40 and 44 teeth respectively are followers.

Fractional Spacing.—As illustrating this application, assume that it is required to space a Vernier to read to 1-12 of a degree or 5 minutes; the Vernier to be used in connection with a scale divided to degrees. Usually the method adopted to accomplish this is to have the Vernier spaces occupy a distance corresponding to 11 degrees and to divide this into 12 parts or spaces, which may be expressed as follows:

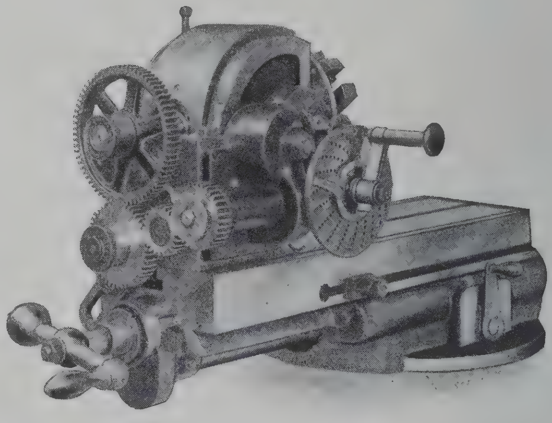

Fig. 3. Indexing for 169 Divisions.

$\frac{11}{360} \div 12 = \frac{11}{4320}$, which is equal to one space. There would, therefore, be $\frac{4320}{11}$ spaces in the whole circle, or 392 8-11 divisions. Indexing of 1/9 or 360 gives the difference between 392 8-11 and 360 or 32 8-11 indexings to be obtained with the gearing. 32 8-11 $= \frac{360}{11}$ indexings, which, multiplied by the value of one indexing, 1/9, gives $\frac{360}{11} \times \frac{1}{9} = \frac{40}{11}$, the resulting gears will be $\frac{200}{55}$ or $\frac{64 \times 100}{40 \times 44}$, one idler being required. It will be noted that the gears called for in this example are the same as those used in the one just previous.

This method of indexing has been applied to all of their universal milling machines by the Brown & Sharpe Mfg. Co., to whom we are indebted for the above description and photographs.

ITEMS OF MECHANICAL INTEREST.

Stud Setter—Cutting Odd Worms—High Pressure Piston Packing—Magnetic Attachment for T-square and Drawing Board—Spindle Boring Machine.

STUD SETTER AND EXTRACTOR.

An English stud setter and extractor of somewhat novel construction was described in a recent issue of the *Mechanical World*. It can be used both for setting studs and for removing them. Broken studs can be removed provided 5-16-inch grip is available. This, of course, applies only when the studs are not "seized" or rusted fast, but are merely broken off in such way that a grip cannot be taken with ordinary tools. A socket *A*, provided with a square *E* to take a tap wrench, is placed over the stud to be removed. The sliding wedges *B B* are then pressed in equally until their serrated edges are in contact with the stud, when by turning the tool by the aid of a wrench the stud is extracted. The stud is removed either by a pipe wrench, or by placing it in the vise and turning the tool in the reverse direction. To change the tool to a stud fixer, the coverplate *C* is removed, the pins *D*, *D*, which are loose in the wedges, pressed through to the other side, the wedges inserted in the reverse position, and the coverplate replaced.

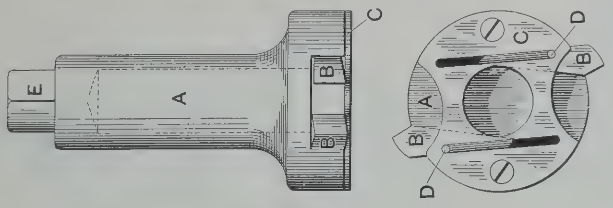

Fig. 1. Device for Setting and Extracting Studs.

METHOD OF CUTTING WORM OF ODD PITCH.

Under the heading "Workshop Practice" in a recent issue of *Feilden's Magazine* a description is given of the method followed in replacing a worm when it was found there were no change gears to the lathe that would permit its being cut. The new worm casting was bored and keyed on a mandrel along with the old worm. A double-ended toolholder was clamped to the cross slide of the lathe. Into the left end was fitted a cutter for chasing the new worm and into the other end was fitted a steel guide filed to fit the old worm, the idea being to make the old worm give the necessary traverse to the lathe carriage for cutting the new worm. All this is clear in the accompanying cut. The steel guide projected ¼-inch further than the cutter when starting the cut; as the successive cuts were taken, the cutter was advanced in the toolholder without moving the cross slide.

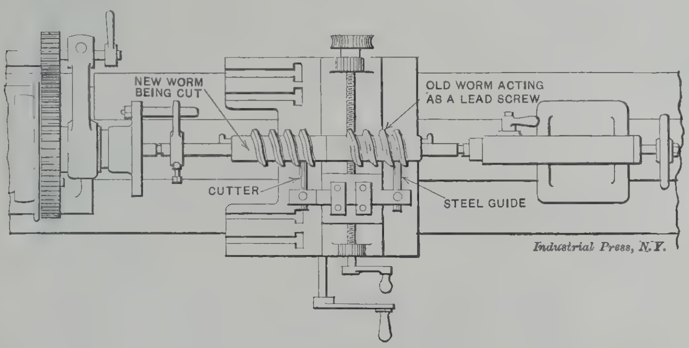

Fig. 2. Cutting Worm of Odd Pitch.

HIGH-PRESSURE PISTON PACKING OF ENGLISH DESIGN

Apropros of the articles that appeared on pistons and packing rings in the July and December, 1902, issues, we reproduce from London *Engineering* a short description of Downie's piston packing for high-pressure steam engines, which is in use in some large marine engines, both for the main pistons and for the piston valves. The packing consists of two rings placed side by side in one groove, which is turned wider at the bottom than at the top. The rings are faced flat on their opposing faces and conical on the piston and junk-ring faces. They are cut and sprung into place so as to "break joints." The object of the inclined upper and lower faces is to prevent undue pressure on the cylinder walls because of the steam pressure. By regulating the distance between the junk-ring and the piston, the diameter to which the rings can expand can be controlled. In fitting the rings a little slack is allowed so as to let the rings wear to the cylinder, after which it is claimed they remain tight, the slight wear that takes place on the conical surfaces being sufficient to keep them full bore. The grooves shown in the sides of the rings, are evidently for "water packing."

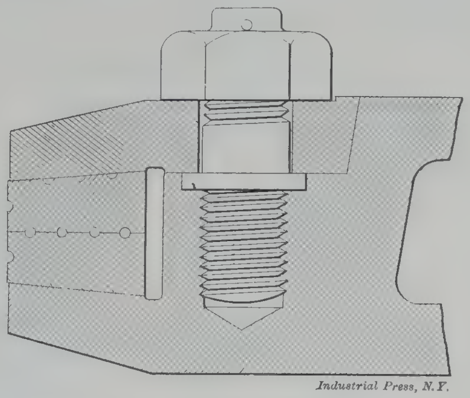

Fig. 3. Piston Packing Ring for High Pressures.

DRAWING BOARD AND T-SQUARE WITH MAGNETIC ATTACHMENT.

An English novelty in drafting room appliances, is a T-square having a number of small horseshoe magnets mounted in the head and so arranged that their poles come in contact with an iron strip attached to the left-hand end of the board, the idea being to hold the T-square to its right-angle position, by magnetic attraction alone. This, of course, allows the draftsman to use both hands at his work more advantageously. The magnets are said to oppose little resistance to movement of the blade to any position parallel with its normal position, but considerable force is required to displace the blade from its right-angle position. A drawing board with this attachment may be used in a vertical, sloping or horizontal position with equal facility.

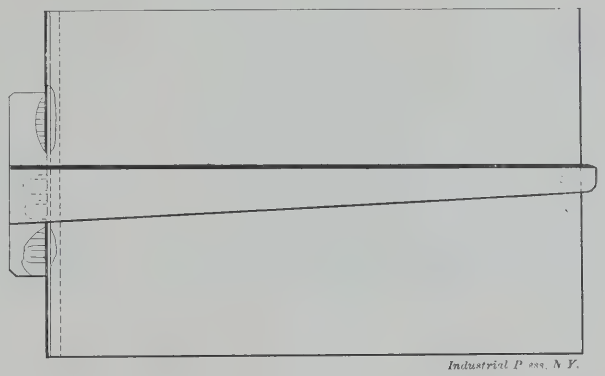

Fig. 4. Drawing Board and T-square with Magnetic Attachment.

STENCILING COUNTERSHAFT SPEEDS.

Extensive additions are being made to the Juniata Shops of the Pennsylvania R. R., at Altoona, Pa., and many new machines are being installed. Mr. A. Timm, general foreman of the machine shop, writes us that they have been considerably troubled by the neglect of machinery houses to give the speeds at which the countershafts for various machines received from them, should run. The machines received direct from the manufacturers, are usually accompanied by a blueprint or letter giving the proper countershaft speed, and the same information is sometimes given in their catalogues. But the machinery received at these shops from machinery houses, has, in all cases, lacked this quite necessary information. Eight small machines were received from one house in one week, and not one of them was accompanied by the countershaft speed. Of course it is a simple matter to calculate the countershaft speed when the spindle speeds are known, but this all takes time and is entirely unnecessary labor. Mr. Timm suggests that machinery builders generally adopt the practice of stenciling, on the countershaft for each machine, the proper speed at which it is to run. This should make a record of sufficient permanence to insure its reaching the customer, even if the machine has passed through a machinery house.

A MONSTER LEATHER BELT.

An exceptionally large leather belt has been put into place at the power house of the Twin City Rapid Transit Co., at Minneapolis. It was supplied by the W. S. Nott Rubber Company of that city. The belt is 100 feet long, weighs 2,000 pounds, is 80 inches in width and three-ply. There are eight hides to every four feet of the belt, which means that 200 head of cattle—a respectable herd for a small stock farmer—were required to furnish enough leather for this enormous belt.

Throughout the entire process of construction no fasteners of any description were used outside of a special belt cement of high adhesive power. Altogether it took 15 men more than a month to fashion it. The size of the belt gives an idea of the diameter of the big wheel which will before long be furnishing much of the street railway motive power. The largest belt ever built by this company was furnished to the Anaconda copper mine at Anaconda, Mont. It was 180 feet long, 66 inches in width and four-ply. It required 360 hides and weighed 3,600 pounds, driving from a 28-foot diameter pulley to an 87-inch driving pulley. Its speed was 5,000 feet per minute, and it transmitted an average load of 1,800 horse power.—*The Age of Steel.*

* * *

A SPINDLE BORING MACHINE.

Of the different problems with which the machine tool builder is confronted probably none have required more careful attention and experiment than that of boring out the hollow steel spindles used on lathes, boring machines, etc. For this purpose many of the different builders have designed and built their own machines, which are generally admirably adapted to the class of work they are to handle. The photograph illustrates one of these spindle boring machines which has lately been built by the Springfield Machine Tool Co., Springfield, Ohio, for their own use. The construction of the head of this machine is clearly shown in the drawing Fig. 6.

This machine is intended to bore holes from 1 inch to 6 inches in diameter in spindles varying from 1½ inch to 7 inches in diameter. The cone is keyed to a spindle which is geared into the main spindle of the lathe with a ratio of three to one. Back gears are provided so as to give eight different speeds, arranged in geometrical progression.

The most important requisite of a spindle boring machine is a wide range of feeds of ample power. The feed power is taken from the coneshaft and transmitted to a cone the shaft of which is geared into the feed rod. In addition to the use of a five-step feed cone, back gears are furnished so that ten different rates of feed are obtainable, giving a range from .0005 inch to .01 inch per revolution of spindle. Motion from the feed rod is transmitted to the carriage by means of a train of gearing and a pair of rack pinions which engage in a pair of steel racks, one of each being located on the top of the bed and at the side of the V's, upon which the carriage travels. This arrangement makes a much steadier feed than could be obtained if only one rack were used, as is customary in engine lathe construction. The feed is engaged or disengaged by means of a powerful friction which is so designed that it will slip should any unusual resistance be encountered. A pilot wheel, keyed to a rack gear shaft provides for a quick return of the carriage.

A duplex single-acting pump supplies a constant stream of oil, which is essential to the proper working of the drill.

As will be noted the spindle of the machine is hollow, which permits of holding the spindles to be bored, at one end with the universal chuck and at the other end with suitable collars which must fit the ends of the spindle that is being bored and the bore of the machine spindle. This construction enables a comparatively short machine to be used for boring long spindles, whereas if one end of the spindle were to be held in the chuck and the other end in a bearing or steady rest, the length of this machine would require to be almost doubled. A rest is provided which guides the boring tool at the commencement of the cut and after a hole has been drilled a short distance, say 2 inches or 3 inches, it may be removed by being swung out of position.

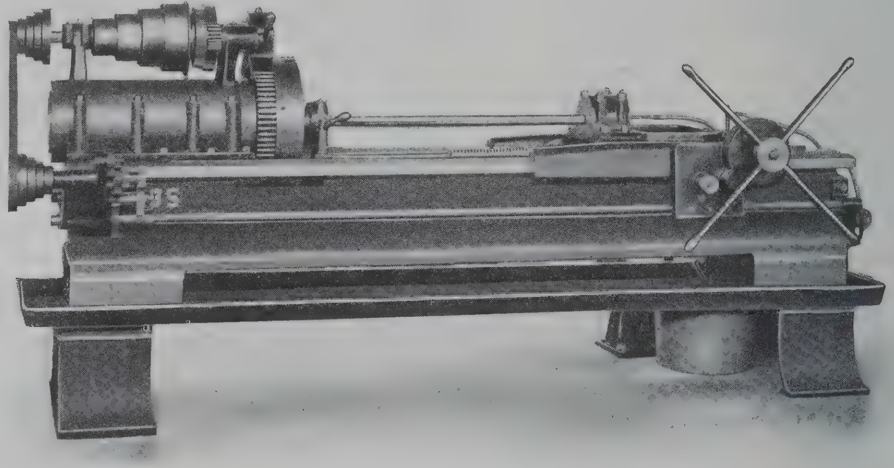

Fig. 5. Machine for Boring Spindles.

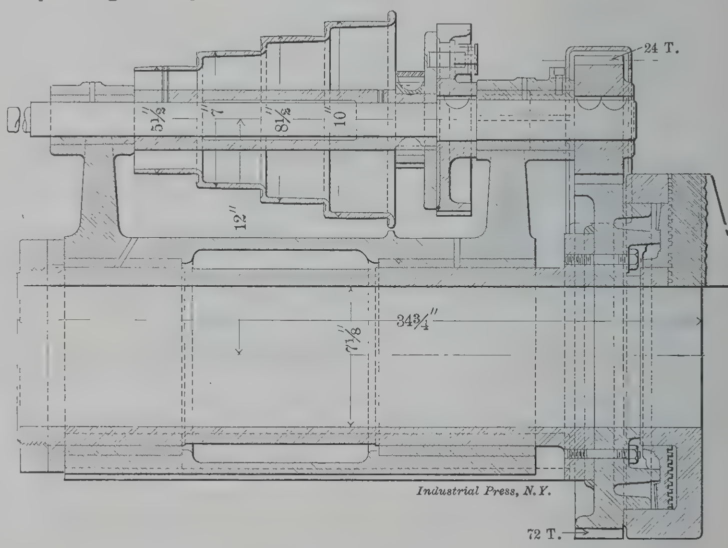

Fig. 6. Section through Head of Spindle Boring Machine.

The carriage has a travel of 5 feet, and therefore, permits of boring a hole 5 feet in length without re-setting the boring bar, and as ample provision is made for this purpose, it is possible to bore holes 7 feet or 8 feet in length without turning them end for end.

* * *

According to a short article recently published in the *Electrical World and Engineer* the thawing of frozen water pipes appears to be a regular winter industry in Sault Ste. Marie. A transformer is mounted on a sleigh and hauled around town to wherever frozen pipes may be. Connection is made to the pipes each side of the frozen section with the secondary wires from the transformer and the primary wires are connected to the 2,200 volt circuit, through a water rheostat. The water generally begins to flow very quickly after the current is turned on, usually within one minute. Pipes as large as 4 inches diameter and frozen more or less for 200 feet, have been thawed out in this manner and at a fraction of the cost of following the usual plan of digging. That the business is profitable may be inferred from the usual charge being about $3.00 for thawing house pipes.

A FORTY-FOUR FOOT PIT LATHE.

DESCRIPTION OF LARGE FRICTION DRIVEN LATHE.

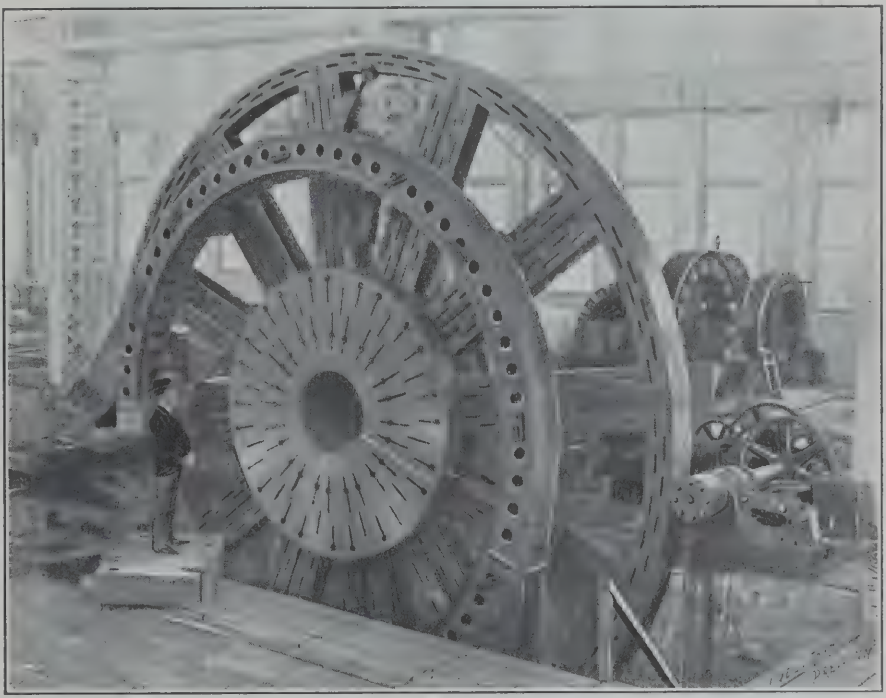
Paper read before the American Society of Mechanical Engineers, December, 1902, by John M. Barnay.

The machine here illustrated was designed to meet the demands of an establishment manufacturing the heaviest type of electrical machinery. The ever-increasing dimensions of this class of machinery make it particularly desirable that the existing heavy machine tools should be capable of extension of capacity with a view to probable future requirements; and that a pit lathe is peculiarly adapted to such extension will, doubtless, be readily admitted.

The faceplate of this lathe measures 30 feet in diameter, and the present dimensions of the pit will admit of swinging 44 feet on centers, with a maximum width of 12 feet. The large faceplate is built up of twelve segments. The rim is of box section, the ends of the rim in each section being finished to make the joint, and the segments being held together at the rim by body-bound bolts. The arms are slotted for bolts, and the space between segments is also shaped to receive the usual square-headed bolts, as the inner end of each segment is fastened to the smaller faceplate by several body-bound bolts. The smaller faceplate is cast integral with the forward section of the spindle which revolves in a babbitted bearing 48 inches in diameter by 68 inches in length, the rear bearing being 22 inches in diameter and 28 inches long. It is calculated that the pressure on the main bearing will, at times, attain a maximum of 125 pounds per square inch.

Teeth were cast into the periphery of the 12-foot faceplate for the purpose of driving same while turning out the spindle bearing. After the spindle was finished by this method the segments of the large faceplate were bolted on, the spindle assembled on the headstock, and the periphery of the 30-foot faceplate turned off, with the spindle in its own bearing.

A novel feature of interest in connection with this machine is the method of drive adopted, which is a friction roller, 18 inches in diameter, made of compressed paper, while the rim of the large faceplate, 15 inches wide, affords the necessary contact surface for driving. Power is supplied by a 75 horse power motor, quadruple geared, the use of the multiple voltage system giving the machine a range covering all diameters from six feet to the present capacity, though the gear train is designed to admit of two changes of back gear in addition.



Friction-driven Pit Lathe.

The tool carriages are supported on massive cast-iron columns resting on the bottom of the pit, and the feed mechanism is driven by an independent motor properly back geared. By the use of the multiple-voltage controller, and a device called a feed regulator, at rate of feed from 3-64 inch to 2¾ inches per minute can be had without a change of back gears. There was also designed for this machine an outboard bearing to support the outer end of mandrels and boring bars which is provided with a geared sleeve connected to a train of back gears driven by an independent motor; the whole being self-contained and constituting a portable boring and facing tool. An approximation of the total amount of cast iron used in the construction of this machine places the weight at 480,000 pounds, of which the spindle and two faceplates together weigh about 155,000 pounds.

As would be expected in this class of tool, the center of gravity of the revolving parts lies very close to the edge of the pit; hence, the matter of a substantial foundation became one of considerable importance, and to meet the severe requirements the design of the headstock provides a large area for the distribution of this pressure, so that the forward part of the headstock alone covers an area of 68 square feet. The masonry foundation consists of a layer of best Portland cement grouting on top, surmounted by a five-foot layer of vitrified brick which, in turn, rests on a massive column of best pressed brick, all laid in first quality of Portland cement.

[In connection with the above-described machine Mr. Barnay furnishes us the following data regarding the power required for operating and the power transmitted by the friction wheel.—Editor.]

The weight of the revolving parts of the pit lathe alone is about 155,000 pounds. Add to this the weight of the casting bolted to the faceplate and we have 210,000 pounds. The diameter of the main bearing of the spindle equals 48 inches. The number of revolutions of the spindle during the operation of boring was ¾ revolution per minute, representing a cutting speed of 45 feet per minute. Assuming a coefficient of friction of 0.10 for the bearings, we have power required to drive machine with casting bolted to faceplate, but without cut,

$$\frac{210{,}000 \times 48 \times 3.1416 \times .10}{12 \times 33{,}000}$$

equals 8 horse power, nearly. To this is to be added the power required to run three cuts each ¾ inch deep with ⅛ inch feed. At forty-five feet per minute cutting speed this is equivalent to removing 64¼ cubic inches of metal per minute. Assuming that it takes 35-100 horse power to remove one cubic inch of cast iron per minute, a good average, as established by numerous independent tests, we have power required to take three cuts as above, about 22½ horse power.

Then 8 plus 22½ equals 30½ horse power, which is the total horse power transmitted by the friction wheel at the surface speed of 74¼ feet per minute.

Now let us compare this result with such published formulæ as have been found available on this subject. Taking, for instance, Prof. Goss' formula published in the transactions, A. S. M. E., XVIII, pp. 102. According to this formula horse power equals .000238 D. W. N., in which D equals diameter of wheel in inches; W equals width of wheel in inches; N equals number of revolutions per minute.

Applying this to our case, we have, D equals 18; W equals 15; N equals 15¾; .000238 D. W. N. equals 1.012 horse power.

As Prof. Goss' formula is based on pressure of contact of 150 pounds per inch, it would follow that the pressure of contact in our case is 150 : X : : 1.012 : 30½, which gives 4,525 pounds.

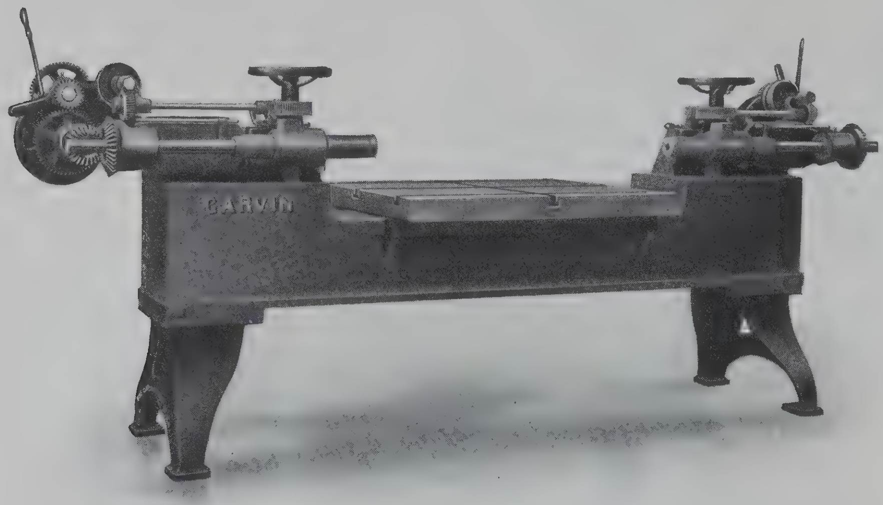
In justice to the author of the above formula it should be said that it was probably never intended to apply at such extremely low surface speeds. As stated in his paper, the experiments conducted at the time of the establishment of the formula covered surface speeds between 400 and 2,800 feet only.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

DUPLEX DRILL LATHE.

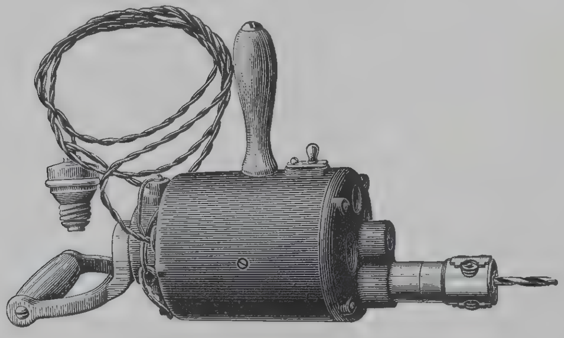
A special manufacturing tool that is simple in construction and well adapted to its work is shown in the accompanying half tone. This is a duplex drill lathe and is used for drilling, through jig eyes, such work as hinge holes in fire doors and their frames, sewing machine treadles, machine frames girths, etc. On either end of the lathe bed is mounted a drill spindle similar in construction and operation to that of an ordinary vertical drill. These spindles are independent, have a light, quick hand movement to and from the work and are provided with power feed and adjustable automatic trip. Each spindle is driven by a four step cone from an independent countershaft, and is back-geared, giving eight changes of speed. The work is held on a heavy T-slotted table on which are also placed the jig eyes and fixtures used for directing the drill. The table is of ample size for handling large work, while for drilling small pieces extension drills are used. In the machine illustrated the distance between the heads is 46¾ inches and the height of the center of spindles above the table is 5¼ inches. These dimensions may be altered to meet any desired requirements. This machine is the product of the Garvin Machine Co., New York.



Duplex Drill Lathe.

ELECTRICALLY DRIVEN HAND DRILL.

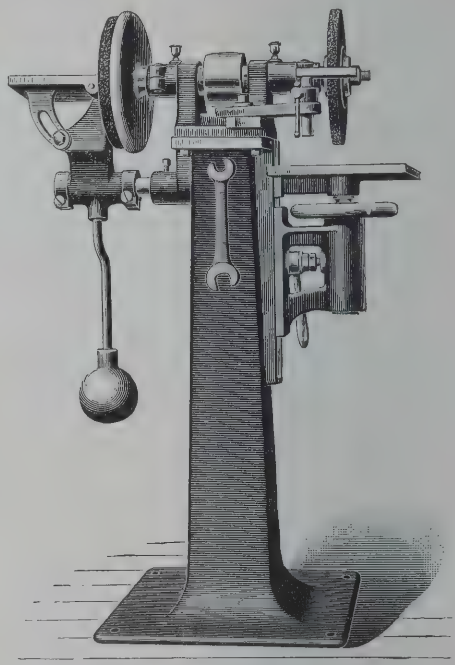
The portable electrically driven hand or breast drill here illustrated is likely to prove of great convenience in any shop where it is used to replace the ordinary hand drill. Owing to its greater speed it performs the work much more rapidly than it could be done by hand, besides saving the strength of the operator. The power is supplied by connecting the flexible wire cord to any convenient incandescent lamp socket, and the range of operation is limited only by the length of the cord. The drill is under perfect control at all times as a switch is provided, where it is within easy reach of the index finger, for starting or stopping the motor. This machine is made by the Hisey-Wolf Machine Co., Cincinnati, Ohio, and is supplied in three sizes, taking drills up to ¼ inch, ⅜ inch and ½ inch respectively.



Electrically Driven Hand Drill.

NEW END AND SURFACE GRINDER.

The illustration shows a grinder, for end and surface work, that is made by the Rowbottom Machine Co., Inc., Waterbury, Conn. This machine possesses features that make it especially helpful for tool and press room work and for a variety of purposes in manufacturing.



Combined End and Surface Grinder.

The table on the right is counterbalanced and provided with a quick method of adjustment for wide ranges by the lever shown under the table. By lifting up the lever the table is released and is free to move either up or down, by pressing the lever down the table bracket is firmly fastened to the column; the handwheel under the table is then available for fine feed. On the left is a swinging table for end grinding by swinging the work across the face of wheel; this table is adjustable for angular work and is provided with adjustment to keep it close to the wheel. The emery wheels for end grinding may be replaced by emery cloth disks or the machine can be provided with both, as the change is readily made from one to the other, thus allowing the machine to cover a large range of grinding. The bearings are dust proof with adjustment for taking up wear, and oiling devices are provided.

The emery wheels are 10 inches diameter and the emery cloth discs 12 inches diameter. The table for surface work is 16 inches long by 10 inches wide, with up and down adjustment of 8 inches and is capable of surfacing 8 inches wide.

LOWE TEST INDICATOR.

Fig. 1, on next page shows a test indicator that has been brought out by H. A. Lowe, Waltham, Mass., and which, owing to the convenience of its manipulation, will be found useful for an unlimited number of purposes in the machine shop.

The shank of this indicator is 7-16 inch by 15-16 inch and is carried in the tool post of the lathe. Being casehardened it is not injured by the tool post screw, and at the same time the channel shaped section of this shank affords protection to the delicate working parts.

The forward end of the holder terminates in a point bearing a pivot about which oscillates a lever the short arm of which is placed in contact with the work to be indicated. The long arm of this lever runs back to a spiral groove in the vertical pointer spindle. This arrangement causes the pointer to revolve over a horizontal graduated disk mounted on the back end of the holder. This disk is graduated to read in thousandths of an inch of movement of the short lever arm and the leverage is such that any movement of the short lever is multiplied one hundred times by the pointer. A flat spring, placed under the long arm of the indicator, keeps the pointer normally at the zero position. This tool may be applied to testing shafting, flanges, gears and all kinds of lathe work, and is also used in the planer and shaper for setting angle plates and work

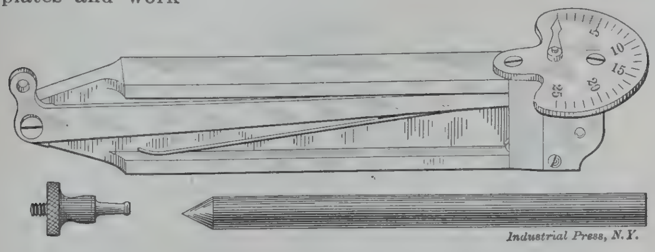


Fig. 1. H. A. Lowe's Test Indicator.

When the indicator is to be used for internal work the screw button, shown beside it in the cut, is inserted into the eye of the short arm and the point of this button is placed in contact with the inside of the hole. This is illustrated in Fig. 2, which shows the indicator in use for re-chucking a gear so that the hole will run perfectly true. The pointed rod, shown just below the indicator in Fig. 1, is used for "wiggling up" or locating work on the faceplate central to a prickpunch mark. One end of this is fitted with a female center which is placed on the tail center of the lathe while the point is placed in the prickpunch mark in the work which is held on the faceplate. Then by use of the indicator, as shown in Fig. 3, the work may be quickly brought to a central position on the faceplate.

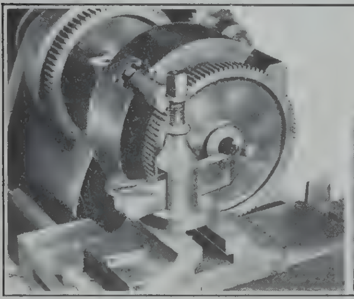

Fig. 2. Re-chucking Gear by Hole.

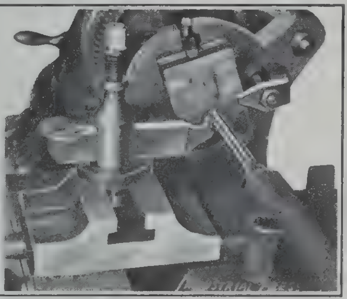

Fig. 3. Setting Jig on Faceplate.

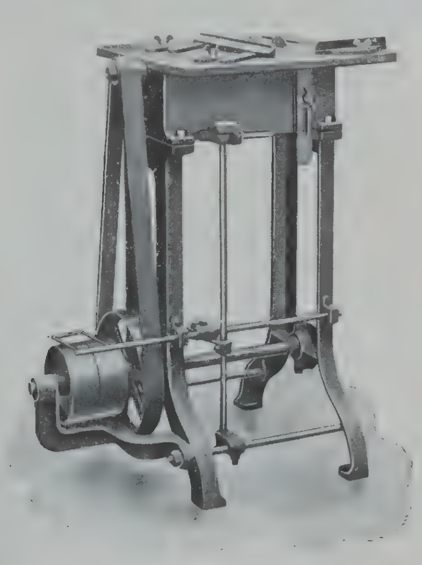
THE ACME METAL SAW TABLE.



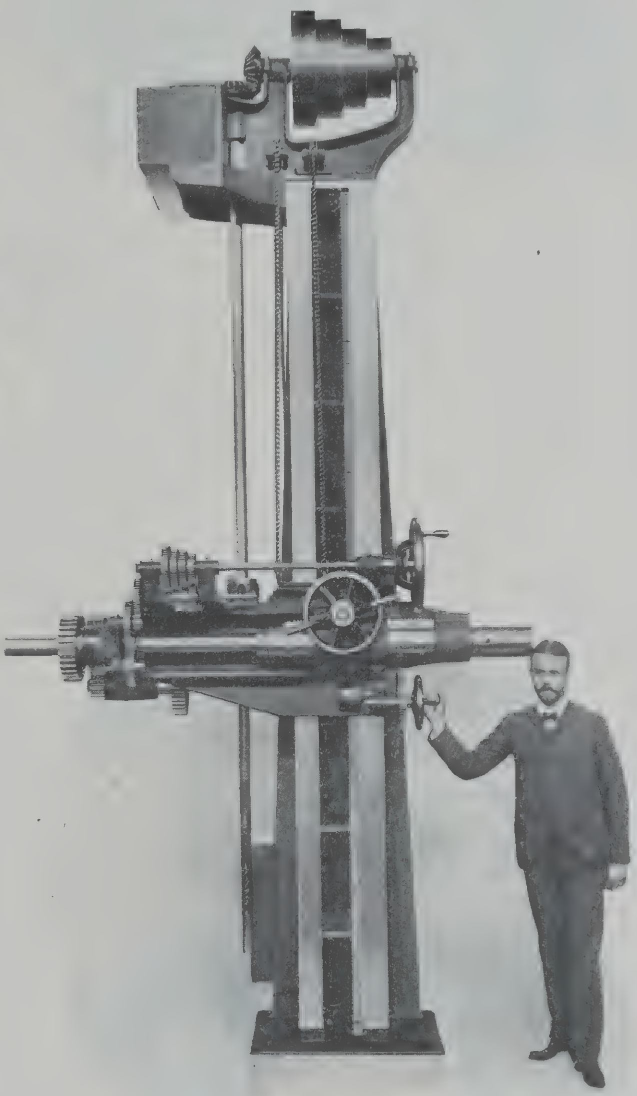
Acme Metal Saw Table.

This saw table is the invention of Mr. F. D. Hazelton and is being placed on the market by Hazelton and Donald, Philadelphia, Pa. The table is the result of the inventor's needs for a saw for cutting sheet, rod and tube brass, fiber, hard rubber, printers' furniture and electrotype plates. The machine occupies a floor space of but 18 x 24 inches, is constructed wholly of metal and is self-contained. One important feature is that the saw arbor is but one inch below the surface of the saw table, thus permitting the use of saws of small diameter and consequently obtaining the greatest power and accuracy. The table swings entirely open or may be set to saw any desired depth while the slitting gage may be adjusted for slitting any width up to 12 inches. The cross cut gage will swing either way to any practical angle. An improved device is provided for holding the arbor from turning while attaching or removing the saws. A removable throat plate allows the use of wood cutting saws up to 6 inches in diameter.

A DRILLING AND BORING TOOL FOR STEAM ENGINE WORK.

The accompanying half-tone illustrates an interesting special machine, for use on large steam engine work, that was recently built for the W. A. Harris Engine Co., Providence, R. I., by the Prentice Bros. Co., Worcester, Mass.

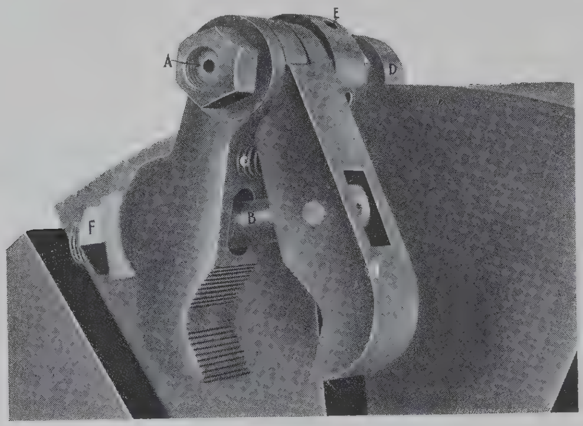
This machine was designed for boring up to 36 inches in diameter and is capable of drilling from the solid up to 6 inches. The base is bolted to a cement foundation while the top is of suitable shape to fasten to the overhead timbers of the shop. The total height of the machine from the base to the top of the cone pulley is 14 feet 4 inches. This allows the spindle to be raised to a maximum distance from the base of 10 feet 6 inches, or it may be lowered to a height of but 14 inches. The head is counterbalanced and its vertical movement in the upright is facilitated by the employment of compound gears. The spindle, which has a horizontal traverse of 23 inches, has four changes of geared feed, hand feed, and quick return motion. This machine can also be used for vertical milling, feeding by hand through the compound gearing.



Prentice Bros. Co.'s Special Drilling and Boring Machine.

A NEW LATHE DOG.

A new lathe dog which is manufactured by the Eddystone Engineering Works, Eddystone, Pa., is illustrated in the accompanying cut. This dog has two jaws which are pivoted about a central stud, *A*, and grasp the work in the open ends, A bolt, *B*, tightens the jaws onto the piece being turned and when this bolt is released the spring *C* spreads them apart and the work is at once released. The steel about which the jaws pivot has at its lower end a T-head *D* and clamping nut *E*, so that it can be firmly clamped at any point on the faceplate. In use, this stud is slid into one of the faceplate slots, as shown in the cut, and the jaws are brought down over the work, which is held on the lathe centers. The jaws are then tightened on the work by the nut *F* and the driving stud is clamped to the faceplate by a turn of the spanner nut *E*. This makes a rigid and powerful clamping dog which is easily operated. When removing the work and introducing new pieces, if they are of the same size, it is only necessary to operate the bolt that clamps and releases the jaws as the stud holds the dog in the proper position for receiving the pieces. This dog is made in four sizes capable of taking work from 1 inch to 12 inches in diameter.



New Lathe Dog.

SPECIAL GEAR CUTTERS.

R. M. Clough, Tolland, Conn., is making two forms of gear cutters, one of which, we believe, is distinctly new and the other is so little known that it will be of interest to most mechanics who may be more or less familiar with gear cutting. The first-mentioned cutter is that shown in Fig. 1. It is made with shoulders at the sides of the regular teeth, for the purpose of milling off the tops of the gear teeth as the cutting of the tooth spaces proceeds. This saves turning the blanks since the tops of the teeth are all milled to correct length at the same time that the tooth spaces are cut. These cutters are made eight in a set for each pitch to cut gears of the regular Brown & Sharpe involute tooth shape, from 12 teeth to a rack.

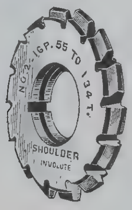


Fig. 1.

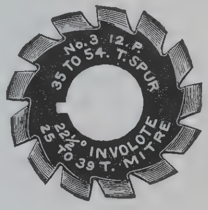

Fig. 2.

The cutter shown in Fig. 2 is for cutting bevel gears at one cut for each tooth which, of course, saves at least one and usually two cuts for each tooth, when done in the ordinary way. This cutter is, to all intents and purposes, a 22½ degree involute cutter, and is made eight cutters to a set for each pitch, for either spur or bevel gears. It is thinner on the points of the teeth than a Brown & Sharpe, or 15 degrees involute cutter, and is used by setting the gear at such an angle as to "shallow" the small ends of the tooth spaces the proper amount. The gears produced in this manner are said to run fully as well as when cut with three operations for each tooth, and the teeth are so shaped as to be somewhat stronger than the ordinary bevel tooth of the same pitch. Firms that are using these cutters prefer the gears to those cut in the ordinary way, to say nothing of the decreased cost.

AUTOMATIC GEAR AND RACK CUTTERS.

The Dwight Slate Co., Hartford, Conn., have recently redesigned and improved their gear and rack cutters in a manner tending to simplify their operation and increase the production. In their automatic gear cutters of earlier design it

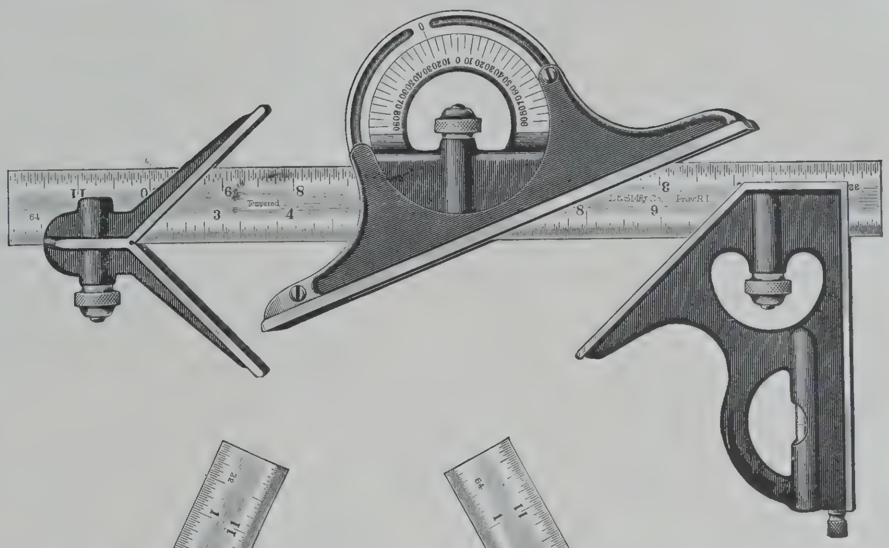
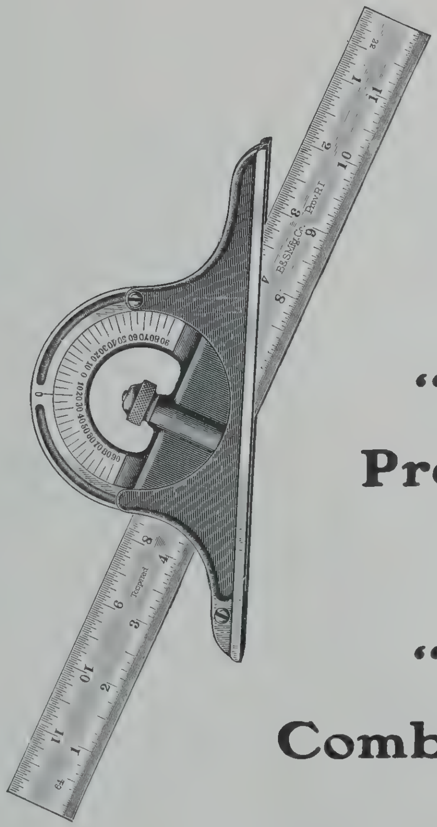
NEW MECHANICAL MACHINISTS' TOOLS.

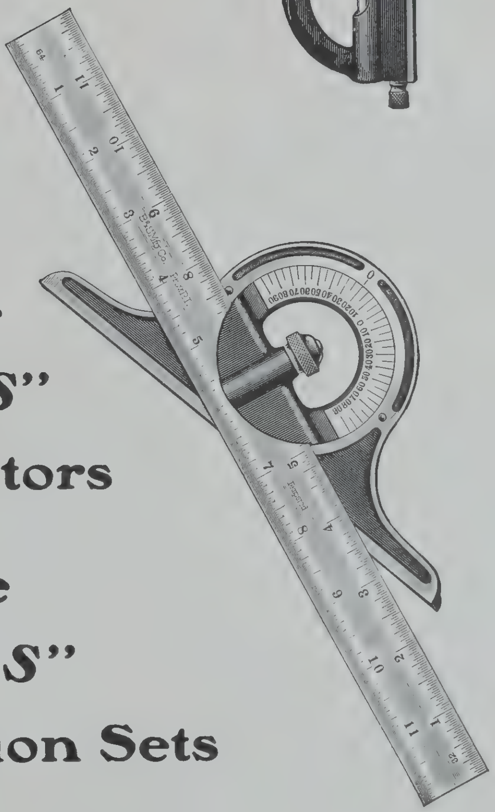
10 Different Styles.





The "B & S" Protractors

The "B & S" Combination Sets



POINTS OF SUPERIORITY—*Square Heads* of Steel, drop forged. *Clamping Groove* round, no sharp corners, forces blade against side of slot square with face of head. *Blades* accurately graduated, have shaded figures that are quickly read. *Protractor Heads* engine divided to 90 degrees either side of zero; Level furnished with head, accurately set parallel to face. **ALL PARTS INTERCHANGEABLE.**

B·S **A Convenience**—Our tools carried in stock by hardware dealers. B·S

CATALOGUE NO. 103 MAILED TO ANY ADDRESS.

was necessary to change the cams that regulated the length of the cut, three cams being required for each machine. In the new machines one cam only is used and this, in connection with the oscillating arm, can be readily adjusted to give any required length of cut within the capacity of the machine. In operation the arbor, carrying as many blanks as can conveniently be placed thereon, is put on the centers and the machine started. Once put in motion, the cutting will continue until the completion of the last tooth, when the feed motion will be tripped out of engagement. After the completion of each cut the table is returned to first position automatically and at the same time the index is unlocked, moved to the proper spacing and securely relocked. Fig. 1 illustrates the No. 2 machine which is capable of cutting gears of 6 pitch and finer up to 8 inches in diameter; extreme length of cut 4 inches. The No. 1 machine cuts gears of 12 pitch and finer up to 4 inches in diameter; extreme length of cut 3 inches.

The new rack cutter is shown in Fig. 2. This machine as formerly built was semi-automatic, the operator being required, after each tooth was cut, to feed the head back by hand and space for the next tooth. It has now been made into a full automatic cutter and when the work is once started it will continue without attention, until the entire rack is cut. This machine will cut racks of 12 pitch or finer, 19 inches long at a single setting, while by resetting any length of rack may be cut.

THE NEW YORK NATIONAL EXCHANGE BANK.

The New York National Exchange Bank, corner of Chambers Street and West Broadway, has just completed a number of improvements and additions which greatly increase its facilities for doing business, and a happy combination of practical experience and good taste has combined not only to utilize every foot of space, but to decorate the new banking rooms so that they equal in attractiveness any in New York—a comparison not to be lightly made.

The screen work forming the partitions is constructed of Pavanozza marble up to the counter level, above which the partitions or cages are constructed in bronze metal finished in verde antique, the interiors being fitted with latest improved counter systems including filing cases of all kinds. The wood work and furniture are of Mexican mahogany and walls finished with green burlap which makes a pleasing contrast with the other fittings. The vaults are constructed with heavy steel linings, inside and outside vestibule doors, and the reserve fund is further protected by being contained in two massive chests of the heaviest construction; the whole controlled by time and combination locks of the latest design.

The New York National Exchange is an old and well-known bank, organized in 1851, and for many years conducted on what may be termed old-fashioned methods; until, about three years ago the management was undertaken by younger and more active men, who have increased its business and resources with such rapidity as to attract the attention of the down town business community. During the period referred to the total resources have moved up from about $2,000,000 to over $7,000,000. The officers of this institution are James Rowland, president; Lewis E. Pierson, vice-president; and Rollin P. Grant, cashier.

FRESH FROM THE PRESS.

Dies: Their Construction and Use. By Joseph V. Woodworth. Published by Norman W. Henley & Co., 132 Nassau St., New York. 384 8vo. pages. Illustrated. Price, $3.00.

This book treats of tools for sheet metal working. Its pages contain descriptions, with illustrations, of dies, press fixtures and sheet metal-working devices, from the simplest to the most intricate, and the author has described their construction in a clear manner, so that any good mechanic will understand how to design, construct and use them. Mr. Woodworth is a practical toolmaker and diemaker and has become well known through frequent contributions to Machinery and other technical papers, and his book on dies is the outcome of his work in this direction. Its various pages contain the articles that he has contributed to the different papers, thoroughly revised, and re-written where necessary, with a great deal of additional matter. The volume is largely the result of Mr. Woodworth's own experience, supplemented by material gathered through observation in different metal-working establishments.

There are twelve chapters in the book, as follows: Single or blanking dies, and double or piercing and blanking dies; simple dies for use in machine shops; gang and follow dies; the adaptation and use of simple dies and press fixtures; bending and forming dies; perforating dies; curling, wiring and seaming processes; drawing processes, for sheet-metal shells; coining processes—operations on heavy stock; feeding sheet metal to the dies; annealing, hardening and tempering—the use of files; miscellaneous dies, presses and fixtures.

This is the most elaborate treatise that has appeared on sheet metal work, and there is probably not a diemaker or a toolmaker who would not find some information of value within its pages. There are over 500 illustrations, most of which are wax engravings made from original drawings by Mr. Woodworth. The development of sheet metal working has been so rapid during the past few years that most mechanics have not had the opportunity to keep pace with the construction of the tools used in such work and the author has done well to gather together so large a fund of information upon the subject, where it may be readily referred to.

ADVERTISING LITERATURE.

The Grant Gear Works, Boston, Mass. Circular and price list of machine chains and sprockets.

The Joseph Dixon Crucible Co., Jersey City, N. J. Booklet descriptive of graphite facings for flat molding and stove plates, for dry sand work, for green sand, etc.

The Garvin Machine Co., Spring and Varick Sts., New York. General catalogue G of universal milling machines, plain and vertical milling machines, Lincoln milling machines, grinders, screw machines, drills, slotters, etc.

The Payne Co., Inc., Elmira, N. Y. Bulletin No. 12 of Payne engines, for electric light and power service. These are either belted or direct-connected, and several views of this engine are given, also views of the parts.

The Burt Mfg. Co. Akron, O. Pamphlet entitled "The American Oil Filter," describing and illustrating the oil filter and purifier manufactured by this company. The Burt exhaust head is also mentioned.

Pawling & Harnischfeger, Milwaukee, Wis. Bulletin No. 12, which describes the standard I-beam trolleys built by this company. Chain block traveling cranes, and electric traveling cranes and hoists are also described and illustrated.

The Shelby Steel Tube Co., Pittsburg, Pa. Price list No. 12, Nov. 1902, of the Shelby cold-drawn seamless steel tubing for mechanical and engineering purposes. Hot rolled tubes are also manufactured by this firm.

The Arguto Oilless Bearing Co., Wayne Junction, Philadelphia, Pa. Catalogue of Arguto oilless bearings to be used in friction or loose pulleys, on shaft bearings, in friction clutch pulleys, on countershafts, etc. They are applicable to light or highspeed machinery where lubricants are undesirable, but not for heavy work. An abstract from the report of the Franklin Institute on Arguto oilless bearings is published in the back of the catalogue.

The Pratt & Whitney Co., Hartford, Conn. Standard size catalogue, Dec. 1902, describing the thread milling machine recently placed on the market by this company. This machine is built for the production of precision screws, worms, lead and feed screws, etc. The various parts are shown in detail, and four handsome half-tones illustrate the work, large and small, that it is capable of turning out. Various useful tables in connection with this work are given. The Pratt & Whitney automatic cutter grinder is also shown.

The Reeves Pulley Co., Columbus, Ind. General catalogue of the Reeves variable speed transmission. This catalogue, just issued, is standard size and profusely illustrated by half-tones and line drawings. The Variable Speed Transmission and its operation are described in detail, and two fine illustrations show clearly the workings of the different parts. Sizes from Nos. 0 to 12 are illustrated and a number of sketches show the application of variable speed to planers, shapers, lathes, milling and boring machines, drills, etc. Several testimonial letters are published and also price lists of the variable speed. The company also publish the "Paper Machinery" issue, which treats of variable speed transmission more at length.

MANUFACTURERS' NOTES.

The National Tool & Stamping Co., is the name of a new concern erecting a factory at Wayne Junction, Philadelphia, Pa. They will manufacture special tools and dies, and do general sheet metal stamping.

The Resck Machine Tool Co., Cleveland, O., are erecting a three-story brick factory building on Quincy and Craw Sts., for the manufacture of machine tools and steel balls, the latter formerly manufactured by the Cleveland Ball & Screw Co.

The Q. & C. Co., Chicago, Ill., recently made a shipment from their factory at Chicago Heights, of one of the largest special metal sawing machines to the United States government, to be used at the Cavite Navy Yard, Manila.

J. T. Slocomb & Co., Providence, R. I., have just put out a new morocco case, plush-lined, to hold their Nos. 1, 2 and 3-inch machinists' set, listed as No. 21. The special advantages of this case, which is illustrated in their advertisement in this number is that it can be readily laid in the tool box.

The name of the system of cost keeping devised by W. S. Rogers has been changed from "Universal Cost System" to "Industrial" Cost System. For information about this system Mr. Rogers should hereafter be addressed care The Bantam Mfg. Co., Bantam, Conn., instead of Keene, N. H.

The Joseph Dixon Crucible Co., Jersey City, N. J., published in their December number of "Graphite," an article on the experiments of Prof. W. F. M. Goss, of Purdue University, on the use of Dixon's graphite in air-brake equipment. These experiments are not only interesting but of value to all who have to do with locomotive engineering.

Mr. Daniel W. Pedrick is no longer connected with the Pedrick & Ayer Co. His entire time and attention are now given to the H. B. Underwood Co., of which firm he is the senior partner. He has been a partner of this firm since its organization, and is superintending the turning out of high-grade portable cylinder boring bars and other portable tools for railway repair shops for this firm.

George William Hoffman, 295 East Washington St., Indianapolis, Ind., manufacturer of the U. S. Metal Polish and "Barkeeper's Friend," informs us that the demand for his product has greatly increased this year. This paste is sold in powdered and fluid form and is used for polishing gold, silver and plated ware, nickel, tin, brass, copper, etc.

The Fox Machine Co., Grand Rapids, Mich., manufacturers of wood-working machinery, have just completed a four-story addition to their plant. They have purchased a larger engine, increased the boiler capacity and erected a new pattern storage building. They report that they have found these additions necessary owing to their rapidly increasing business.

The Crocker-Wheeler Co., Ampere, N. J., manufacturers of electrical machinery, report the shipment of eighteen orders for engine type generators of various sizes, to different parts of the United States. They state that their new mill building is now being occupied, enlarging their floor space by 60,000 square feet, and giving increased facilities for prompt deliveries on large orders.

W. S. Rogers, formerly of the Roller Bearing and Equipment Co., Keene, N. H., and of the Ball Bearing Co., Boston, Mass., has become the general manager of the Bantam Mfg. Co., Bantam, Conn. This company was organized two years ago for the manufacture of ball and roller bearings and under Mr. Roger's management will make the regular line of goods formerly manufactured by the companies at Keene and Boston.

MACHINERY.

February, 1903.

THE GREAT WEST-ALLIS PLANT

OF THE ALLIS-CHALMERS COMPANY, MILWAUKEE, WIS.

Edwin Reynolds.

THE views accompanying this article were recently taken at the new works of the Allis-Chalmers Co., Milwaukee, Wis., and we think all our readers will be glad of the opportunity to see how this immense plant looks now that it has so nearly reached a state of completion. The present Allis-Chalmers company operate the old E. P. Allis works, Milwaukee, as well as the new works; also the Fraser-Chalmers and the Gates Works, Chicago, the works of the Dickson Manufacturing Co., Scranton, Pa.; and they have absorbed the business of the Lake Erie Engineering Co., Buffalo, and transferred it to their other plants. The Chicago and Scranton plants build the mining machinery contracted for by the company, the latter taking some of the engine work also, leaving the Milwaukee plants free to carry on the bulk of the enormous engine business for which the company is best known to the public. The old E. P. Allis works are to be continued in operation, the same as before the new works were built, the latter serving simply to increase the resources of the company by doubling the capacity of the Milwaukee shops and to afford almost unlimited opportunity for future growth.

The new Milwaukee plant is situated at West Allis, a suburb of Milwaukee, which has the shipping advantages afforded by two railroads and is destined to become an important manufacturing village. Several other manufacturing plants have been located there and many houses are being built. The land controlled by the Allis-Chalmers company is about 100 acres in extent and if the business should become large enough to require all the buildings called for in the original plans, Milwaukee will have one of the largest groups of machine shop buildings in the world. Unlike nearly every other large establishment, however, they will not represent a haphazard growth, with buildings erected to meet present needs, without any particular regard to the future. The whole plan was carefully laid out by Mr. Reynolds, with whose name the accomplishments of the E. P. Allis company are inseparably connected. The floor areas of the machine shop, pattern shop, foundry, erecting shop, etc., as far as erected are carefully proportioned from data secured at the old works and additions to the plant may be made in such a way as always to maintain these ratios, if desired.

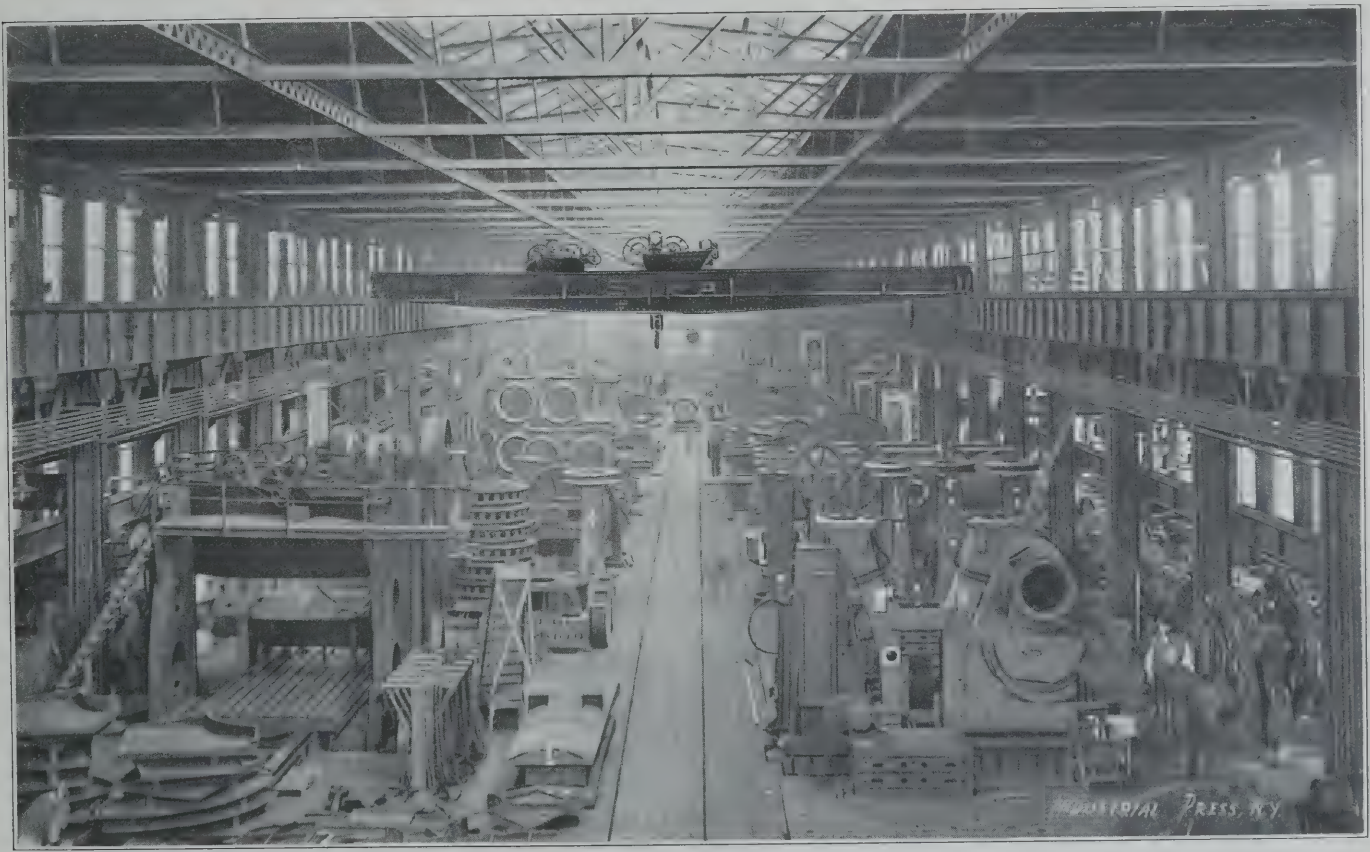

Fig. 1. One End of Machine Shop No. 1 of the West-Allis Plant of the Allis-Chalmers Co. A 10 x 12 Planer appears in the Foreground, and in the Right is a Floorplate 24 x 200 feet, on which Massive Portable Tools are used.

As shown in the ground plan, Fig. 3, the plant is constructed in units, entirely similar in principle (to use an illustration) to the unit system of filing cabinets and book cases now so generally employed in business offices. One complete unit has now been built and consists of a pattern shop and storage building, foundry, machine shops, power house, blacksmith shop, erecting shop, and yard storage, with cranes, tracks, etc. This unit consists of three buildings, the pattern shop, foundry, and erecting shop, which may be extended northward indefinitely, as indicated by the heavy dotted lines, and of three smaller buildings for machine shop and blacksmith shop purposes extending east and west.

These smaller buildings, and their proportionate parts of the larger buildings, really subdivide the main unit into three sections, and in making additions the shops may be extended to include one, two, three or more of these sections, as required; but in any case it will be possible to preserve the balance between the pattern and foundry work and the machine shop work.

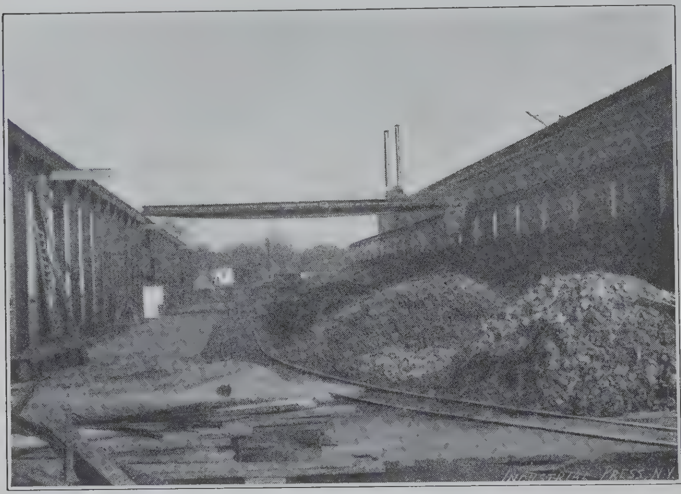

Fig. 2. Foundry Yard—Pattern Shop on the Left, Foundry on the Right.

Entering the works from the office indicated at the lower left-hand corner of the plan, the first building to be reached is the pattern shop and the pattern storage building, between which and the foundry is yard room for the storage of pig iron and coke and other supplies for the foundry. A view of this yard is shown in Fig. 2, and it will be noted that it is served by a traveling crane, supported by runways on columns. The material is brought to the yard on cars on a standard railroad track—part of an elaborate system of tracks extended through the different departments and to different sections of the yard on which the Company operate their own locomotives.

The pattern shop and storage building, as already stated, is one of the three buildings extending north and south, and which in the event of the enlargement of the works will be lengthened as much as required. The part of the building utilized for pattern storage is four stories high, with concrete floors supported by steel construction carefully protected by fireproof material. The part used as pattern shop is next to the foundry and is only one story high, giving excellent light over the whole floor area. Two views of this building appear in Fig. 5. That in the upper left-hand corner shows the pattern storage section and indicates the proportions of the structure, while that in the lower right-hand corner shows the pattern shop and part of the runway for the traveling crane mentioned above in connection with the foundry yard.

The next building to be reached is the foundry—another of the three structures running north and south. This is the building which appears at the center in Fig. 4. It is 220 feet wide, of the same length as the pattern building, and is divided into three bays, the center bay being higher than the two outside bays or wings, after the usual custom in such buildings, so as to admit side light through windows at the top. The foundry is equipped with three cupolas and approved apparatus is provided to facilitate charging with the proper mixtures of iron and coke. The traveling crane collects the material and brings it to the base of the inclined tracks shown in Fig. 6, where it is transferred by jib cranes to hydraulically-operated cars which convey it up the inclines to the charging floor above. The complete scheme embraces a pair of scales suspended from the hook of the traveling crane by which the pig or scrap iron

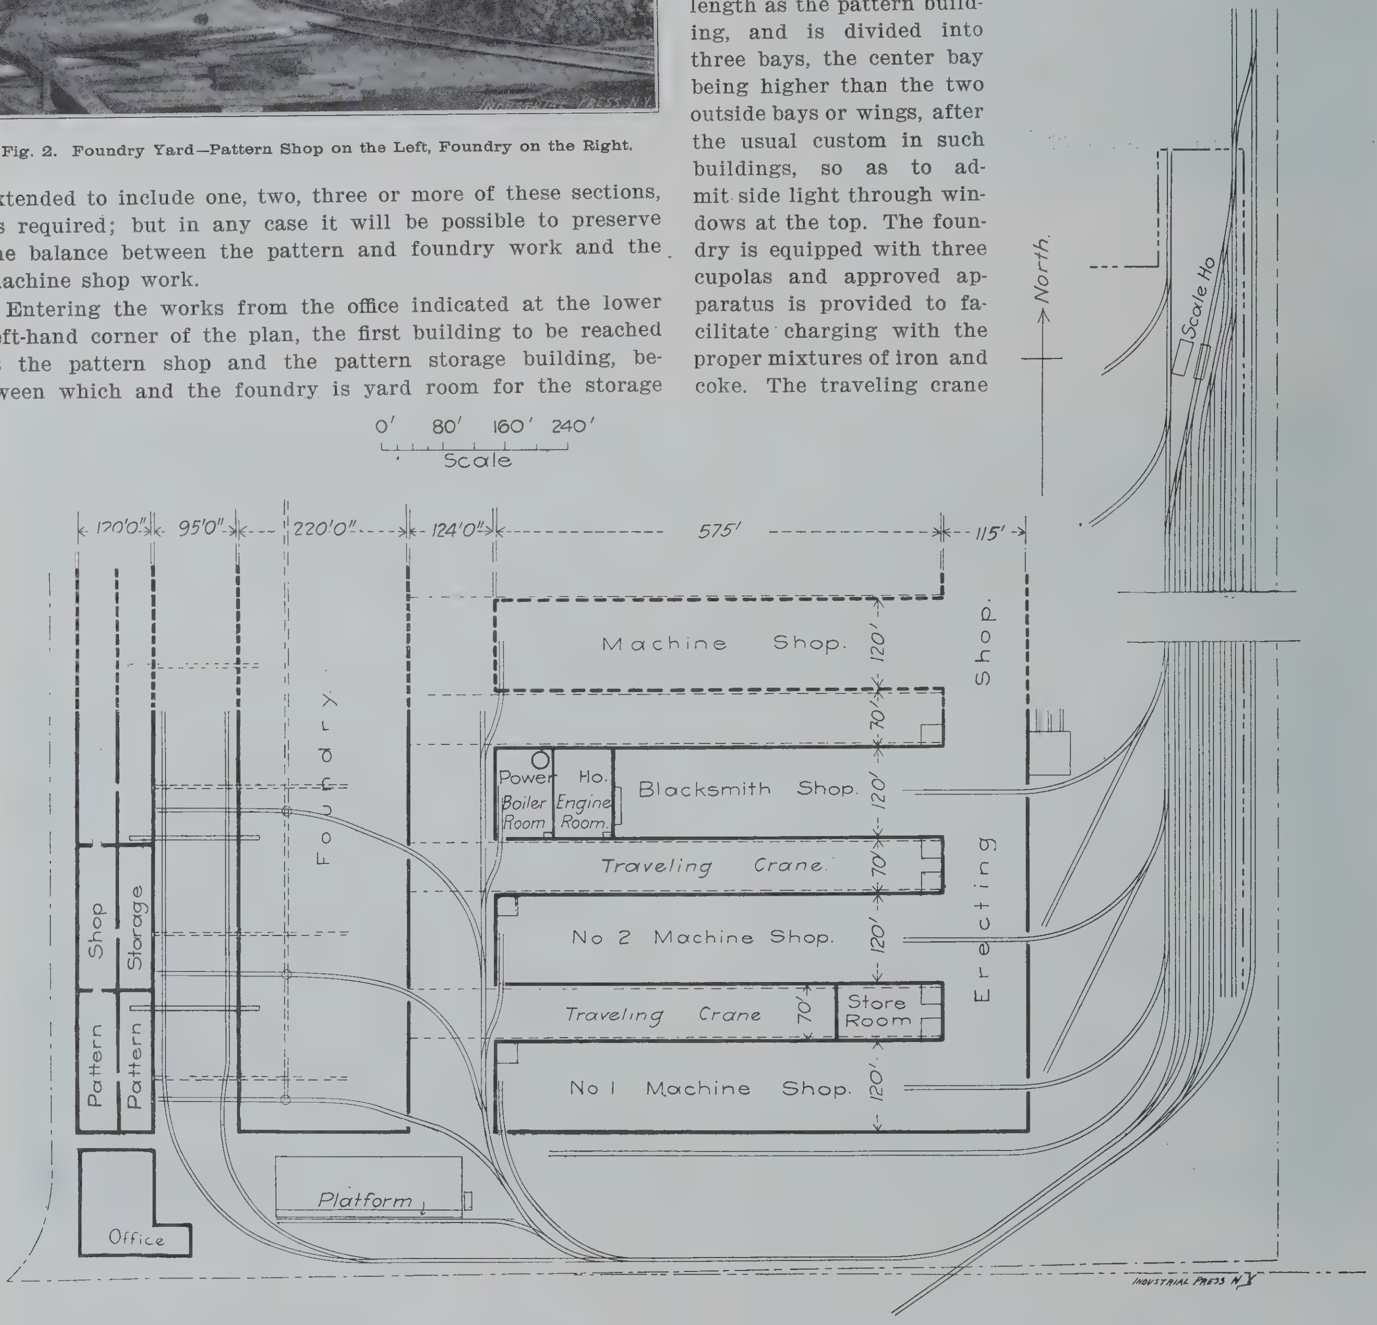

Fig. 3. Plan of the new Allis-Chalmers Plant.

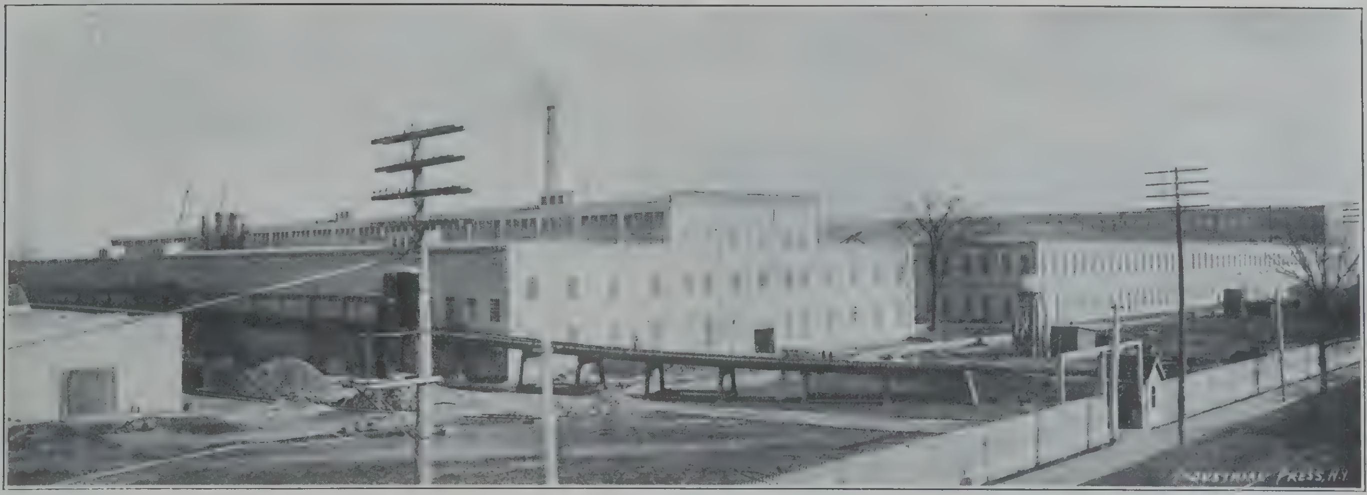

Fig. 4. General View of the New Works, looking Northeast. The Building in the Center is the Foundry. On the Right is Machine Shop No. 1, connecting with the Erecting Shop at its further end.

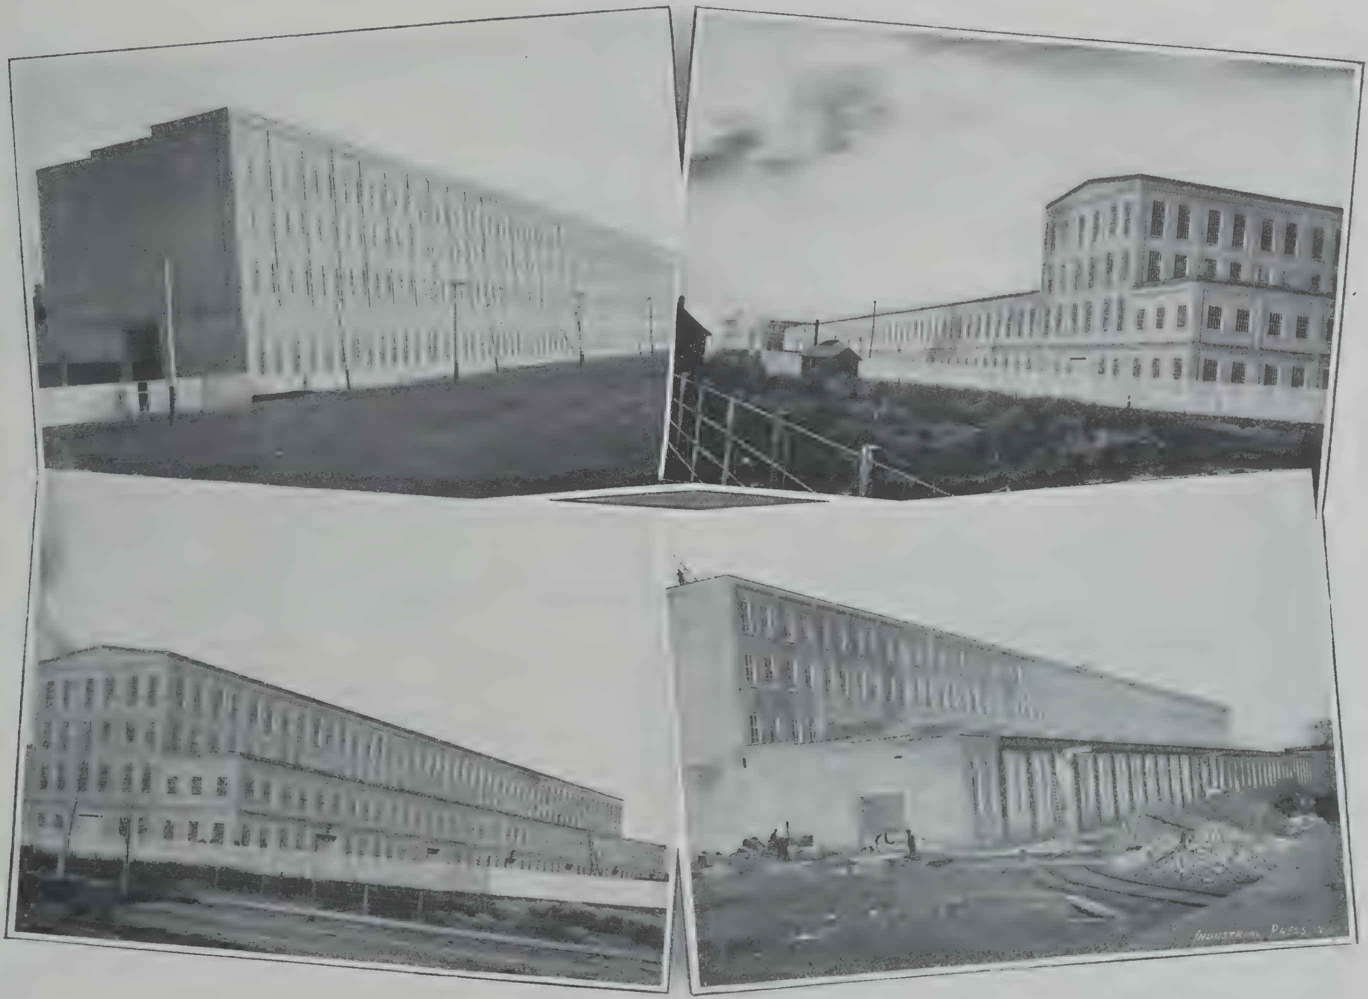
can be weighed before being deposited at the base of the inclines.

It has already been mentioned that the foundry yard is served by a railroad track, but to facilitate the disposal of sand and other material within the foundry itself there is also an elevated track, indicated clearly in the general view, Fig. 4, and which runs adjacent to the foundry one side of the building. Supplies of sand or other material are drawn up onto this track and discharged into bins provided for them, without further handling.



Pattern Storage Building.
Erecting Shop, looking Northwest.

End of Erecting Shop and No. 1 Machine Shop, looking Northwest.
Foundry Yard and Pattern Shop.

Fig. 5.

Next in order are the three buildings running east and west—two of which serve the purpose of machine shops and the third as a powerhouse and blacksmith shop. Beyond and communicating with these is the erecting shop shown in the lower left-hand view in Fig. 5. One end of it also appears in the upper right-hand view of this group, and in the distance is the No. 1 machine shop which adjoins it. Each of the machine shops and the blacksmith shop is 120 feet wide and 575 feet long. Shop No. 1 has a central crane span of 67 feet with two cranes of 80,000 pounds capacity. The sides are constructed on the gallery system and have auxiliary cranes of 20,000 pounds capacity. An interior view of this building is shown in Fig. 1. In shops Nos. 2 and 3 we believe the crane equipment is somewhat different, being adapted in each case to the class of work to be done. Most of the heaviest machine work is done in shop No. 1, which contains several unusually massive and striking machine tools. The main feature of the building is a floorplate 24 feet wide by 200 feet long, embedded in a substantial concrete foundation and equipped with several very massive tools of semi-portable character for machining the heavy frames and other engine parts that can be more conveniently and quickly handled by the floorplate system than by any other method.

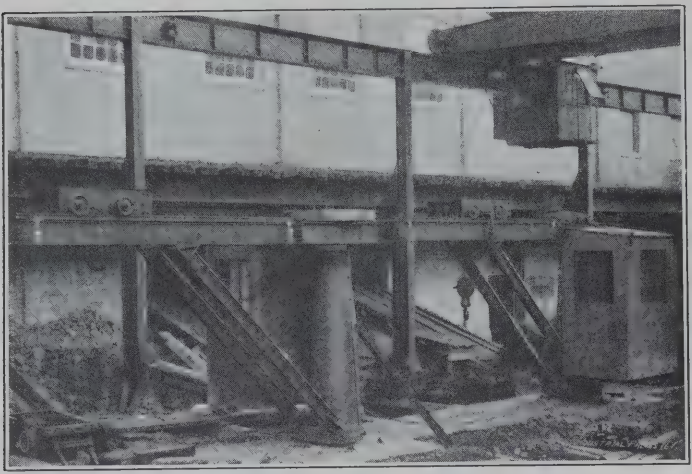


Fig. 6. Jib Cranes and Inclines used in Charging Foundry Cupolas.

The construction of this floorplate is the result of much study, and it is believed to be so substantial that it will stay in alignment a long time. There is ample provision, however, for adjustment, should it get out of level. The floorplate is built up of deep cast-iron sections 24 feet long by 8 feet wide, heavily ribbed and having T-slots for clamping tools or work. At intervals there are depressions in the upper top surface of the floorplate, for accommodating the projecting ends of foundation bolts and their nuts, and also the heads of the adjusting screws which, in each case, are placed beside the foundation bolts. These adjusting screws extend through the floorplate and bear against a small cast-iron plate embedded in the concrete, so that by slackening on the foundation bolt and turning the adjusting bolt the plate can be raised or lowered to bring it into adjustment; then, when the nut on the foundation bolt is again tightened the plate will be held solidly through the binding or clamping of the two bolts. After adjusting the sections of the plates in this way and leveling them, they are grouted in with cement.

The machine tool equipment of the floorplate is a remarkable collection of tools and indicates a disposition on the part of the management to provide every facility for turning out the heaviest class of work economically and accurately. Among other floorplate tools are two large Morton traveling shapers, 48x48x72 inches and one 72 inches by 72 inches by 11 feet, the latter being the largest shaper of this type ever built. The ram of this machine is of steel, cast hollow, 10x12 inches in cross section. The length of stroke is 72 inches, the saddle carrying the ram will feed vertically on its supporting column a distance of 6 feet, and this column in turn will feed on the bed of the machine 11 feet. The saddle is counterbalanced by an air cylinder on the rear of the column, furnished with pressure by a small compressor, motor-driven. The machine also has a milling attachment whose arbor is 6 inches in diameter, and may be used either for boring or milling, and which carries a 12-inch mill on its outer end. As in all Morton shapers this machine works with a draw cut.

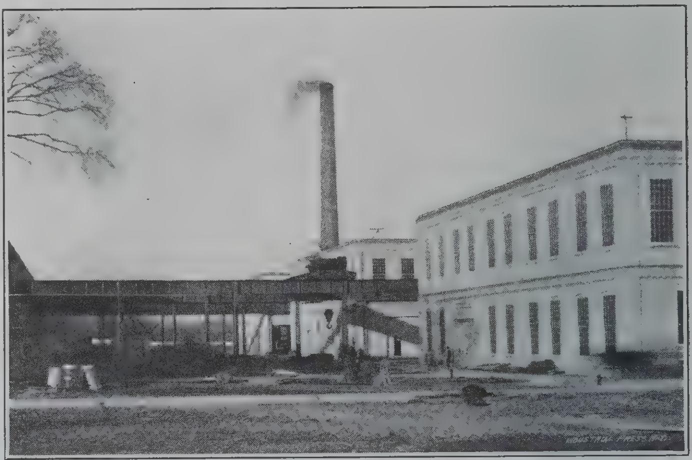

Fig. 7. Showing Runways for Traveling Cranes which Operate between the Machine Shops.

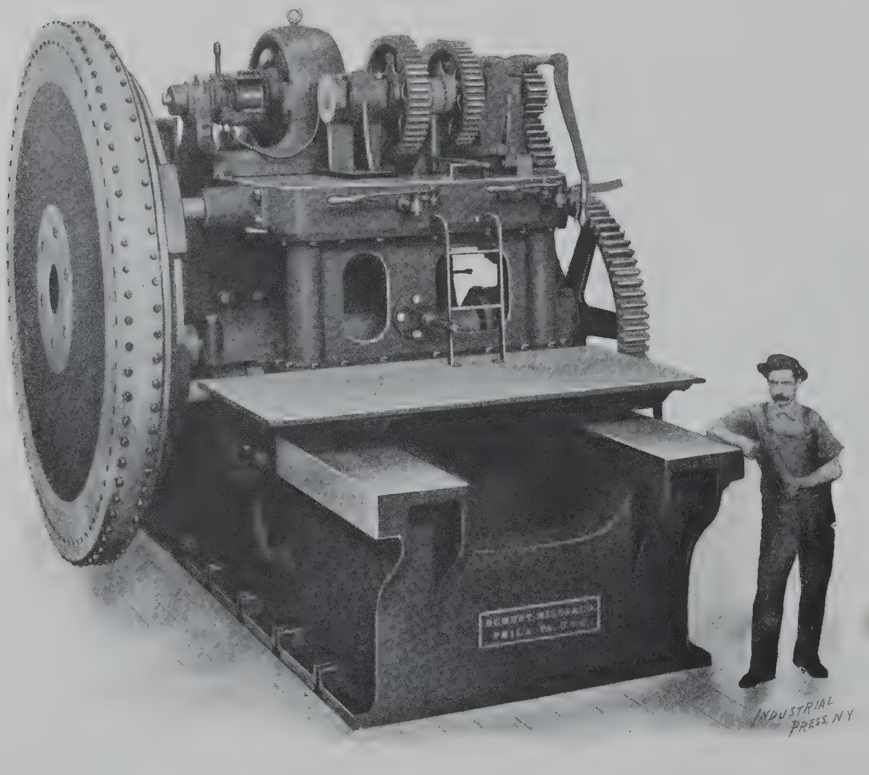
The most striking tools on the floorplate are a pair of 10-foot rotary planers built in the Bement-Miles shops in Philadelphia and which are the heaviest and largest tools of the kind we have seen. A view of one of them appears in Fig. 8. The cutter heads of the planers face each other and one of the machines will ordinarily remain in a fixed position while the other can be adjusted so as to take in work of greater or less length or width between the cutter heads. The movable machine is provided with rollers and is so designed that it can be raised off the foundation and supported by these rollers to facilitate moving along the floorplate, thus bringing it approximately to the correct position. The final adjustment is obtained by an endwise movement of the main spindle of either planer which can be adjusted out or in a distance of 7 inches. The following specifications of the machine were kindly furnished us by the builders. The saddle has a traverse of 16 feet on a bed 26 feet long. The faceplate is 10 feet 7 inches outside diameter and holds 75 cutting tools. There are three cutting speeds—of 22, 30 and 40 feet per minute, with feeds of 2, 4 and 8 inches per revolution, or an equivalent of 10 inches per minute at 40 feet cutting speed. A moment's thought on the part of the reader will show what this means in the way of rapid surfacing by comparison with the usual methods of removing stock. All of the gearing and clutches are mounted on a platform and are controlled by levers within reach of the operator, who need not change his position at all. For heavy surfacing, provision is made for backing up the periphery of the faceplate by means of adjustable slides that can be brought solidly against its inner surface.

Of the other interesting tools in this shop may be mentioned a 12x10 and a 10x10 planer, the former planing work 30 feet long, and two large boring mills, one 12x12 and the other 12x14, furnished by the Niles-Bement Pond Co. The largest planer appears in the foreground in Fig. 1. There is also a port boring machine of somewhat unusual



One of two 10-foot Rotary Planers in use on the Floor Plate of Machine Shop No. 1.

construction, built by the Grant Tool Co., Franklin, Pa. This was described in the June, 1902, number of MACHINERY.

The galleries of this building and of machine shop No. 2 are equipped with a great variety of smaller tools, furnished by different builders, which we will not undertake to enumerate; though it may be mentioned that a conspicuous installation is the large number of lathes furnished by the Lodge & Shipley Machine Tool Co. An interesting device in shop No. 2 is a dashpot-testing apparatus by which the valve gear mechanism of an engine can be run for any length of time and up to any speed. It is interesting to note also that the dashpots and similar engine parts are made on turret lathes, being turned out in quantities just as are the small parts of any machine which is manufactured by modern methods.

In the blacksmith shop there are, at present, four steam hammers, the largest being of 12,000 pounds capacity. Oil burners are used for the heating furnaces. On the outer end of this building, room has been left for the installation of the power plant, and at the time of the writer's visit one unit was running, and others were in process of erection. The engines are to be of the Reynolds-Corliss vertical type and there will be one unit of 100 K.W., one of 350 K.W., and one of 500 K.W. capacity. There is room here for two more 500 K.W. units, to meet future requirements. Both Westinghouse and Crocker-Wheeler generators are used and the Bullock multiple voltage system is employed for the distribution of the current in the works. The crane equipment throughout the plant is by Pawling & Harnischfeger, Milwaukee.

Continuing now to the erecting shop we find a building running north and south, 115 feet wide by nearly 560 feet long, arranged in two bays, one of which has 60 feet head room under the crane hook, served by a 75-ton crane. A 40-ton crane will be installed later. This section of the shop will be for assembling vertical engines, pumping engines, etc., which can be completely erected here before shipment. The other bay of the shop has 25 feet head room under the crane hook and will be used for the collecting of parts before they are needed for the erecting floor, and for shipping. The general design of the erecting shop and its relation to the machine shops which connect with it will be evident from the upper right-hand view in Fig. 5.

The first essential in an erecting shop is a substantial floor, and this has been secured by laying two feet of solid concrete on top of the clay soil which serves as foundation for all the buildings. Oak stringers were embedded in the concrete and leveled by the aid of a transit and grouted in. On these stringers a heavy plank flooring was laid.

The track and yard arrangements of the West Allis plant are complete in every respect. Connection is to be had with the Chicago, Milwaukee and St. Paul Ry. at the north, and with the Chicago and Northwestern Railway at the south.

Ranged on the easterly side of the yard are the tracks for the reception and shipment of freight, with spur tracks running into the erecting shop and to other sections of the yard. As represented in the drawing, Fig. 2, there is a break in the continuity of the tracks, this being done in making the sketch, because it was desired to show the arrangement of the upper or northerly switches, which in reality are beyond the limits indicated by the drawing. The switches are so placed that two tracks are open to the C. M. and St. P. Ry. for shipment or delivery, and two to the C. & N. W. Ry. for the same purpose. One of the tracks, in each case, is to be used solely for cars that are being loaded for shipment, and the other for cars containing freight to be delivered. This plan will reduce to a minimum the amount of switching to be done.

Beginning at the right, the first track is to be used for connecting the two railway systems. The next two are the shipping and receiving tracks for the C. M. & St. P.; the next two are for the C. & N. W.; and the next three are tracks through which connection may be had with the shops, foundry, and all the various departments of the works. To reach these tracks, however, by either railroad system, it is necessary that cars should pass over the single track at the north part of the yard, where the scales are situated, as indicated on the plan, thus ensuring that no supplies shall enter any part of the works without first being weighed and checked.

The yard crane equipment is no less complete than the railroad facilities. The crane arrangement between the pattern shop and foundry has already been described. There are traveling cranes similarly arranged between machine shops No. 1 and 2 and between the latter and the blacksmith shop, the runways for these extending across the yard space between the easterly ends of these shops and the foundry. In Fig. 7 the ends of these three buildings appear, and the crane tracks and one of the cranes are clearly visible. In the distance is the stack of the power plant.

It is a fortunate and pleasing circumstance in the life of Mr. Reynolds that he has lived to see the culmination of his efforts in the design and completion of this plant. He is over 70 years of age and his life has been marked by aggressive and original work in various branches of constructive engineering. Before going to Milwaukee he was prominently connected with the Geo. H. Corliss engine works, Providence, R. I., which, under the direction of their founder, became the leading works of their kind in the world. When Mr. Reynolds went to Milwaukee the E. P. Allis Co. were far from flourishing; but he has succeeded in doing with this concern in the West what Mr. Corliss did so long ago in the East; only on a more magnificent scale, and with the most elaborate plans for the future ever projected in the engine business.

* * *

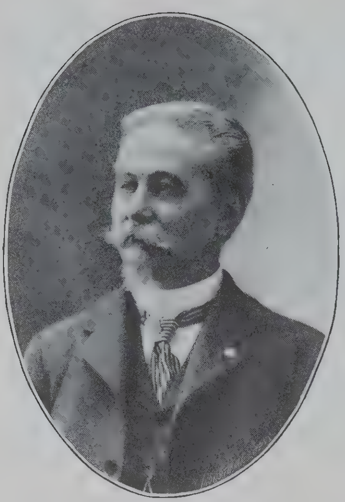
MUM'S THE WORD.

A curious tale of machine shop secrecy is told by a New England manufacturer of machines who recently made a trip to Australia and the neighboring islands, including New Zealand, where at Auckland he had the following experience: A local dealer in machinery asked the New England man if he wished to see a remarkable machine, one of which the like was not to be seen in all New Zealand. Of course an affirmative answer was given, whereupon the proprietor of a local jobbing machine shop was approached and asked for the privilege of seeing the machine in his shop. After much argument and a lengthy explanation of the visitor's business, the country from which he came, etc., the privilege was reluctantly granted. A portion of the main workroom had been partitioned off and the door leading into the little room thus made was always kept carefully locked. Even the belt holes were carefully screened so that none of the workmen in the main shop could peek through into the "holy of holies." The proprietor unlocked the door, fearfully ushered his guests within and quickly shut and locked the door behind them. There before them was a machine carefully covered with a tarpaulin which having, with due ceremony, been removed, revealed to the bewildered New England man, a Brown & Sharpe universal milling machine! His astonishment can be imagined; also his embarrassment. He did not know whether to laugh at the matter as a practical joke or to get angry, so made some non-committal remarks and withdrew as soon as he decently could. When once safely away from the shop he took his New Zealand friend to task and asked him why in the name of common sense he had been taken to see a machine with which he was, of course, perfectly familiar. The reply was that he, the New Zealander, wished to give the New Englander a practical demonstration of the difficulties which he met in selling new machinery. The proprietor of this shop had been enterprising enough to buy a milling machine and he did not propose that any of his rivals in business should get a glimpse of the machine or know anything about it. The proprietor had unboxed and set up the machine alone, and did all the jobbing work that came within its range. If the visitor had been from New Zealand or the neighboring island of Australia, he would have not been permitted to see it. So the dealer in machinery was unable to take prospective customers to this shop and there visually demonstrate to them the great advantages of the, to them, new machine.

SHOP CONSTRUCTION.—5.

FLOORS.

Oscar E. Perrigo.

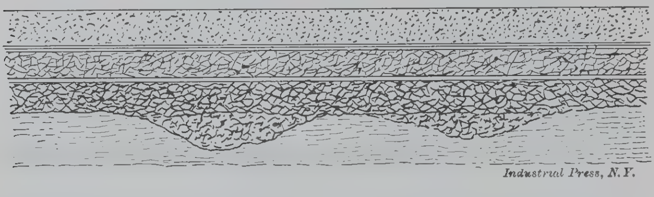


In the construction of modern manufacturing buildings there are many methods of constructing a floor, varying all the way from the almost primitive "dirt floor" of the forge shop to the close-jointed smoothly-finished hardwood floor of the modern watch factory. Those which principally concern us in these articles, however, are such as are necessary in the modern machine shop, forge shop, iron foundry, etc., and these we may properly divide into six classes, viz:

First, those composed exclusively of earth, as the floor of the forge shop. Second, those composed of earth and concrete, like the floor of an iron foundry, as shown in vertical section in Fig. 1. Third, those of stone and concrete, as the main or ground floor of a machine shop designed for constructing and erecting heavy machinery, shown in Fig. 2. Fourth, those composed of stone or bricks, as required for engine and boiler rooms, etc., shown in plan in Figs. 3 and 4. Fifth, those of wood, supported by iron beams, as illustrated in vertical section in Figs. 5 and 6. Sixth, those composed entirely of wood, as shown in Fig. 7.

There are also certain conditions which will, in a great measure, determine the kind of floor to be adopted, as, for instance, the situation, the kind of work to be done and the weights which the floor will have to support. As to materials, there are those of each kind which it might be perfectly proper to use in other portions of the work of construction, but which would be objectionable in a floor. Stone should be of such nature and quality as to remain firm and hard, with no disposition to crumble away. Hence granite is the best, although there are other kinds which are nearly as good for certain purposes, and much cheaper. Generally, such as can be obtained near the work are used, to avoid the cost of transportation.

For paving, a hard, smooth-surfaced stone is needed. Sandstone wears away easily, and, therefore the harder varieties are preferable. Slate makes a very smooth-wearing and satisfactory floor. Granite is not usually employed for this purpose owing to the expense of obtaining it and the cost of cutting. Paving bricks should be hard-burned and of a quality to insure toughness, so that they may not be easily broken by accident. Many brick companies, in different parts of the country, now manufacture bricks for street paving which possess as good wearing qualities as most kinds of stone. Gravel should be free from soil, although a moderate quantity of sharp sand is not objectionable. When earth is used in making a floor a certain amount of clay should be added, to give an adhesive quality to the mass. Sand should be clean and sharp, free from soils and alluvial earth, and not too fine.

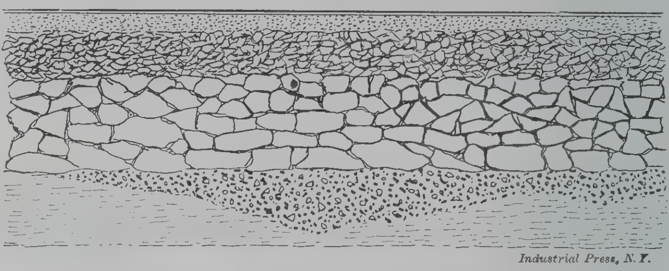


Industrial Press, N.Y.

Fig. 1. Earth and Concrete Floor.

Lumber should be so cut at the mill that the grain of the wood shall run as nearly as possible at right angles to the face of the board or plank, as shown in Fig. 9, rather than with the grain running in a direction nearly parallel with the face, as in Fig. 10. The reason for this is that the surface of the planks shown in Fig. 9 will wear smoothly even under very hard usage, while in the other case it will easily splinter up and present a very unsightly appearance, and will not last more than half as long as when properly cut from the log. Then, too, while the plank shown in Fig. 9 will warp very little, if any, that in Fig. 10 has a great tendency to warp, owing to the direction of the grain, and to the fact that the sap or outer portion of a log, being the newer growth, is less dense and consequently will contract more in the process of seasoning. Therefore the tendency is to distort the plank to the form shown by dotted lines in Fig. 10. Logs are usually cut up at the mill on the lines shown in Fig. 11. The boards taken off at the right and left, called "sidings," are trimmed on their edges separately and sold at a reduced rate, while the remaining center portion of the log is cut into stock boards, or planks of regular width and thickness.

To preserve the direction of the grain with relation to the faces of the boards or planks, the form of cutting shown in Fig. 12 would be advisable, but not as economical. This latter method is on the principle of quartering, as referred to in the furniture makers' term of "quartered oak," for instance. This form of cutting is shown in Fig. 13. It gives comparatively narrow boards, is expensive, and generally used for expensive woods, and for expensive work, as for fine furniture.



Industrial Press, N.Y.

Fig. 2. Stone and Concrete Floor.

The main, or ground floor of the machine shop being intended to sustain moderately heavy weights, both of machines and materials—as well as the hard usage in moving them from place to place, and the shocks of heavy work—is now usually made of concrete, and laid as shown in Fig. 2. In some cases those portions of floor included in the side wings are constructed of wood. This form is objectionable on account of the obstruction formed by the joining of the concrete floor and the planks; for at this point the former is apt to be cracked and broken, and the latter dented, split and defaced. This is particularly so if the planks are a trifle higher than the concrete, as is likely to be the case when newly laid down. Then, too, where such a floor is of wood it is necessary to excavate a foot or so below the floor timbers, to provide an air space for preventing the decay of the materials.

To lay a concrete floor for this purpose the earth should be excavated to the depth of from 18 to 24 inches, according to the weights which the floor is to carry. For ordinary purposes of machine shop work 22 inches is desirable and sufficient. If the ground is sufficiently firm at this level, no further preparation need be made. If soft and yielding, the excavation should be carried down to solid ground, and then filled up with solid earth, or still better with gravel, the excavation being flooded with water and the filling material thoroughly puddled as it is put in. On top of this bed should be placed a layer of coarsely broken stone, from 8 to 12 inches deep; and upon this a layer of crushed stones, none of which should exceed 2 inches in dimension. This layer should be from 4 to 6 inches thick. On this is spread a layer 2 to 4 inches thick of concrete composed of one part Portland cement, two parts clean, sharp sand, two parts clean gravel, and three parts fine crushed stone—all taken by measure, and not by weight. These ingredients should be mixed rather wet so as to settle well down into the spaces between the stones of the previous course. The concrete should be rammed hard and made perfectly level. Then comes a coating of from ½ to 1 inch thick, consisting of a mixture of one part Portland cement and two parts clean, sharp sand, which should be laid before the former course is dry, in order that the two courses may firmly unite. This last course is laid quite wet, to facilitate "floating"—that is, the levelling off and smoothing.

Sometimes the intermediate course of concrete work is made up of shingle (coarse gravel, stones, or pebbles), mixed with hot coal tar or Portland cement; but this has the objection that, whatever be the medium used for cementing the mass, it will not adhere to the rounded surfaces of the pebbles as effectively as it does to the more porous surfaces of crushed stone. Therefore, where subjected to hard usage, this shingle is more likely to disintegrate and break up, than where crushed stone is used.

The gallery floors of the machine shop are supported on built-up girders 20 inches deep, placed at each of the columns dividing the wings from the central part of the building. Carried upon angle bars riveted to the girders at a proper height, are the ends of 3x16-inch floor joists, placed 20 inches from center to center, their upper edges coming 2½ inches above the top of the girders, which space is occupied by a spiking piece. On these joists is laid a floor of 2½x6-inch planks, planed on both sides and matched with tongue and groove. This construction is shown in vertical section in Fig. 6. The girders here shown may, of course, be solid I-beams, with angle bars riveted on them for supporting the ends of the joists.

Where a lighter construction may be safely resorted to, on account of less weight to sustain, the form shown in Fig. 5 is proper. In this case an I-beam is used, say 10 to 15 inches deep, and the ends of the joists rest upon the lower flange of the beam. They should be of such depth as to project a couple of inches above the top of the beam, as shown, to provide a space for a spiking piece. In either case the ends of the joists should be beveled as shown, so that they may drop out clear in case of fire, without displacing or warping the I-beams.

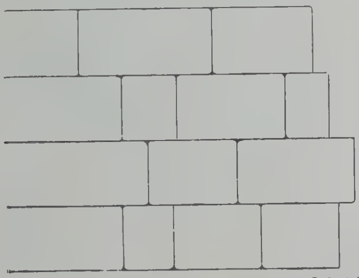


Fig. 3

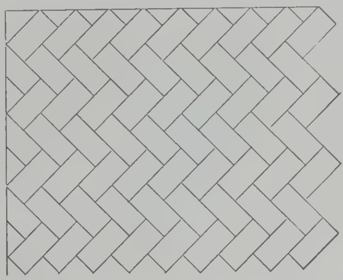

Fig. 4

Industrial Press, N.Y.

Stone or Brick Floors.

Wood joists may be dispensed with altogether, if safety from fire is of more consideration than first cost. In this case I-beams of proper strength are laid upon the girders, or with their ends resting upon the lower flanges thereof—say 4 to 8 feet from center to center—and upon them are laid planed and matched floor planks from 3x6 inches to 5x8 inches, according to the distance between supports and the load to be sustained. These are bolted to the upper flange of the I-beams. This arrangement is shown in Fig. 8. The vertical space occupied by these methods of construction varies considerably, as is shown in the engravings, and must be taken into account in designing the building.

Where it is desired to support floors by wooden beams, the form shown in Fig. 7 is proper. The dimensions of the beams must be sufficient to carry the load, taking into consideration also the distance between supports. The ends of the beams resting in the brick wall should be upon a "header course" of bricks, as shown, and the ends of the beam bevelled off the same as if used in connection with an iron girder or I-beam, so that in case of fire the beam will fall freely out of the wall without injuring it. Floor joists are laid upon the beams in the usual manner and spiked to them. Wooden floor joists should be braced by a "bridging" of, say 2x3-inch scantling, as shown, placed at intervals of from 4 to 8 feet, according to the dimensions of the joists and the weights they have to support.

In using floor planks of 3 inches or over in thickness it will be found more economical to groove both edges of the planks and insert a separate piece as a tongue, than to cut a groove in one edge and a tongue on the other.

The selection of proper lumber for floors has already been referred to. It is often profitable to consider those things that have failed since it has been well said that "we learn as much by one failure as by two successes." And the failures in shop floors are prolific sources of much annoyance and expense. A certain machine shop floor was laid upon round chestnut timbers, flattened on top and bedded in gravel laid over "made land," that is, loosely filled in with refuse matter of any sort easy to obtain. The floor proper was of 2-inch spruce planks. The result was that within a year the chestnut timbers and the under side of the planks began to decay, and since that time about one-half of the timbers, and nearly all the floor planks have been replaced each year, the patching-up process going on at intervals, and the result being an unsightly as well as expensive and annoying affair. Within a hundred feet of this floor was another of 2-inch planks laid on 3x12-inch joists, supported on 12x12-inch timbers resting on piers, raising the floor about two feet above the ground. Twelve years after this was laid some planks were removed to put in a machine foundation, and the joists and timbers were found looking nearly as fresh and new as when they came from the lumber yard. Their elevation above the ground and the ventilation of this space by small gratings in the side walls were evidently the cause of their preservation. These cast-iron gratings, say 10x18 inches, should be inserted at least every fifty feet in the walls of buildings whose ground floors are of wood, and at least a foot of ventilating space should be left between the ground and the floor.

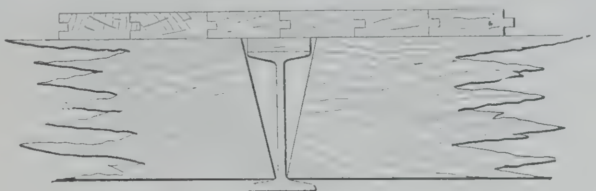

Fig. 5

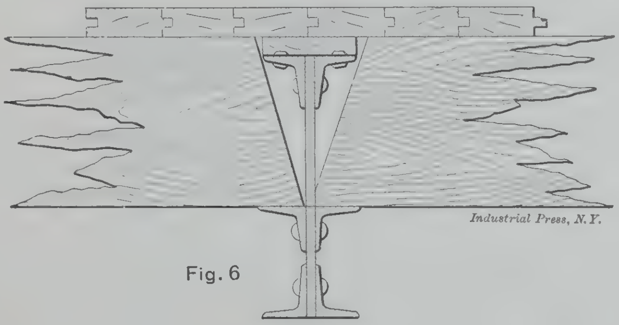
Floor Supported by I-beam.

Another example, equally instructive, was a second floor of a machine shop. It was of 2½x6-inch spruce planks, properly supported. They were grooved on each edge ¾-inch wide and strips were inserted as shown in Fig. 14. The builders evidently thought that planks 2½x6 inches, with inserted tongues, would make a good and substantial floor. And so they would have, but the unfortunate selection of the planks included many with the grain running in the wrong direction, which caused much warping and distortion. Fig. 15 is from a sketch taken at the head of a stairway, careful attention having been given to the direction of the grain and the distorted form of the planks. It is, perhaps, needless to say that the tongues were split, and in some cases the planks also.



Industrial Press, N.Y.

Fig. 6

Floor Supported by Built-up Steel Beam.

Formerly the timbers most used in ordinary construction were of spruce. While this wood is well adapted for floor planks, it has very serious objections when used as supporting timbers. There is great liability to warp, twist and crack as the seasoning process goes on, while its strength is not as great as some other easily obtained woods. For instance, hard pine is superior in this respect, while it is about 35 per cent. stronger than spruce, and its usual cost is only about 20 per cent. greater.

The foundry floor is subjected to a very considerable weight, both in molding sand and in the castings produced, but the rough usage and shocks which the machine shop floor is called upon to withstand, are not met with here. Consequently there is no need of such an expensive preparation. The ground is prepared in the same manner as for the machine shop floor, except that it is only 12 inches below the floor line. This space is first covered with a 4-inch layer of crushed stone, over which is poured a thin mixture of one part Portland cement and two parts sand, mixed rather wet. Then a concrete is made of the same mixture and finely crushed stone, and laid to a depth of about 3 inches. On top of this is spread a flowing coat of the cement and sand mixture from ½ to ¾-inch thick, which is properly levelled off. All this having thoroughly set, the remaining portion of about 4 inches is made up of molding sand.

Pits are dug in the central portion of the foundry floor, of such number, area and depth as the contemplated work renders necessary. The bottom is covered with 6 inches of concrete and laid with two courses of hard bricks. The side walls of the pits are 8 inches thick and are built of hard bricks, all laid in cement mortar. The top of the wall is level with the final cement coat of the floor. If castings of ten tons or over in weight, and with comparatively small bases are to be made in one of these pits it will be necessary to put down a more substantial bottom. Excavation should be made to solid ground, or "hard pan," and large stones laid in cement mortar built to within about a foot of what is to be the bottom of the pit. Then proceed as above for making ready for the side walls. Care should be exercised in ramming or puddling, or both, to fill in around the side walls.

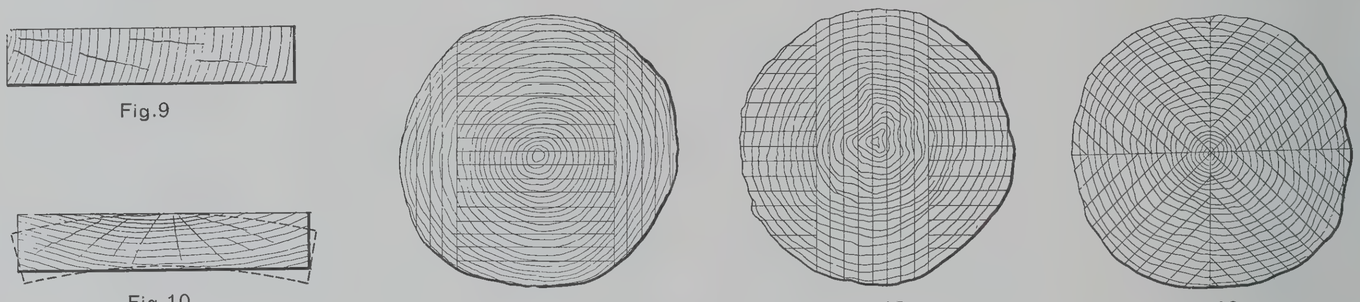


Fig.9

Fig.10

Fig.11

Fig.12

Fig.13

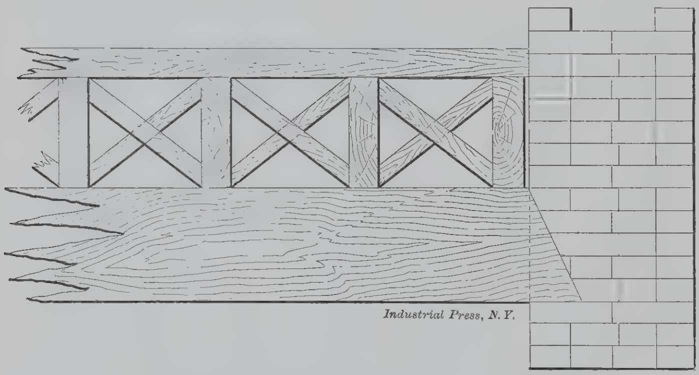
Methods of Sawing up Timber.

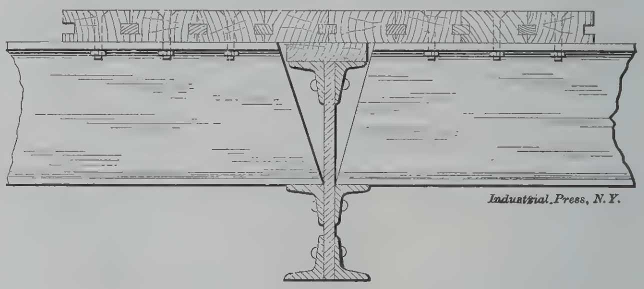
The floor of the forge shop is a still more simple matter than that of the foundry. The ground is prepared as before, and levelled off a foot below where the top of the floor is to be. This space is filled in with clean gravel mixed with clay, in the proportion of three parts of the former to one of the latter, laid down wet and thoroughly rammed down with a broad-faced rammer. Sharp sand, or the fine cinders from forges are sifted over this to prevent the surface from becoming muddy when accidentally wet. In the case of a forge shop, concrete is hardly advisable, being liable to be broken up by the heavy shocks from hammers and the rough usage to which it would be subjected. Of course it might be made thick enough to endure these conditions, but would be quite expensive and would answer the purpose no better than a hard-rammed floor of earth, as above described.



Industrial Press, N. Y.

Fig. 7. Floor with Wooden Beams.

For the floor of the boiler room, flag-stones, or hard-burned bricks may be used, whichever is found most convenient. If stones are used they should be cut to a certain width, in one direction at least, in order that they may be laid in courses so as to "break joints," as shown in Fig. 3. They should be from 1½ to 2½ inches thick. Supposing the ground to be sufficiently solid for the purpose, it is prepared by levelling, the same as heretofore described and at least 4 inches plus the thickness of the stones below where the top of the floor is to be. Sharp sand should be filled in 4 inches deep, and the stones laid upon this, the sand being rammed closely under each course as laid. When completed, dry sand to the depth of ½ inch is spread over the whole and swept back and forth to force as much as possible down through the joints. This is the cheaper and more simple method. If it is desired to make a more substantial pavement, the earth should be levelled off at such a height that only an inch space is left between it and the stones, and an inch course of a mixture of one part Portland cement and two parts of sharp sand worked up rather soft. The stones are laid on this while it is wet, and all spaces filled as each course is laid and levelled. Some masons may prefer to make this mixture with a portion of lime added, the same as in cement mortar.



Industrial Press, N. Y.

Fig. 8. Floor Supported Entirely by Steel Beams.

Should bricks be used they may be laid on either the sand or cement bed the same as described for stone, except that about half the depth of sand will be sufficient. They should be arranged in the form shown in Fig. 4, by which method they are firmly bound together, and, if laid only upon sand, will retain their places for a long time. They are in some respects to be preferred to stone. Where the ground is soft or has soft spots, it will be necessary to excavate to comparatively hard ground and then fill in with solid earth—preferably gravel—which is to be tightly rammed or puddled to make it firm. Upon this the layer of sand may be placed as described.

It is sometimes desirable to have engine room floors paved also, and occasionally with much larger and heavier stones than those described above. They should be carefully laid in cement mortar on a good concrete bed. If rolled-iron plates, or cast-iron plates are to be used they should be supported by brick piers and iron bars, or by brick walls supporting their ends, and at other points if their dimensions render it necessary. Cast-iron plates may be made with strengthening ribs on their under side, by which means the supports may be much further apart.

The modern engine room is a much better appointed department than formerly. It should have a floor of narrow, matched hard pine, smoothly levelled off by hand planing, and the surface kept oiled with boiled linseed oil. The floor of the storehouse is of 2-inch planks laid on 3x12-inch joists, placed 15 inches from center to center, which in turn are supported by timbers 10x12 inches, placed 10 feet apart, from center to center and resting on piers, leaving 15 feet between supports. If the load which this floor is to carry warrants it, this distance should be reduced to 10 feet. The floor planks may be matched if desired, but for a floor for heavy machinery storage they need not be either matched or planed. The carpenter shop floor is of similar construction to the above except that the joists are 2x10 inches, laid 18 inches from center to center, and supported at distances of 13 feet by 8x10-inch timbers, resting on piers 10 feet apart.

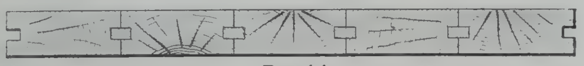


Fig. 14

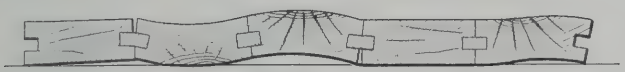

Fig. 15

Industrial Press, N.Y.

A Floor that Warped out of Shape.

The cupola platform of the foundry is of 2½-inch planks laid on 3x12-inch joists, placed 12 inches from center to center, and supported in their centers by a 10x12-inch beam, whose ends rest in the brick walls, and its center upon an 8x8-inch post. The floor, at least in the vicinity of the cupola, should be protected by sheet iron smoothly nailed down. If preferred, the floor may be constructed entirely of iron. In this case, plate girders or I-beams should carry cross supports and the floor be composed of cast-iron plates reaching from one support to the other, and having supporting ribs cast on their under sides. This form would, of course, make a much better method of construction, and in such a situation, much safer from the danger of fire, although more expensive.

The floors of the washrooms in the power house are of 1½x6-inch matched planks, planed on both sides, and laid on 2x12-inch joists placed 16 inches from center to center.

Floors in the office building, including the drawing room and pattern shop, are laid with a lining of ordinary pine ⅞-inch thick, and covered by 1⅛-inch hard pine, planed and matched, and not over 3½ inches wide, with the grain of the wood as shown in Fig. 9 The floors are laid on 3 x 12-inch joists placed 16 inches from center to center and supported by 10x12-inch beams set 12 feet from center to center. For the second floor these beams are supported on iron columns in the office and on 8x8-inch posts in the tool room, set 16 feet apart, making four posts or columns in the building 50 feet square, outside measurement. The timbers of the ground floor are supported on brick rising from the ground, which is excavated to a depth of at least three feet below the floor. One of these piers is under each post or column. In place of wooden beams and joists, iron or steel girders or I-beams may be introduced, making a construction more nearly fireproof, particularly for the second floor, but adding materially to the expense.

The floor of the pattern storage loft is of 1½-inch matched planks laid on 3 x 12-inch joists placed 16 inches from center to center and supported by I-beams 15 inches deep, one end resting in the front wall and the other on an 18-inch box girder carrying the rear wall and resting on iron columns, as shown in the plan.

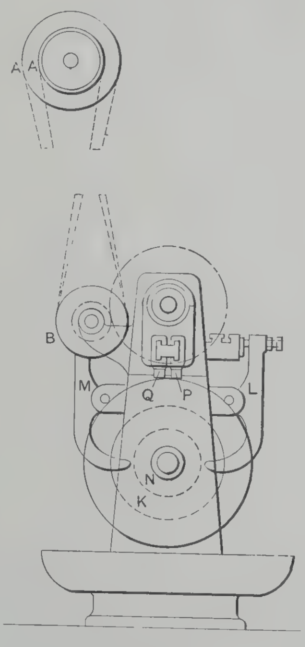

Fig. 2.

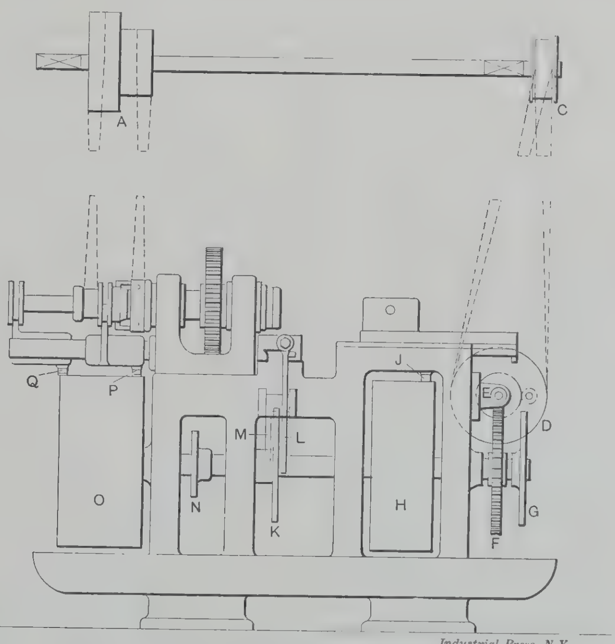


Industrial Press, N.Y.

Fig. 1. End and Side Elevation of Screw Machine.

As to the kind of lumber used in the floors of manufacturing buildings, spruce is by far the most common, and if properly selected is best for all ordinary purposes. Hard pine makes an excellent floor and is preferable where extra expense is not an obstacle. Occasionally when cost is a secondary consideration, and a perfectly smooth surface is necessary, floors of hard maple are laid and carefully surfaced off by hand-planing. This makes probably the most durable of any of the wood floors.

The writer saw a floor about 125 x 250 feet, prepared with a concrete bed and then laid on the wet flowing coat with hard maple blocks 2-inch x 4-inch x 12-inch laid on edge and in the "herring-bone pattern" shown for bricks in Fig. 4. After the concrete had thoroughly set the surface was hand-planed and oiled. Of whatever kind of wood floors are made the material should be well seasoned, and if shrinkage cracks are to be avoided, the narrower the planks are the better, although three inches may be the minimum width. If they are three inches thick or more, then six inches should be the minimum width.

* * *

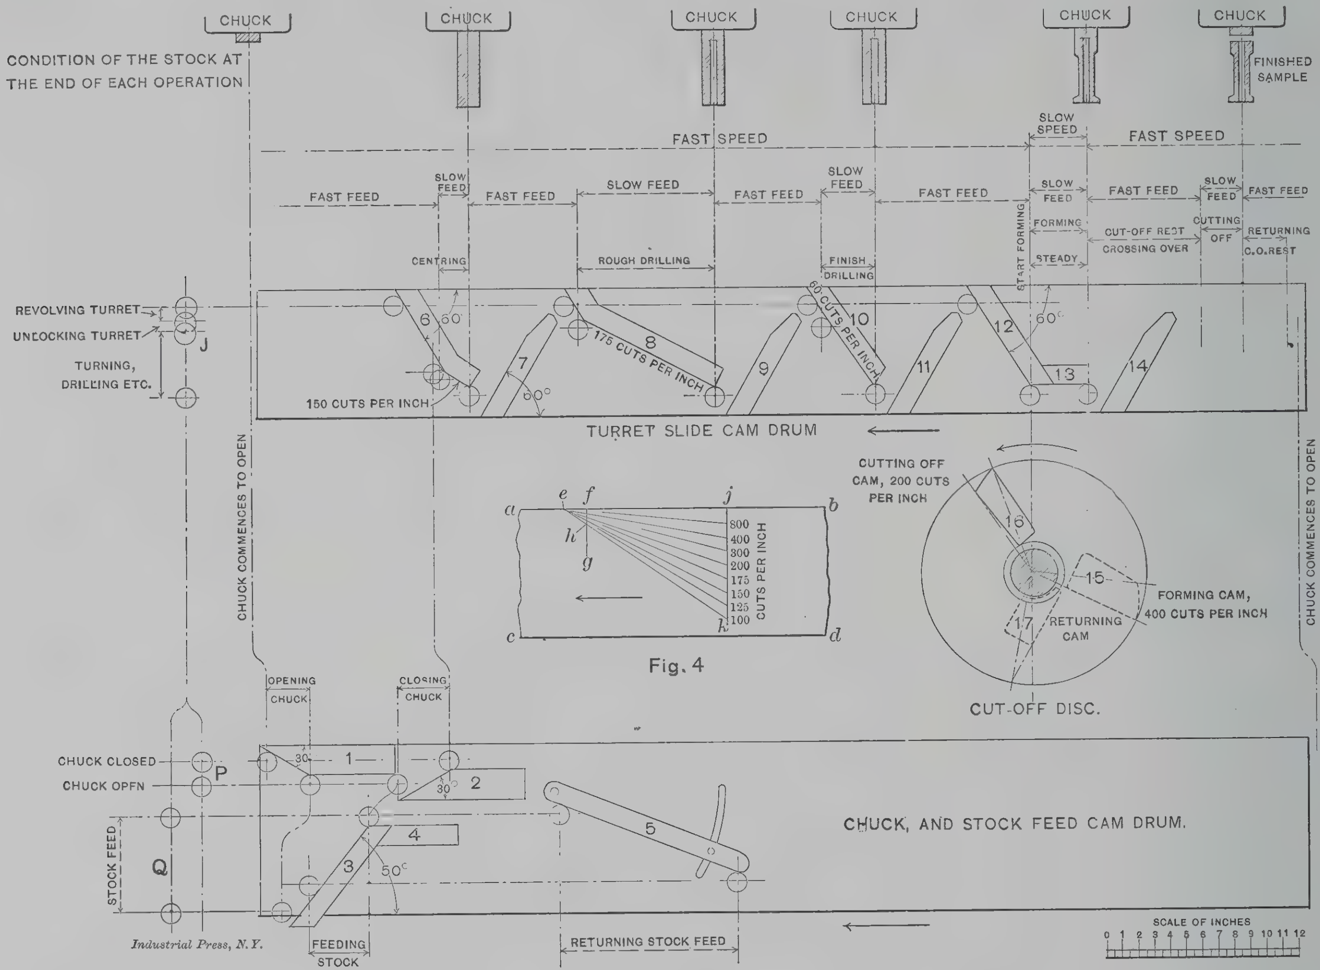
CAMMING AUTOMATIC SCREW MACHINES.

EXPLANATION OF PRINCIPLE, AND DEMONSTRATION.

Very little has ever been published on the subject of camming automatic screw machines of the Spencer or Hartford type for the reason, we believe, that the problem has been usually attacked by the "cut-and-try-method" in which "judgment" and the personal experience of the tool-maker doing the camming were the principal factors, calculations being ignored as much as possible. We do not mean by this that the universal practice is to follow this method for, happily, it is not; but the methods pursued by those who handle the problem intelligently have not, with possibly a few exceptions, been given to the public. For this reason we think the following reprint of an article on the subject by W. A. Jeboult published a few weeks ago in the *Mechanical World* (Manchester), will be found to be of unusual interest. We hope to get something on the same subject from our contributors who may be able to give information of further interest.

Fig. 1 is a side view, and Fig 2 an end view of the machine to which the cams are to be fitted. *A A* are the main driving pulleys on the countershaft. The drum shaft is driven from the countershaft by the feed pulley *C*, thus driving either of a pair of pulleys *D*, which contain a differential gear, and so can drive the worm *E* one revolution for one revolution of the differential gear pulley (the fast feed), or one revolution of worm *E* for 60 revolutions of the differential gear pulley (the slow feed), the ratio of the differential gear in this case being 60 to 1. The fast feed is used when bringing the tools, etc., up to the work, unlocking and revolving the turret, also when opening and closing the chuck, feeding the stock, etc.; the slow feed is used when the tools are actually cutting. The worm *E* drives the worm wheel *F*, and thus revolves the drum shaft to which the drums and disks are keyed. To the change feed disk *G* are clamped adjustable dogs, which engage with a pin on the end of a belt-striking lever (not shown), and so shift the belt from the fast feed differential gear pulley to the slow feed differential gear pulley and *vice versa.* The turret slide cam drum *H* has cams fixed to it, and moves the turret backward or forward by the cams pressing against the bowl (roller) *J*. As the turret is brought backward, a fixed cam on the turret slide withdraws the locking pin, and as soon as this is effected a lever engages with an indexing ring fixed to the under side of the turret, and so revolves it, thus bringing the next tool into line, the locking pin then being forced in by a spring. The cut-off disk *K*, to which are fixed the forming and cutting-off cams, etc., works the cut-off rest through the double-ended levers *L* and *M*, which are placed one on either side of the disk. The change speed disk *N* has adjustable dogs clamped to it, which alter the position of the driving belts on the head to fast or slow speed, or forward and reverse, etc., as required. The chuck and stock feed cam drum *O* has cams fixed to it, which open and close the drawback collet chuck by means of the bowl *P*, etc.; this drum also takes the cams which work the stock feed by the bowl *Q*. The following are the particulars required for the case under consideration:

Main driving pulleys *A*	Diameter 12 and 8 inches
Feed pulley *C*	Diameter 7½ inches
Back shaft pulleys *B*	Diameter 9 inches
Ratio of gear in head	3 to 1.
Differential gear pulleys	Diameter 12 inches
Ratio of differential gears, fast feed	1 to 1.
Ratio of differential gear, slow feed	60 to 1.
Worm *E*	Single thread
Worm wheel *F*	No. of teeth, 104
Cam drums *H* and *O*	Diameter 21 inches
Cut-off disk *K*	Diameter 14 inches
Bowls *J*, *P* and *Q*	Diameter 1¼ inches



Industrial Press, N.Y.

Figs. 3 and 4. Diagram showing Method followed in Laying Out the Cams of Automatic Screw Machines.

We also measure the distance from the edge of the turret-slide cam drum (see Fig. 3, left-hand side) to the farthest "out" and "in" positions of the bowl *J*, and see at what distance from the edge of the drum the unlocking and revolving of the turret take place. On the chuck and stock feed cam drum we measure the distance from the edge of the drum to the position of the bowl *P* when the chuck is closed, and again when the chuck is open; also the position of the bowl *Q* when the stock feed collet is as far forward as it will go. This position had better be taken when the chuck is open. The distance from the edge of the drum to the position of the bowl *Q*, to give the longest feed of stock that the machine is capable of taking, is also measured. Now, referring to Figs. 1 and 2, the bowl *J* is on the vertical center line, but it will be seen that the bowls *P* and *Q* are not on the vertical center line, but at equal distances on each side of it; this distance should be measured. These positions of bowls can be drawn down to any convenient scale, as shown to the left of Fig. 3. We also draw two rectangles to represent the two cam drums, developed as shown. The chuck and stock feed cams may also be drawn in. To start with, we assume that the chuck is closed, and that the bowl *P* runs up the cam 1 until the "open" position is reached. We now lay out the position of the stock feed bowl *Q* to feed the longest amount of stock the machine will feed, and at the same distance between *P* that there is between *P* and *Q* in Fig. 2. We next draw in the stock feed cam 3 just clear of the bowl, to be sure that the chuck is quite open before the stock commences to move. The bowl *Q* runs up the stock feed cam 3 (which is set at 50 deg.) until the farthest "in" position is reached; then the corresponding position of *P* can be laid out, and the chuck-closing cam 2 drawn in just clear of the bowl *P*, which runs up cam 2 and closes the chuck. The retaining cam 4 is to prevent the closing of the chuck from forcing out the stock feed. The stock feed returning cam 5 is adjustable, the amount of stock fed forward being regulated by the position in which cam 5 leaves the bowl *Q*. This cam can be put in any convenient position on the drum, but it is advisable to keep all the cams on this drum within half the circumference, so that should a job have to be done on the machine necessitating the chuck and stock feed to be operated twice in one revolution of the cam drum, the extra set of cams could be put on without displacing any already fixed. It should be noticed that in the example the stock feed cam 3 will feed forward the greatest length of stock that the machine will take, although not required in the present case. These cams can therefore be considered as standard for the machine.

The turret slide cams are not quite so simple, and a few calculations must be made previous to starting; also the list of operations and travel of tools settled. The sample under consideration is first to be centered at 150 cuts per inch; then to be rough-drilled at 175 cuts per inch; then finish-drilled at 60 cuts per inch—all these operations being done on the fast speed of the spindle. Then a steady is to run up, and the forming to be done at 400 cuts per inch on the slow speed of spindle, the steady to return, and cutting off to take place at 200 cuts per inch on the fast speed of spindle, thus using all four holes in the turret and maximum travels.

Now construct the diagram of cutting angles of turret slide cams, Fig. 4. It should be noticed that all the machining operations performed by the turret are done when the machine is running at the fast speed and slow feed, so that the diagram is to be constructed for the fast speed and slow feed only. The first thing to know is the number of revolutions made by the spindle when running at the fast speed, for one revolution of the cam drum. This can be obtained from the list of particulars, thus:

Worm wheel *F*, 104 teeth.
Worm *E*, single thread.
Differential gear shaft = 104 revolutions.
Ratio of differential gear, slow feed, 60 to 1.
Differential gear pulley $D = 104 \times 60 = 6240$ revolutions.
Differential gear pulley $D = 12$ inches diameter.
Feed pulley $C = 7\frac{1}{2}$ inches diameter.

$$\text{Countershaft} = \frac{6240 \times 12}{7.5} = 10{,}000 \text{ revolutions.}$$

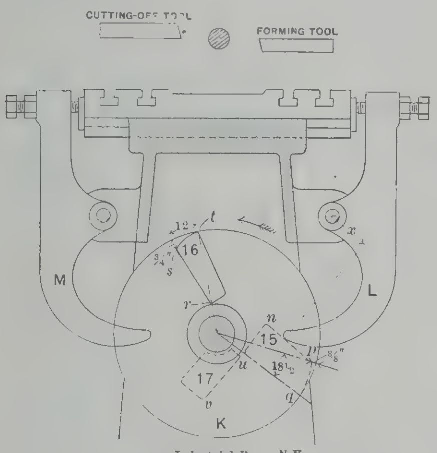
Main driving pulley *A*, fast speed, 12 inches diameter.
Back shaft pulleys *B*, 9 inches diameter.

$$\text{Back shaft} = \frac{10{,}000 \times 12}{9} = 13{,}333 \text{ revolutions.}$$

Ratio of gear in head, 3 to 1.

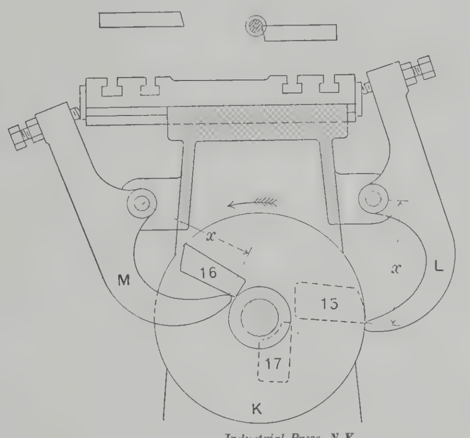
$$\text{Revolutions of spindle for one revolution of drum, } \frac{13{,}333}{3} = 4444$$

The diameter of the cam drum is 21 inches, and the circumference is 65.973 inches, so that the number of revolutions made by the spindle for 1 inch circumferential travel of the drum $= \frac{4444}{65.9} = 67.4$. Then the circumferential length of drum to equal 100 revolutions of spindle $= \frac{1 \times 100}{67.4} = 1.48$ inches. Assume *a b c d*, Fig. 4, to be a portion of the turret slide cam drum laid out flat. From *e*, at the distance 1.48 inches, drop the perpendicular *f g*, and *h*, 1 inch down on *f g* measured from the line *a b*, draw a line joining *e*. Now it will be obvious that if a cam is fixed on the drum to coincide with the line *e h*, while the drum moves from *e* to *f* the turret will move from *f* to *h*; and as the distance *e f* is equal to 100 revolutions of the spindle, and *f h* is equal to 1 inch, then the angle *e f h* is the angle for a cam to give 100 cuts per inch. For convenience it is necessary to construct the diagram larger than *e f h*, so we multiply *e f* and *f h* by any suitable number (in the example it is 7, this giving a diagram large enough to work from). To obtain any other number of cuts per inch, it will be noted that 200 is half the length of the line *j k* for 100 cuts per inch; 400 is half the length of the line for 200, and so on.



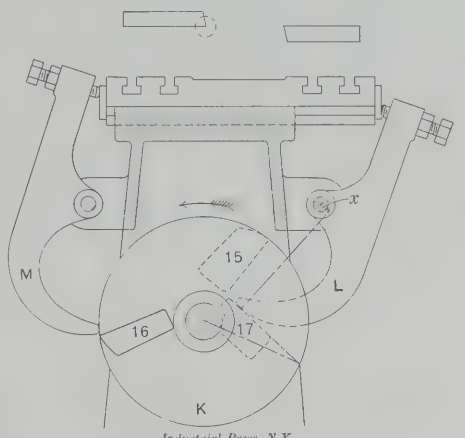
Industrial Press, N.Y.

Fig. 5.



Industrial Press, N.Y.

Fig. 6.



Industrial Press, N.Y.

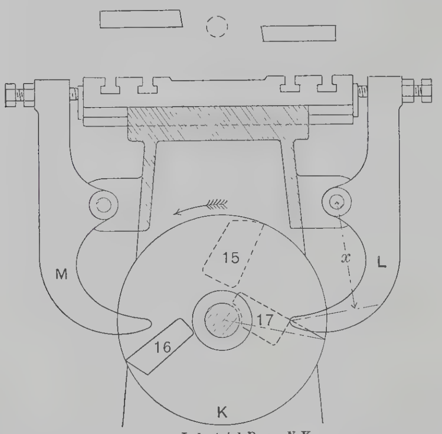
Fig. 7.

The turret slide cams can now be proceeded with. Referring to Fig. 3, while the chuck was closing, the cam 6 had carried the bowl *J* nearly up to its work, allowing a little clearance, to be sure the chuck was closed before the centering tool began to cut. The amount of travel on the slow feed for centering having been decided on, the angle of the cam for 150 cuts per inch can be obtained from the diagram, and drawn in. The bowl *J* can then be shown at the end of its travel. It is understood that no cams are to be placed on the drums that would force the bowls further than their extreme positions shown at the left of Fig. 3. The returning cam 7 can next be drawn in, allowing room for the bowl to pass between the cams 6 and 7; the end of cam 7 is taken off to revolve the turret a trifle slower, and bring the turret to rest with less shock; the rough and finish drilling cams can be treated in a similar manner to the centering cam 6.

The steady cam 12 can be drawn in, and at the position where the bowl *J* has carried the steady up to its work, a line can be erected showing where the forming is to start. The forming and cutting off being done by cams on the cut-off disk, these must be considered separately, and then referred back to the turret slide cam drum. The cut-off and forming tools are to be kept far enough apart when in the mid-position to let the box tools pass between; this is very important on some jobs.

Fig. 5 shows the cut-off rest in mid-position and the forming lever *L* about to run the cut-off rest up to the job; the cut-off and forming levers are the same length on each side of the fulcrum. For the job in hand it is necessary to form ¼-inch deep; to this we add an extra ⅛-inch for contingencies, making ⅜-inch deep at 400 cuts per inch on the slow speed of the spindle. The number of revolutions made by the spindle when on the slow speed for one revolution of the drum is 2,963, which number is obtained by the same method as used for the fast speed. The revolutions of spindle required to form ⅜-inch deep at 400 cuts per inch is $\frac{400 \times 3}{8} = 150$. While the drum makes one revolution or moves through 360 deg., the spindle on the slow speed makes 2,963 revolutions; then the number of degrees moved through by the drum while the spindle makes 150 revolutions on the slow speed $= \frac{360° \times 150}{2963} = 18.2°$, say 18½°. The portion of the cam 15 is laid out as shown in Fig. 5. The radius for *p q*, which is the part of the cam used when the forming tool is cutting, is approximately correct if taken as half the diameter of the disk; but in the case of a cam containing a large number of degrees, a correct spiral form should be used to give a uniform cut.

Fig. 6 shows the forming lever *L* after forming is finished and the cut-off lever *M* is about to move the cut-off slide across and bring the cut-off tool into action. We leave for the present the portion *s t* of the cutting-off cam 16, Fig. 5, used when machining takes place. The portion *r s* of the cam that moves the cut-off rest up to the job quickly had better be considered, and what applies to this cam, equally applies to the portion *n p* on the forming cam 15, and *u v* on the returning cam 17. It is usually necessary to move the cut-off rest over the idle portion of its travel for the least possible movement of the disk. In the present case it is necessary to move the cut-off rest after the forming is finished to where the cut-off commences, and again after the cutting is finished to the mid-position, for the least possible movement of disk, and so save a lot of idle or waste space on the turret slide cam drum. In the case of the forming cam it is of less account as there is a lot of space on the drum previous to where the forming starts that is used for returning the finish drill and running down the steady, and this space can be utilized when running the forming tool up to the job. The effective leverage *x* should be kept as long as possible, but of course the shorter the effective leverage the quicker the slide moves. Another point to watch when working on these quick portions of the cams is that the opposite lever clears the cam it is leaving.



Industrial Press, N. Y.

Fig. 8.

Having settled that portion of the cutting-off cam 16 that moves the cut-off rest up to the job, the portion *s t* that is used when machining can be considered. It is required to cut off ⅝-inch deep at 200 cuts per inch; and allowing an extra ⅛-inch, this makes ¾-inch total depth. The number of revolutions of the spindle, when on the fast speed, to one of the drum equals 4,444; the revolutions of spindle to cut off ¾-inch deep at 200 cuts per inch $= \frac{200 \times 3}{4} = 150$. Then using the same method as described for the forming cam, the number of degrees moved through by the drum while the spindle makes 150 turns on the fast speed $= \frac{150}{4444} \times \frac{360°}{1} = 12.1°$, say 12°. This portion of the cam 16 is set out as shown in Fig. 5.

Fig. 7 shows the cutting off finished and the forming lever *L* about to return the cut-off rest to the mid-position. Fig. 8 shows the cut-off rest back in the mid-position.

The disk cams have been dealt with at some length so that their action might be thoroughly understood. When laying these out it is only necessary to draw the forming lever *L* and the cut off lever *M* in the mid-position, and at the "finish forming" and the "finish cutting off" positions; then to draw the cams on a piece of tracing paper on the top, which can be moved round for the different positions of the levers, in a similar manner that the positions of the disk and levers are shown in Figs. 5, 6, 7, and 8.

These cams can now be referred to the turret slide cam drum in the following manner. From the "start forming" to the "finish forming" the cut-off disk moves through 18½°; then the equivalent distance on the drum is $\frac{65.97'' \times 18.5°}{360°} = 3.39$ inches, which can be laid off on the drum from the "start forming" line. Again, the number of degrees moved through by the disk from the "start forming" to the start cut off is 59°; the equivalent distance on the drum is $\frac{65.97'' \times 59°}{360°} = 10.8$ inches. This can be laid off on the drum from the "start forming" line, other positions being obtained in a similar manner.

Having laid down all the cams, it is necessary to see that the cutting-off tool is well clear of the job before the chuck commences to open. Possibly it will be found that it is not, in which case the cams on the turret slide cam drum and cut-off disk should be looked through to see if any space on the drum can be saved. If this is insufficient, a different size of feed pulley *C* should be used.

No hard and fast rules can be laid down as to what angles should be used, as these will vary for different machines owing to the difference in details, and hence each machine must be considered independently.

* * *

MACHINE TOOLS AND MACHINE SHOP PRACTICE DURING THE TEN YEARS FROM 1890 TO 1900.

Regarding the development of machine tools and machine shop practice during the ten years that elapsed between 1890 and 1900, Mr. Edward H. Sanborn says, in Bulletin No. 247 on Metal-working Machinery, that progress has been marked by the following significant features:

1. The automatic and semi-automatic principles have been extended to new and larger classes of work than before.
2. The forming tool has become a recognized shop appliance.
3. The "oil-tube drill" has been developed from an exceptional to a regularly used tool.
4. Compressed air portable tools have been developed substantially from the beginning.
5. The application of the power press has been greatly extended.
6. Electrical driving has come into general use.
7. The system of heavy portable machine tools in conjunction with a massive iron floor plate has been originated.
8. The grinding machine has been largely increased in size, power, and extent of use.

Closely related to machine shop practice, though scarcely coming within mechine-tool classification, may be mentioned:

9. The development of traveling cranes.
10. The origin of high-speed steels for cutting tools.

These lines of development may be discussed briefly in the above order.

1. The extension of the semi-automatic principle, as illustrated by the hand-operated turret lathe, has been chiefly toward the execution of larger and heavier work, while the use of the entirely automatic turret lathe has been not only in the same direction, but has been adapted to entirely new classes of work. An illustration of the first line of development is found in several types of turret lathes which, although employing certain methods of attacking the work which were not known before their advent, is nevertheless essentially an extension of the turret principle to larger work than had before been done by it.

An illustration of the second line of development is to be found in the "magazine feed" full automatic turret lathe. Prior to the advent of this machine, the full automatic machine had been employed exclusively for making screws, studs, etc., from bar stock which was fed to the machine through the hollow live spindle, the pieces being first turned, threaded, etc., and then cut off, when the bar of stock was fed downward and another piece made, the operation continuing until the bar of stock was used up. The new machine applied the automatic principle to the machining of parts which, when in the rough, were already in separate pieces, i.e., castings or drop forgings. In doing such work the finished piece must be taken bodily from the machine and a new rough piece inserted. This is a fundamentally different operation from merely pushing a long bar of stock to a new position. It is effected by the "magazine feed," the magazine being filled with rough parts by the workman, these parts then being automatically inserted in the machine and removed therefrom when finished. The line of development exemplified by the machine first mentioned belongs to the entire decade, while that exemplified by the other belongs to its close.

Another line of development in this class of machines which should be mentioned is the use of multiple spindles, whereby the output of certain classes of work is very greatly increased—to the extent of a threefold ratio in some instances. An outgrowth of this development has been the making of small brass screws and similar articles without money consideration, the chips cut off in making the articles being accepted as sufficient payment for doing the work.

2. The use of the forming tool goes back of the decade under consideration, but its use prior to 1890 was chiefly, if not entirely, for the making of articles from very soft composition castings, examples of the work being seen in the caps of salt and pepper boxes. The application of the principle to harder material came about in connection with the bicycle industry, one of its final applications to articles of steel being in the making of bicycle-wheel hubs. If this is not the first application of the method to steel, at least it familiarized the mechanical public with it, and from this it has come to have quite an extended application.

3. By the "oil-tube drill" is meant a drill—either flat or twist—having an oil tube or oil channel leading to or near its point, through which a current of oil may be forced to lubricate and cool the cutting edges and to wash away the chips. It is used chiefly for deep drilling in steel and usually in machines of the lathe class, in which the work revolves against a fixed drill, although the arrangement is also used in upright drilling machines, in which the tool revolves. The history of this appliance is almost exactly parallel to that of the forming tool. It was known and used to a limited extent before 1890, having first been used for the drilling of gun barrels; but its more extensive application must, like that of the forming tool, be credited to the bicycle industry, the development of the two tools being, in fact, simultaneous. The forming tool having been successfully applied to the machining of the outside of bicycle-wheel hubs, it was found that a portion of the gain due to its faster action was lost because the simultaneous drilling of the hole required more time than the work upon the outside of the piece. This condition of things led to the adoption of the oil-tube drill for this work, and from this application the use of the appliances has become widely extended. Of the two, the oil-tube drill is no doubt the more important. The increasing use of hollow-spindle lathes and automatic and hand-operated turret lathes, in which the spindles are necessarily hollow, not to mention milling and other machines having hollow spindles, has given a wide field of usefulness to this tool.

4. The numerous class of small and unpretentious pneumatic tools which came into prominence and extended use during the decade under review may, it is quite possible, be looked upon as the most important single machine tool development of the decade. Of these, the first in order of importance as well as of time is the pneumatic hammer. Originally devised as a substitute for the hand hammer and chisel in the machine shop and in stone-cutting, it has extended its field of usefulness to many other fields, and is to-day an indispensable tool in shipbuilding and in the erection of steel-frame buildings. Of the general class of compressed air tools, the next in importance to the hammer is perhaps the rotary drill, which, in its numerous forms and applications has introduced mechanical power in place of hand labor for classes of work to which the application of mechanical power seemed almost hopeless. These and numerous other applications of compressed air to machine and similar work stand almost wholly to the credit of the decade 1890 to 1900, the hammer alone having been in use prior to 1890.

5. The great expansion in the use of power presses which has taken place during this decade must be credited largely to the growth of the electrical industries. The advent of the laminated armature for electric generators and motors called for accurately-made punchings of sheet metal of a size and in numbers previously unknown. The power press furnished the natural method of making them, and in its development the capabilities of the machines were demonstrated as they had never been before.

6. The electric motor as a means of driving machine tools was first seriously proposed about or shortly before the middle of the decade, and was generally looked upon by mechanical men as a fad of the electrician. The innovation nevertheless obtained a foothold, and advantages which were not foreseen were found to attend it. It has become the accepted method of driving factories (*a*) which are composed of many departments, the flexibility and economy of the system in distributing power over a considerable area from a central station being here the factor of dominating importance, and (*b*) those which are of a nature requiring tools and machines to be located at considerable distances apart, especially if they are also to be intermittently operated. It is also making rapid progress in machine shops, to which the above limitations do not apply, though in such applications opinion regarding its merit is still unsettled. A leading controversial point is the attachment of individual motors to each machine tool *versus* group-driving of several machines through a single motor and a line shaft. There are well-defined conditions under which each method is suitable, but there is still a wide intervening field of debatable ground. As a matter of fact, in this field the individual motor is making rapid progress—more so perhaps than can be readily explained.

7. Like the increased development of power presses, the floor plate portable tool system of attacking heavy work must be credited to the electrical industries, which in this instance, curiously enough, furnished both the work for which the system was first devised and the means for doing the work. It was to the machining of the ring or magnet frames of large electric generators that the system was first applied, and the electric motor supplied the only practicable method of driving the tools which form part of the system. The system has not yet found much application outside of electrical work, although a beginning has been made, and this growth will doubtless continue.

8. The grinding machine was first devised during the past decade as a means of doing superior work, but it was not long before it became evident that it was a source of economy as well as a means of securing superior workmanship. The full significance of this was, however, slow to be realized, and it was not until toward the close of the decade that the movement began toward a very marked increase in capacity, weight, and power of the machine.

9. In no feature of machine shop practice has there been greater progress in American shops during this decade than in the provision of crane facilities. Twenty years ago the absence of these facilities was a national reproach, but to-day there is undoubtedly better crane service in the United States than exists elsewhere. This development is to be credited to the electric motor, without which it is at least doubtful if the present stage of progress could ever have been reached. The mere transmission of the power required for cranes of present capacities by the old square shaft or flying rope would be a serious problem. Electricity furnishes, in fact, an ideal method of driving cranes, and the necessary installation of an electric plant for operating cranes has no doubt greatly furthered the adoption of electric power for other purposes.

10. Within the last few years discoveries have been made whereby certain classes of tool steel are made to endure cutting speeds which before were impossible. Like all other

useful things these steels have certain limitations and it is too early to state definitely what their ultimate economic importance will be. It is reasonably certain, however, to be considerable.

* * *

STANDARD EQUIPMENTS FOR MOTOR-DRIVEN PLANERS.

The G. A. Gray Co., manufacturers of planers, Cincinnati, O., have devoted a great deal of attention to the arrangement of motor drives for their machines, and have so systematized the methods for motor attachment as to have certain standard forms of brackets and connections between motor and planer adapted to all requirements. They are prepared to furnish three different types of standard drives for their spur-geared planers and two types for their spiral-geared planers.

A motor drive is made up of two parts, the electrical, or motor equipment, and the mechanical, or supplementary equipment, which latter includes the countershaft, pulleys, etc., with brackets cast on the housings, and shelf fitted to same, for supporting the apparatus. These latter are so designed as to be adapted to any type of motor that may be applied to the planer, so that it will not be necessary to prepare special drawings or patterns to meet the needs of different customers. Thus, if a customer orders a planer and states that he wishes to use a motor of certain make and which runs at certain speed, the particular style of drive adapted to the specifications is selected and the brackets are cast on the housings from the regular patterns in stock.

The three types of motor drive adopted for the spur-geared planers are as follows:

The silent chain-geared drive, Fig. 1 on the opposite page;
The direct-connected drive, Fig. 2;
The motor-belted drive, Fig. 3.

The two types of drive for the spiral-geared planers are:

The self-contained drive, illustrated in Fig. 4;
The motor-belted drive, illustrated in Fig. 5.

It will be noticed that the silent chain-geared drive, Fig. 1, is entirely self-contained, and permits the use of a medium or high speed motor, instead of the more expensive slow speed motor required for the direct-connected drive shown in Fig. 2. The countershaft is mounted on a shelf, bolted to brackets cast on the housings, and is driven by means of a Renold silent chain, from a motor mounted close to it on the same shelf.

With such necessarily short center distances, a belt might not work satisfactorily, and spur gearing might gradually wear noisy, on account of the difficulty of maintaining the permanency of alignment necessary to smooth and quiet running.

The silent chain may be run slack and cannot slip like a belt. It does not require fixed centers, as is essential with gearing. It is, therefore, peculiarly adapted to this type of drive.

The direct-connected drive, Fig. 2, is also entirely self-contained. The motor is mounted on a shelf, bolted to brackets cast on the housings, and the driving pulleys are placed on the motor shaft; thus making it possible to belt directly down to the planer.

This type of drive makes it necessary that the motor run at countershaft speed; and the motor-shaft must be extended to carry the driving pulleys, and the pulley which operates the power-elevating device. In order to relieve the motor bearing from the undue strain, an independent outside bearing is furnished.

The motor-belted drive, as shown in Fig. 3, permits the use of a medium or high-speed motor, the pulleys being so proportioned that the countershaft will be run at regular speed. This countershaft is mounted on a shelf, bolted to brackets cast on the housings, and is driven by belt from a motor placed on the floor, or in a more convenient location.

In the self-contained drive, as applied to *Spiral*-geared planers, and shown in Fig. 4, the countershaft is mounted on a shelf, bolted to brackets cast on the housings, and is driven by belt, from a motor mounted on same shelf.

This type of drive permits the use of a medium or high-speed motor, the pulleys being so proportioned that the countershaft will be run at regular speed; and the center distances are such that a belt drive is perfectly practicable; the motor being provided with means for taking up the slack of belt.

In the motor-belted drive for spiral-geared planers, Fig. 5, the countershaft is mounted on a shelf, which is bolted to a bracket cast on the front housing, and which is furthermore supported by an outboard column resting on the floor. The countershaft is driven by a motor placed on the floor alongside of the planer, or in a more convenient location. This type of drive also permits the use of a medium or high speed motor.

When a complete motor equipment is furnished by the planer manufacturers, the outfit includes a multipolar iron-clad motor, a universal motor-starting rheostat with automatic release; overload and current indicator; main switch and covered fuse connections. The rheostat, indicator and switch are mounted on a slate slab, and wired complete. It is therefore only necessary to fasten the slab in position and connect the binding posts with the line wires and motor, in accordance with the diagram sent with each outfit. If a customer prefers, however, he may supply the motor equipment himself and the builders will then furnish only the supplementary equipment, which would include the brackets, shelf, etc., as mentioned above.

Where a customer orders a planer complete with regular countershaft, but intends at some future time to apply electric drive, the housings can be prepared by casting on the brackets, ready to receive the Standard motor-shelf. The motor power required for driving a planer obviously depends upon such a variety of conditions that the company generally recommend such powers as they consider ample for average service. It should be remembered, however, that the amount of power necessary at the moment of reversal, and for the "quick return," is vastly in excess of what is required to merely drive a planer while cutting, and for that reason it is advisable to provide a larger motor than the actual work would require.

* * *

MAKING SCREWS WITHOUT WASTE OF MATERIAL.

The latest development of automatic screw machinery about which we have been informed, is a machine that makes machine screws from a coil of wire without entailing any waste of the material. That is to say, the product from a coil of wire, weighing 50 pounds, would be 50 pounds of screws. This surprising result is obtained, of course, by the avoidance of all tool cutting action except that necessary to separate the screw from the stock, the screw being formed, head and all, entirely by swaging and rolling. This machine which is being perfected by a Springfield, Mass., inventor, first straightens the wire from the coil, then the end is caught between swaging dies of peculiar construction and given a rapid series of blows which form the body of the blank and partially form the head. The body of the blank which is to be threaded, is swaged to a smaller diameter to allow for the increase of diameter due to rolling the thread. After the first swaging operation, the blank is cut from the wire and thrust into a die where the head is fully formed, and the slot for the screwdriver punched at the same time. This punching action removes no stock, but expands the head so that it fills the die. After this has been done the blank is picked up and carried between two hardened threading rollers which roll the thread and complete the making of the screw.

Just what future there is in store for such a machine, we would not care to predict, but it appears that there is always a field open for any machine that effects a saving in time, material or attendance. When all three features are combined in one machine, its advantages seem obvious. The first machines for making wire nails, wasted a small portion of the wire between each nail in cutting the points. This waste, we believe, has been eliminated in the later machines and the economy resulting is of considerable importance, making almost the difference between profit and loss at times in the past.

* * *

It is stated that the largest steel plate ever rolled was one recently turned out by the Parkgate Works, England; it is 30 feet long, 10 feet 6 inches wide and seven-eighths of an inch thick.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

FEBRUARY, 1903.

NET CIRCULATION FOR JANUARY, 1903,–28,870 COPIES.

The entire Engineering Edition is printed on coated paper, and a data sheet containing four 6 x 9 pages of notes, tables, charts, etc., for note-book use, is furnished with every copy—price $2.00 a year. The Shop Edition is printed on super-calendered paper—price $1.00 a year.

ENVIRONMENT IS RESPONSIBLE.

The reasons for the success of American competition abroad and the avowed "supremacy" of the American workman have been investigated by the so-called Mosely commission of English workmen. The commission was composed of secretaries of 23 leading trade unions, who made an extended trip through this country, visiting important plants like the Schenectady Locomotive Works, the works of the General Electric Company, the Niagara power plant, the steel works of Cleveland and Pittsburg, the Cramp and Baldwin works of Philadelphia and many establishments in other fields of industry.

In a recent number of the *Outlook* certain features of the report of the commission are touched upon by Mr. George Lynch, a London correspondent intimately acquainted with the work of the visitors. He mentions—what we have already contended in these columns—that the mechanic is very much the same man on either side of the Atlantic, and that it is his environment, rather than his nationality, which stimulates or retards his progress. In America he is more productive because his influences are such as to make the product of his labor much greater than when under the more conservative and less favorable conditions which exist abroad.

To begin with, American climate is invigorating and conducive to work. The American workman lives in better surroundings, and works under better and more healthful conditions in the factory. He is influenced by the natural tendency to push work at its most rapid rate, devising where possible, mechanical ways to do this. The delegates repeatedly remarked that American mechanics do not seem to work harder than those in England, but they accomplish more because they make their minds save their hands. They make the machine take the wear and tear, if they can.

In this country, where so many factories are of recent construction, it is not surprising that they should be filled with new machinery; but the delegates were apparently surprised to find the scrap pile heaps so large in the vicinity of the older works, indicating that the American is disposed to throw out any machine almost as soon as it has been improved upon. Not the least important phase of the subject, however, is the fact that the workman in America indulges less in alcoholic beverages than the English workman, statistics showing that the consumption of these is more than twice as great per capita in Great Britain as in the United States.

Incidental to the trip should be mentioned the expressions of surprise on the part of the Englishmen that the manufacturers of America should have so universally kept "open house" for them. It was well known that no body of American workmen, skilled in the various arts and who would be quick to pick up ideas, could investigate the ways and methods of English shops, with anything like as great a degree of freedom. In other words, the country which is acknowledged supreme in its trade accomplishments has fewer secrets to hide than its less aggressive rival. May it not be that the same rule holds in respect to individual firms? We not only believe it does, but know that it does in many instances.

* * *

AN APT PHRASE FOR THE MECHANIC.

The veteran Senator Hoar of Massachusetts, in his recent speech upon the trust problem, drew a very pretty picture of Worcester, Mass., as a mechanic's home and alluded briefly to the many inventors who had at one time or another lived near that city. Eli Whitney, who doubled the value of every acre of land on which cotton grew, was born near Worcester; so was Bigelow, the inventor of the carpet loom; and so, also, was Blanchard, the inventor of the lathe for turning irregular forms. Elias Howe, the inventor of the sewing machine, was born and lived near Worcester, and the card clothing machine and the envelope machine were also invented or developed in that city. In referring to the results that have come from the work of such mechanics, the Senator very aptly said that "it was not water power or steam power or electricity that wrought this miracle; it was brain power."

This is a good phrase to remember and to live by. While plenty of men get along without brain power, they are generally men who are held up by props of some kind or other, and if the props were knocked out they would fall with them. Even the great trust, of which the Senator spoke, with all its wealth and untold resources cannot get along without brain power, which it will always have to pay for.

Especially would we commend the phrase to the young mechanic. Do you wish to succeed in the world? It is very easy to enumerate the things that *will not* contribute to that end. No mechanic will advance because he does not do his work intelligently; nor because he does not study; nor because he does not cultivate the power of observation or the habit of reading the technical papers, which tell him what others are doing in his own field of work. In short, no man ever succeeded because he did not use his brain. Not all mechanics can rise to the distinction of Eli Whitney or Elias Howe, or perhaps to any distinction at all. But it is morally certain that great mechanics like these would never have been heard of if they had not used their brains. Whatever may be the industrial conditions of the country through the great movements of modern times, let it be remembered that brains are the one staple commodity that the world cannot do without. The moral is to cultivate and develop the brain as well as the muscle and the future will take care of itself.

* * *

EFFECT OF GAS ON COAL TRANSPORTATION.

One of the great changes possible in future industrial development may be the establishment of great gas-making plants in the near vicinity of coal mines, and the conveying of the gas to cities by immense pipe line systems. This would largely do away with the present wasteful and expensive method of getting fuel to market by hauling coal in railway cars. A modern steel coal car weighs forty per cent. as much as the coal it can carry, and the car has to be hauled both ways. This, with weight of the locomotive, makes it practically about the same as hauling a ton of dead weight one way for each ton of freight. The proportion of dead weight hauled is usually much greater, especially when older equipment is used. The principal expense attending the movement of gas in mains is entailed by the pressure necessary to force it through, which would have to be developed by pumps. In the past, however, the cost of making gas has been a bar to its competing with coal in the manner outlined, so the only places where gas is generally used for fuel are those where natural gas is cheaply supplied. The price of natural gas varies in different localities, being from ten to fifteen cents per 1,000 cubic feet in some western Pennsylvania towns. In the future the conditions will be different, if a gas-making process developed by a Pittsburg mechanical engineer is as successful as reported. By this process it is claimed that fuel gas can be made at a cost of $.0108 (1.08 cents) per 1,000 cubic feet. A ton of coal produces by the new process 25,000 cubic feet of gas having a heat efficiency of 560 B. T. U. per cubic foot at a cost of $1.43. The by-products are 600 pounds of coke, 10 gallons of tar and sufficient ammonia liquor per ton to reduce the cost to the extremely low figure quoted. Even if there was no market for the by-products the cost of the manufactured gas would still be extremely low.

ELECTRIC RAILROADING.

In the last number of the *Technology Quarterly* is an article by Prof. Louis Duncan upon long-distance electric railroading that gives an interesting survey of electric traction as the problem now presents itself. Prof. Duncan is an engineer of wide experience, and has recently been appointed professor of electrical engineering at the Massachusetts Institute of Technology. He does not see the doom of the locomotive as plainly as perhaps some of the more enthusiastic members of the profession, for he believes there are several important factors that will tend to retard the progress of electric traction between distant points, especially with the through-train service of the leading roads. He contends that for through service a single car or even two cars are not enough to give the comfort to which the traveler is accustomed. This requires heavy trains of a number of cars, and even for a certain class of suburban traffic where a large amount of traveling is concentrated at certain hours, heavy trains must be used, requiring a great deal of power for each train.

In the transportation of freight, also, the tendency is toward heavy trains, because the minimum cost is attained with the maximum weight of train. The average train load on the Pennsylvania Railroad has increased about 75 per cent. in twenty years, and the capacity of the cars is over 100 per cent. Under these conditions he contends that continuous-current motors, receiving current either directly from a central station or from substations, are not applicable. The possibilities of congestion of traffic, especially in freight transportation, would make it necessary to have the capacity of substations enormous as compared with the average power required on the line, which would involve an immense increase in the original investment and some increase in the operative expenses.

Another difficulty is in the large amount of switching to be done, much of it of a complicated nature. If electricity is to be used in terminals and freight yards, a locomotive must be designed which is economical at all speeds, and which is under perfect control, and current must be supplied to these locomotives by some means which will not endanger the lives of the train hands. Railroading is dangerous enough as it is, and any additional source of danger must be avoided.

While the position of Prof. Duncan is very well taken, supposing that future railroading operations on electrically-equipped lines were to be conducted as they now are on steam railroads, it seems that this would be a mistake and directly against the tendencies of electrical operation (as manifested in passenger traffic, at least) which are, to run short trains and many of them. By doing this the public is better served and earnings increased without at the same time disproportionately increasing the operating expenses. The same should hold true to a large extent with freight traffic. Because we are used to having freight cars take a week or more in going from New York to Chicago, it is no sign that this is the proper condition of affairs or that it is one that will always exist in railroad operation. Long heavy trains necessarily mean slow movement of freight with possibly a minimum expense for wages of the trainmen; short trains mean quick freights and a slight increase per ton mile in wages, it is true, but the gross and net earnings would undoubtedly be greatly increased. The road bed of a railroad earns interest and dividends only while trains are passing over it and cars earn only in proportion to their mileage. If a freight car makes the round trip from New York to Chicago in a week, it earns just double what it does when making the trip one way in a week, and fewer cars are required for the same volume of freight. Without going into further argument in the matter it seems to us that the future of railroading lies more in the direction of shorter trains at high speeds, both for passenger and freight service, than in following the present trend with steam locomotives as the motive power.

NOTES AND COMMENT.

In his diary for 1843, Samuel F. B. Morse wrote: "The inference is that telegraphic communication on my plan may with certainty be established across the Atlantic. Startling as this may seem now, the time will come when this project will be realized." Yet this was only sixty years ago and men who were then old enough to have laughed at such a suggestion have lived to witness wireless communication across the ocean.

* * *

The *Philadelphia Record*, in a department devoted to scientific and mechanical notes, reproduces a cut of the motor-driven grinders manufactured by the Ransom Mfg. Co., Oshkosh, Wis., which have the motor armature directly on the grinder spindle, with the following description: "The familiar old grindstone is growing out of date and its place is being taken by the piece of machinery shown above. The stone wheels are driven by an electric motor encased in the base of the machine." Comment is unnecessary.

Some small work is not thought much of, and the doers of it are apt to receive scant consideration. Never despise, however, the maker of the small paragraph in a dire emergency to fill the corner of a page. Some of the quickest work of the editor is often done in those corners, and no wonder it does not always match what precedes it.—*American Machinist.*

There are notes and notes. The foregoing filled "the corner of a page" and was probably written in "dire emergency." A certain religious paper, so we are informed, has a stock of short prayers on hand, ranging from half-a-dozen to a score or so of lines in length, ready to be set in type for any and all occasions when a note is required to fill a certain space. But it is seldom that a technical editor has to practice sacrilege to fill his columns. There are usually enough pertinent facts at hand to supply the material for pithy notes, and it is frequently a matter of surprise to find that the notes published in MACHINERY bring numerous inquiries to this office, sometimes, in fact, more than the longer articles. This would indicate that some of the "small work" of the editor receives its fair share of attention, and we trust that the prayers of the religious editor may be answered as frequently.

As an illustration of what can be done with the new tool steels now appearing on the market, Prof. J. J. Flather, in an address before the Association for the Advancement of Science, stated that he had recently seen some steel locomotive driving wheels which had been turned in two hours and forty minutes, whereas the regular time previously had been not less than eight hours, with the old steel. Even better results might have been obtained, but the belts would not carry the load. Prof. Flather also related an anecdote to show how the tendency to increase the number of compressed air devices in machine shop work has sometimes led to extremes, and that in many cases the work could have been done just as cheaply by hand. The case in point was an apparatus that at one time was in use on one of our prominent Western roads. It was a sort of portable crane hoist which could be fastened to the smokestack of a locomotive, whereby one man could lift off the steam chest casing. The hoisting apparatus weighed about twice as much as the steam chest and took three men to put it up. When piece work was adopted two men easily lifted off the steam chest and this "labor-saving device" was relegated to the scrap heap.

A NEW INTERNAL COMBUSTION ENGINE.

LARGE HORIZONTAL GAS ENGINES DESIGNED BY THE WESTINGHOUSE MACHINE CO.

Much interest has of late been aroused by the exhibition abroad of numerous makes of high-power engines of the internal combustion type, and subsequent reports concerning their probable manufacture in America. Although much more attention has been devoted to this type of prime mover abroad, and its development has therefore been more marked, it is noteworthy that American manufacturers have in the meantime been conducting operations along this line with the result that internal combustion engines of American design and American manufacture, in sizes as high as several thousand horse power, are in evidence for service as exacting and severe as that for which the high-grade steam engine is now almost universally employed.

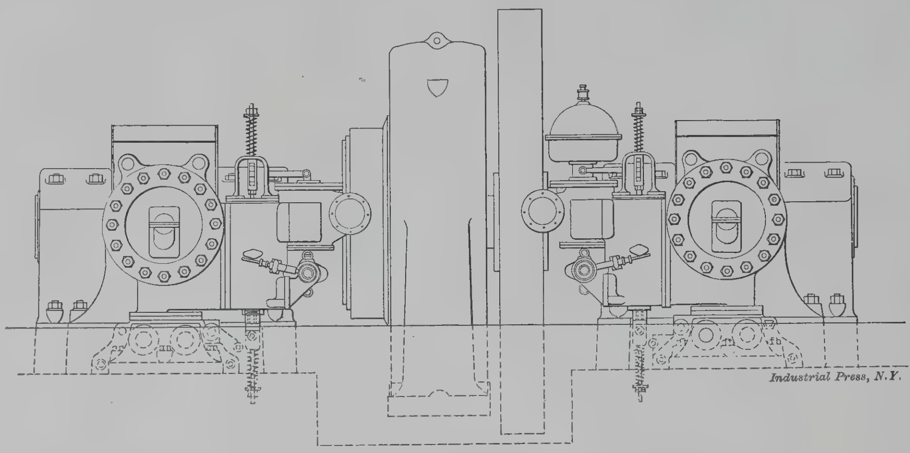

Fig. 1. End View of 1500 H. P. Double-crank Gas Engine, Direct Connected.

In the domestic field, few makers have ventured above 250 horse power, and none above 500 horse power, until recently, with one exception—the Westinghouse Machine Company, whose three-cylinder vertical single-acting engine is well known. The company have, however, been for some time engaged in developing the double acting engine, and are now prepared to build this type for powers ranging as high as 3,000 horse power. As this type of engine possesses features somewhat novel to those accustomed to the usual reciprocating engine design, a brief description may be of interest.

Fig. 3 is from a photograph of a single-crank engine of the new type, and Figs 1, 2 and 4 the general design of a 1,500 horse power double-crank engine, direct connected to a D. C. or A. C. generator.

The general design of the engine somewhat resembles that of the modern high-speed tandem compound steam engines in the arrangement of cylinders, frames, bed-plate, bearings, flywheel and generator. This resemblance is further carried out in the matter of crank effort. The engine operates on the four-stroke cycle, and as there are two double-acting cylinders an impulse is given at each stroke of the engine as in the steam engine.

The employment of the four-stroke cycle involves the important feature of positive scavenging which is here accomplished by the piston during its exhaust stroke, thus avoiding all weakening of the incoming mixture by the inert gases from the previous explosion, and insuring uniform operation. In all engines employing the two-stroke cycle, scavenging must be accomplished either by a special piston movement or by a blast of air from an auxiliary pump directed in such a manner as to force out the remaining burned gases, thus clearing the way, so to speak, for the incoming pure mixture. This latter method is the most practical, but has the inherent disadvantage of the incoming gas mixing with more or less of the air used in scavenging, causing a variation in the calorific value of the explosive mixture, which, for a gas of given constituency, should remain constant for the best results.

The Westinghouse design employs a mixture of unvarying quality, which is initially proportioned according to the nature of the gas used, but which remains constant under all conditions of load. As the loads upon the engine increase or decrease, a corresponding greater or lesser quantity of mixture is admitted to the cylinders, thus utilizing at all times an explosive mixture of maximum strength, resulting in

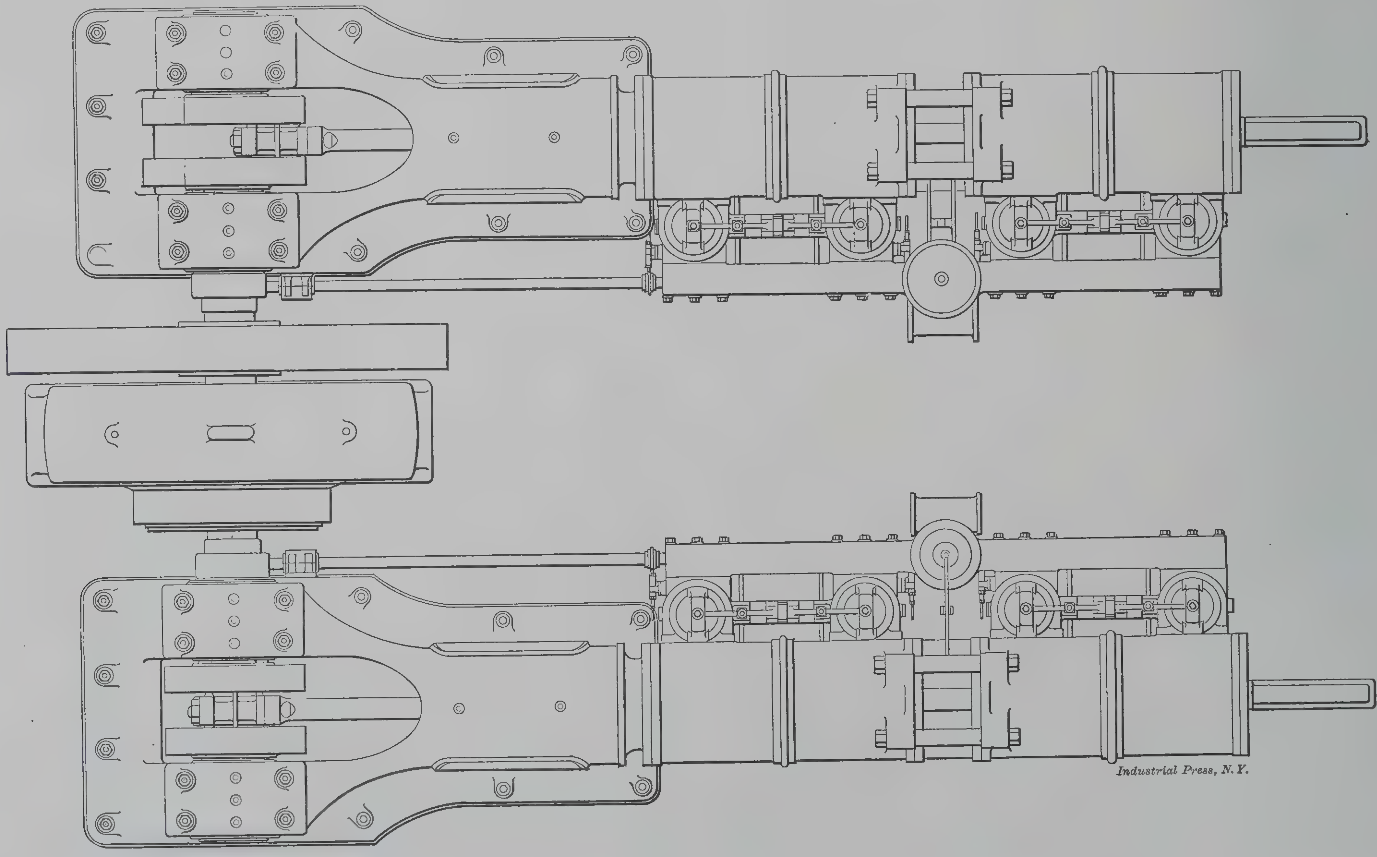

Fig. 2. Plan View of 1500 H. P. Engine.

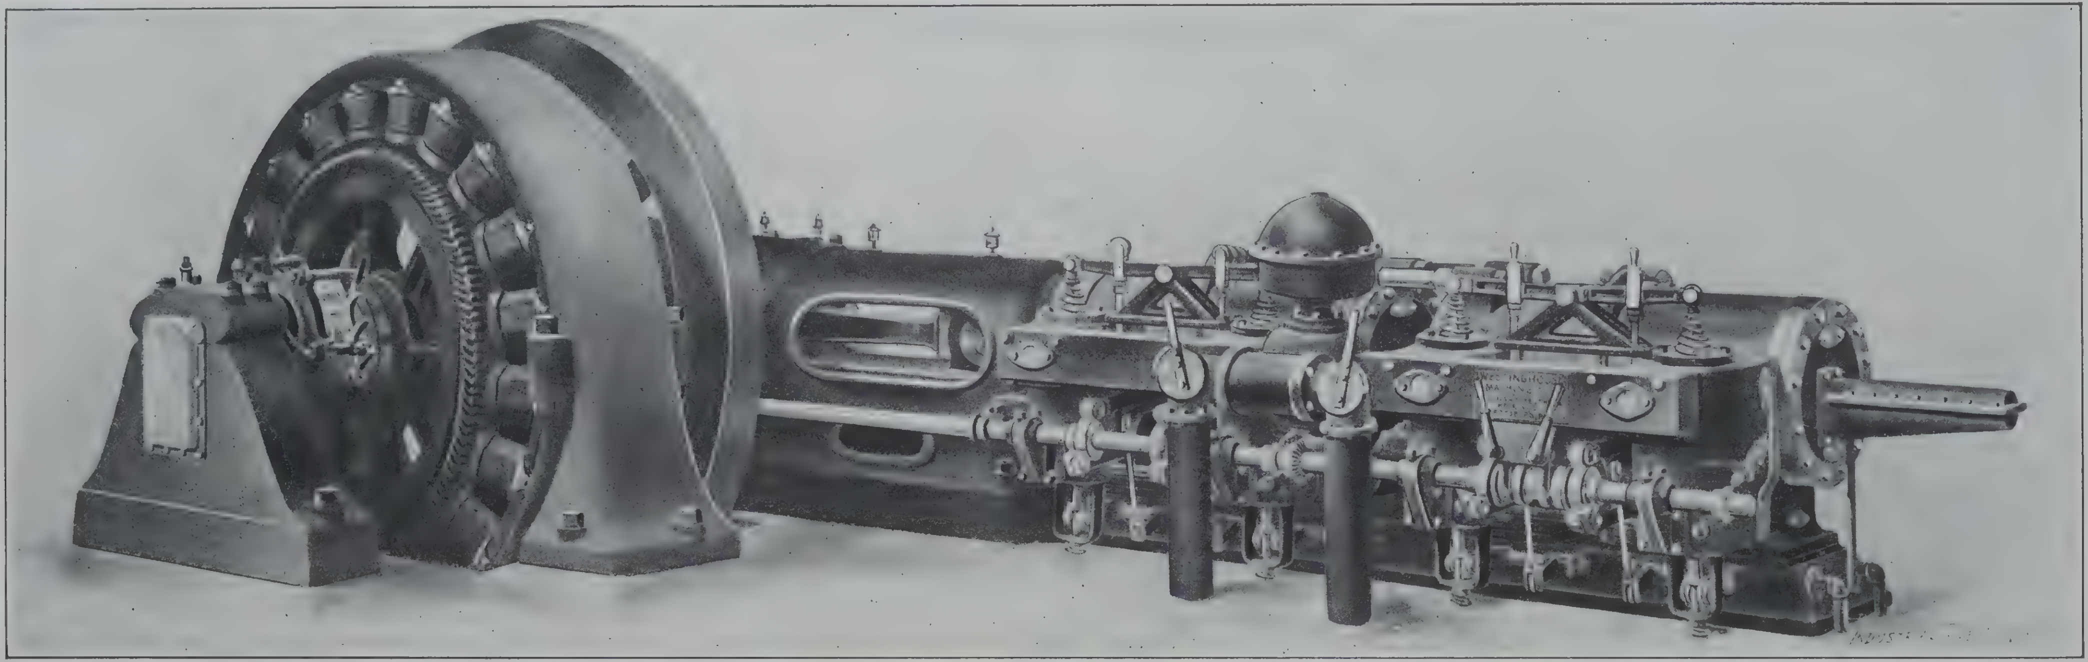

Fig. 3. General View of 750 H. P. Double-acting Single Gas Engine. (Photograph copyrighted.)

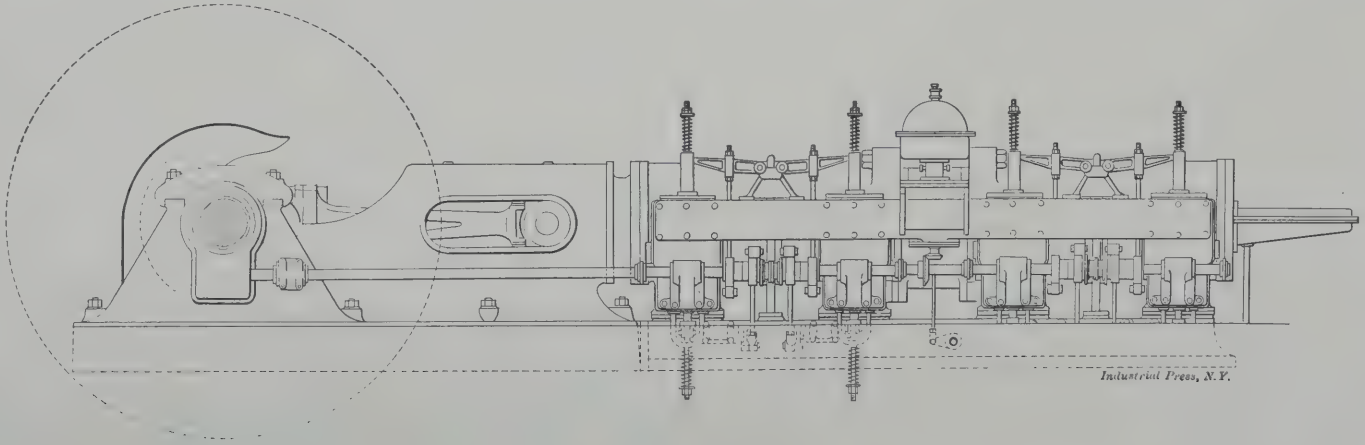
high thermal efficiency and economy of fuel. That this method is productive of the best results in engines of high power is apparent from the fact that reputable European builders, such as the Deutz Cockerill and Nurberg companies are abandoning the variable for the constant mixture method of governing.

The construction of the engine under description departs materially from the accepted European design and embodies many features of modern steam engine practice. The design of cylinders, pistons and valves, of course, departs materially from steam engine practice. The cylinders are double walled, with the outer walls split peripherally to permit independent expansion and contraction without placing the cylinder casting under stress. The two cylinders are united at the top by heavy tie-rods, engaging peripheral bosses, and at the bottom by a stout cast-iron distance piece. The rear section of the bed-plate which supports the two cylinders is cored hollow with a central dividing wall, and serves as a reservoir for incoming and outgoing circulating water. All connections are piped directly to these reservoirs, thus avoiding a large amount of piping about the engine. Through the bed-plate extend the four vertical exhaust pipes, which connect immediately below with an exhaust main. The exhaust passages leading from the valve chambers are cast integral with the cylinders, upon their sides, and are water cooled.

At the ends of each cylinder occur horizontal side ports, resembling straight steam ports, which communicate with removable combustion chambers, bolted to vertical bosses. The cylinders are closed by water-jacketed heads, split diametrically for facility in inspection of the interior, and the two halves are united with a ground fit, no packing being found necessary. This feature obviates the necessity for completely dismantling the engine for inspection.

The arrangement of valves and combustion chambers in the new design is simple and in marked contrast to the complexity of numerous European types. The latter still make use of the cylinder head or "breech end casting" for the location of combustion chambers, admission



Industrial Press, N.Y.

Fig. 4. Side View of 1500 H. P. Engine.

and exhaust valves, mixing and igniting chambers, and supports for the cam shafts, rocking levers, etc. This concentration of so many important functions in a single casting, which at best is already complex, is questionable. The arrangement shown in the accompanying illustrations accomplishes the same purpose at less cost and with less complexity. The combustion chambers are independent castings, with plain machined faces, circular valve liner seats, and cored out passages for circulating water. Both admission and exhaust valves, which are of the standard poppet type, operate vertically and with opposite throw. They seat under pressure, open by cam movement and close by spring pressure. The central space, closed by the admission valve above, and the exhaust below, communicates directly with the cylinder port before mentioned; the exhaust space with the exhaust passages on the under sides of the cylinder; the admission space with the supply pipe. This supply pipe is a rectangular cast-iron main extending along the entire front and provided with openings opposite each admission valve. It receives its supply from the governor chamber located midway between the two ends, this in turn communicating with a mixing chamber supplied on the one hand with gas, and on the other with air, through suitable valves. These two valves are shown in Fig. 4, and are provided with graduated indices, so that the exact proportions of gas and air may at all times be visible and under the control of the attendant. Each valve, together with its spindle and seating spring, is independently mounted, and by simply removing the bolts from the bonnet, the entire valve, seat and liner may be drawn out for inspection or replacement by another. Similarly, the igniters, which are of the "make and break" electrical contact type, are mounted in a removable plug extending into the combustion chamber through the side walls. The valve gear is of the cam and roller pattern, and is driven by a helical gear, engaging a similar split gear bolted around the main shaft. The entire gear may be instantly disengaged by a special trip coupling inserted on the driving rod.

The method of circulating cooling water is unique. This water enters a cavity in the crosshead by means of a flexible tube connection with the reservoir in the bedplate. It then flows througs the hollow piston rod to the forward piston, around which it circulates thence through the second rod to the rear piston; thence through a brass tail rod extending through the rear head and there empties into a cast-iron jacket bolted to the rear head and communicates with the hot water outlet pipe. Similarly cold water is conducted through suitable pipes to the cylinder jackets, thence to the jackets surrounding the exhaust valves and ports, and finally to the return pipe, emerging at a sufficiently high temperature for use in heating and drying coils, radiators, etc.

The engine pistons are constructed in two parts, with packing rings and babbitted bearing surfaces. They are secured in position on the rods by internal nuts and present plain convex surfaces to the burning gases. Piston rods are of forged steel, with bored water ducts. Between the two cylinders close fitting brass sleeves are used for packing, and split ring bushings in the outer cylinder head.

The engine is started by compressed air pumped into a steel reservoir during a previous run before shutting down. For this purpose a special disengaging gear is provided which isolates the rear cylinder. In starting, this air is admitted to the rear cylinder by the regular valve mechanism temporarily connected to the compressed air system and the explosion cycle in the forward cylinder is immediately started. The rear cylinder may then be thrown into action. Oiling is accomplished by steam engine appliances, such as sight feed cups, cylinder pumps, and oil rings for crank pins.

The engine is governed by a sensitive fly-ball governor of the standard design, protected by a circular housing. It operates a vertical piston valve supplying a fuel mixture of constant quality, but in quantities proportionate to the load.

The single crank engine is at present manufactured in sizes ranging from 150 to 750 horse power, and the double crank from 750 to 1,500 horse power. In the latter, the cranks are placed at 90 degree angularity, giving four impulses per revolution, and crank effort corresponding to that of the cross-compound double-acting steam engine.

It is of interest to note that several installations of this type of engine are in progress. The first will be at the works of the Consolidated Industries Company, Batavia, N. Y., which will employ 250 horse power single-crank double acting engines. A special coke and gas process, known as the Lowe, will be employed, yielding three products—metallurgical coke and coal and water gas, the former to be retailed and the two latter combined and used for power purposes. The second installation will be put into operation at the works of the Atlantic Refining Company, Philadelphia. The engines are double-crank, double acting, of 500 horse power each, and will operate upon a rich oil gas of approximately 1,200 British thermal units per cubic foot—a by-product of the refining process. Both these installations will be direct-connected to Westinghouse generators.

A third interesting installation at Hillburn, N. Y., will supply the entire Ramapo Valley with light and power from a new station now building for the Rockland Electric Company. This plant will also operate upon producer gas, using the Loomis-Pettibone process. The producer plant is located in a separate building and supplies water gas to the Ramapo Iron Works and the Ramapo Foundry Company for heating and metallurgical purposes, as well as power gas to the generating station. The electrical distribution system will supply power to local industries, as well as lighting for the Ramapo Valley, some fourteen miles in extent. The equipment aggregates 1,200 horse power, employing 350 horse power single-crank engines of the double-acting type, and a small vertical single acting engine for driving the exciter. Each main engine is direct connected to Westinghouse polyphase generators, arranged for parallel operation. This plant will be one of the first alternating current stations in the country to be operated from gas power.

A further and more recent instance of the confidence placed in gas power apparatus is that of the Potosina Electric Company, of San Luis Potosi, Mexico, a town of 70,000 inhabitants, situated at an elevation of about 6,000 feet above sea level, about 275 miles northwest of Mexico City. The town was formerly supplied with electric light and power from a D. C. steam-driven plant which passed into the control of the present company and has been converted to a gas power alternating current central station arranged for parallel alternation upon a single distributing system.

The plant has been laid out for five main units, an exciter unit, and a compressor, aggregating 1,225 horse power, and will also employ the Loomis-Pettibone process for generating a power gas of approximately 120 British thermal units per cubic foot, calorific value.

The four installations above noted are among the first applications of fuel gas to power purposes, and the advent of the modern high power gas engine should serve to open up an entirely new field in gas engineering. A number of power gas processes are now available, including the Loomis-Pettibone, Taylor, Mond, Otto Hoffman, Lowe, Dellwick, Fleischer and Dawson and the results obtained from installations now in service give every reason to believe that the gas-power station will shortly be much in evidence. At present three main and two auxiliary units will be installed, the remaining two units, each of 340 horse power, being added as required.

* * *

Modern Machinery reports that a peculiar affection has appeared in the glass windows of York Cathedral, England. The glass has become dull and fragile and filled with holes. Windows that have been in place for six or seven hundred years have lately been removed in order to arrest this curious form of deterioration. The trouble, which may properly be named a "disease," is ascribed to a fungus, but in what way it attacks glass is not yet definitely known. Possibly it dissolves the silica in order to form a shell such as those of the microscopic diatoms that make up the fine siliceous deposits found in Germany and other countries. Glass is not the only hard substance that may succumb to such attacks, for a species of bacteria is known to disintegrate the hardest cements, and has thus wrought havoc in water reservoirs.

BOILER HORSE POWER FOR HEATING AND POWER.

CHAS. L. HUBBARD.

The standard for one "boiler horse power" is the evaporation of 30 pounds of water from a temperature of 100 degrees into steam at 70 pounds gage pressure. This is equivalent to the evaporation of 34.5 pounds from a temperature of 212 degrees into steam at atmospheric pressure, and requires $34.5 \times 966 = 33{,}327$ heat units, which for all practical purposes we may take as 30,000.

It has been found by experience that in plain tubular boilers, one square foot of heating surface will evaporate about 2.3 pounds of water "from and at 212 degrees," which corresponds to 15 square feet of heating surface per H. P. ($34.5 \div 2.3 = 15$). In well proportioned boilers, with careful firing, this can be somewhat reduced and some engineers give as low a figure as 11.5 square feet per H. P. All computations and tables given in this article will be based on 15 square feet per H. P., which experience has found to be safe and to result in durable construction. In computing the heating surface of tubular boilers it is customary to take one-half the area of the shell, two-thirds the rear head less the tube area, and the interior surface of all the tubes.

The H. P. required for heating a building may be computed in different ways, according to the data at hand. It may be based on the radiating surface to be placed in the building, or upon the heat loss through walls and windows. If ventilation is to be provided for a part or the whole of the building special allowance must be made for this also. Let us first take up the case where the amount and kind of radiation to be supplied by the boiler is known. One square foot of direct radiation, provided with low pressure steam (2 to 5 pounds), will give off from 200 to 300 heat units per hour. We may take for the average cast-iron radiator of medium height and thickness, an efficiency of 250 heat units; for a pipe coil, 300; for indirect pin radiators or other cast-iron indirect radiators of similar form, 600; although indirect radiation is not so efficient in heating the room itself, and for steam blast, 1,500. From this we have:

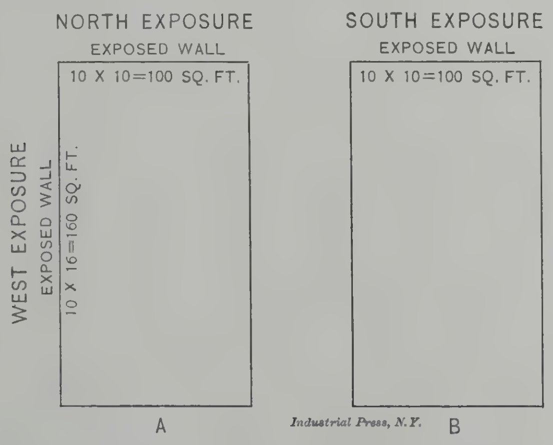
$$\frac{30{,}000}{250} = 120 \text{ sq. ft. direct radiator per H. P.}$$

$$\frac{30{,}000}{300} = 100 \text{ sq. ft. direct pipe coil per H. P.}$$

$$\frac{30{,}000}{600} = 50 \text{ sq. ft. indirect radiator per H. P.}$$

$$\frac{30{,}000}{1{,}500} = 20 \text{ sq. ft. steam blast per H. P.}$$

When the radiating surface of a building is not known we must either first compute it by one of the various methods in use or calculate the horse power directly from the heat loss through the walls and windows of the building.



Industrial Press, N.Y.

Fig. 1.

It is common practice among steamfitters and others to base the radiating surface required for any given room upon its cubic contents. While this is a convenient way of making approximations or of checking up results obtained in other ways, it is not accurate enough for computing the sizes of radiators for separate rooms unless the results are corrected for different conditions by a person of experience. This is made evident by an illustration. Take the case of two rooms having the same cubic contents and located as shown in Fig 1. *A* has an outside wall exposure of $100+160=260$ square feet toward the north and west, while *B* has only 100 square feet of exposure toward the south. While a person of any experience would make a difference in the size of radiators of the two rooms, I have seen important pieces of work in which the radiating surfaces had been computed from the cubic contents of the room, regardless of the wall exposure.

When we come to deal with whole buildings instead of separate rooms the method becomes more rational and may be used with a fair degree of accuracy.

The following table has been made up from the averages of several different rules in common use, and gives the cubic feet of space that may be warmed by 1 square foot of different kinds of radiation for various types of buildings. From this table we may easily calculate another which will give the horse power per 1,000 cubic feet of space for the different types of buildings named above.
